INTRODUCTION. We have previously observed a potential association between thrombocytopenia and the presence of a continuous cardiac output pulmonary artery catheter (CCO-PAC). Once the CCO-PAC was removed, platelet counts increased [1]. A potential explanation is the extraordinary sensitivity of platelets to intermittent heat pulses produced by the thermofilament of the CCO-PAC. It is known that platelets are more easily damaged by temperatures >42◦C than erythrocytes or leukocytes [2].
OBJECTIVES. The main objective of our initial experiment was to measure the temperatures produced by the thermofilament of the CCO-PAC under simulated blood flow.
METHODS. We constructed a circular tubing system, with a mechanical one-way valve, which was able to replicate pulsatile flow of water at 37◦C, in which the CCO-PAC was centrally positioned, along with a thermistor with a high sensitivity and a high time resolution. A compatible monitor (Edwards Lifesciences) was connected to the CCO-PAC and to an ECG-simulator. The pulsatile blood flow and ECG-simulator generated frequencies were both set at 60 /min. Once the CCO-PAC system generated regular heat pulses compatible with actual continuous cardiac output measurements, we started recording the temperature generated by the thermofilament. Under this simulated blood flow, temperature was measured both internally in the distal lumen halfway the thermofilament and external to the CCO-PAC directly in contact with the thermofilament.
RESULTS. It took the monitor about 10 minutes to calibrate and measure a cardiac output. During stable CO measurements we observed a constant repetitive pattern in de temperatures generated by the catheter. At a 'blood' temperature of 37◦C we measured rapidly varying temperatures inside and directly near the thermofilament. Such pulses were generated approximately 4 times /min. Once a pulse terminated, the temperature rapidly dropped to the temperature of the surrounding fluid. The surface temperature was 8◦C above the 'blood' temperature for 35% of the cycle, equivalent to 45◦C at a blood temperature of 37◦C.
CONCLUSION. Under simulated conditions catheter temperatures >42◦C were observed for a considerable fraction of the CCO-PAC heat-pulse cycle. We believe the sustained emission of thermal pulses may be a key contributor to thrombocytopenia in patients with this catheter in situ. Further studies could confirm and further analyze this phenomenon.

Diagnosis of Acute Myocardial Infarction after Coronary Artery Bypass Graft (CABG) Surgery: A Systematic Review

A. Shoala
Cardiac icu, national heart institute, cairo, Egypt
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000612

INTRODUCTION. Myocardial infarction after coronary artery bypass grafting is a serious complication and one of the most common causes of perioperative morbidity and mortality. Multiple mechanisms have been proposed to explain myocardial injury after CABG. Diagnosis will be established according to creatine kinase (CK) values more than five times the 99th percentile of the normal reference range during the first 72 hours following CABG, (or Troponin or CKMB more than ten time increase) when associated with the appearance of new pathological Q-waves or new left bundle-branch block (LBBB), or angiographically documented new graft or native coronary artery occlusion, or imaging evidence of new loss of viable myocardium, should be considered as diagnostic of a CABG related MI.
OBJECTIVES. : to identify the methods of diagnosis of post coronary artery bypass graft (CABG) acute myocardial infarction.
METHODS. Data sources: MEDLLINE (PubMed), EMBASE, Google Scholar and the Cochrane Library and all materials available in the internet till 2017.
Study selection: this search presented 23 eligible studies which studied the diagnostic methods for acute myocardial infarction after coronary artery bypass graft (CABG) surgery.
Data extraction: if the studies did not fulfill the inclusion criteria, they were excluded. The methodological quality of included studies was assessed using an adjusted QUADAS-tool.

Data synthesis: comparisons was made by structured review with the results tabulated.
RESULTS. Troponin I and T can both be used to indicate myocardial damage, with the level correlating well with the level of injury. However until issues such as a 'gold standard' for peri-operative MI are addressed, one single cut-off point cannot be recommended for either test.
CONCLUSION. Troponin I and T can both be used to indicate myocardial damage, with the level correlating well with the level of injury. However until issues such as a 'gold standard' for peri-operative MI are addressed, one single cut-off point cannot be recommended for either test.

INTRODUCTION. The knowledge and monitoring of cardiac output give us fundamental information in critically ill patients. Fick's method, previously used to calculate it, has been replaced in clinical practice by minimally (transpulmonary thermodilution) or non-invasive techniques (echocardiography, bioimpedance) obtaining cardiac output measurements in a patient-safe, fast and reliable way (1,2).
OBJECTIVES. To compare the estimation of stroke volume and cardiac output by non-invasive methods in critical patients. To determine if there is a correlation between indicators of cardiac preload and systolic function between both methods.
METHODS. Prospective observational study. An echocardiographic study and bioimpedance monitoring were performed in adult patients admitted to ICU. Stroke volume (SV) and cardiac output (CO) values were collected; systolic function parameters: aortic acceleration index (AI); heather index (HI); aortic velocity index (VI); preload parameters: end-diastolic volume (EDV); inferior cava vein diameter (ICV); thoracic fluid content (TFC) were also retrieved. Correlations between parameters were scanned.
RESULTS. 7 adult males were studied, 57,1% receiving invasive mechanical ventilation and 28,6% vasoactive support. The demographic characteristics and the hemodynamic study are shown in the table.
000840
No correlation was observed between values of stroke volume and cardiac output nor between parameters of contractility and cardiac preload. Determination of stroke volume and cardiac output by bioimpedance tends to overestimate values respect to ultrasonography: +9,7 (-2,5 a 21) ml (p= 0,1); +0,6 (-0,6 a 1,3) l/min (p=0,07).
CONCLUSION. In our sample, there is no correlation in serial haemodynamic assessment by echocardiography and bioimpedance. Cardiac bioimpedance may overestimate stroke volume and cardiac output relative to echocardiography.

Age does not independently predict one-year survival in patients undergoing renal replacement therapy: a dual-centre observational study

D. Roberts, L. Hodgson
Intensive care, Worthing Hospital, Worthing, United Kingdom
Correspondence: D. Roberts
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000795

INTRODUCTION. In the UK and other Western countries, the proportion of elderly patients admitted to intensive care units (ICUs) is rising (1-3). The challenge of determining which treatments will be beneficial to this older cohort is significant(4) and one specific decision, undertaking renal replacement therapy (RRT) holds a delicate balance of risks and benefits. The South Coast of England where this study was performed has a population significantly older than the UK average with 14% over 70 years of age(2), therefore well placed to examine this issue.
OBJECTIVES. To understand contemporaneous, longer-term outcomes for older people undergoing acute renal replacement therapy (RRT) in the intensive care unit (ICU) setting.
METHODS. A retrospective observational cohort analysis of data collected (2013-2018) on adult patients commenced on RRT in two non-specialist UK ICUs (consisting of a 12-bed and a 10-bed unit) using data collected as part of routine care. Baseline characteristics and outcomes between patients younger or older than 75 were compared.
RESULTS. After excluding cases previously on long-term dialysis (n= 65) the cohort included n=698 admissions with a median age 69 (IQR 57-77), 33% (n=231) were ≥75 years old and 17% (n=121) were ≥80. Mechanical ventilation was required in 62% and cardiovascular support in 56%. Median ICNARC score was 28 (23-35) and APACHE II score 23 (18-28).
Between those aged <75 and ≥75 there was no significant mortality difference in ICU (42.4% vs 46.3%, OR 1.17 (95% CI 0.85-1.61), P= 0.332), in-hospital (47.8% vs 55.0% OR 1.34 (0.97-1.83), P=0.077) and at one year (58.9% vs 63.3% OR 1.21 (0.85-1.71), p=0.329), respectively. In logistic regression age was not an independent predictor of 1-year mortality whilst lactate, and requirement for cardiovascular support were.
CONCLUSION. 1-year mortality in patients who have required RRT is substantial, however age alone did not predict survivors.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000800

INTRODUCTION. Acute kidney injury (AKI) is one of the common complications after liver transplantation (LT) which associated with increased mortality, long-term risk of chronic kidney diseases, and prolongated length of hospital stay. Nutritional status, especially prognostic nutritional index (PNI), has been used as a predictive value for postoperative complications. However, there is a lack of prognostic value applied for PNI to the prognosis of LT. We suggested a new predictive model modified by PNI and investigated which model has the highest predictive accuracy for AKI in patients who underwent LT
METHODS. Data from a total of 423 patients underwent LT were collected retrospectively. Based on Acute Kidney Injury Network (AKIN) criteria, the patients in the AKI group are confirmed to AKI within 1-week after LT. PNI was calculated as 10 X serum albumin (g/dL) + 0.005 X total lymphocyte count (per mm3). After the univariate analysis, multivariate statistical adjustment for post-operative variables of AKI was performed. As a new predictive model was developed. It was called the modified PNI model (mPNI). The mPNI was calculated as 6.9 X serum bilirubin (mg/dL) + 134 X INR – 29 X PNI + 250. The individual diagnostic accuracy in AKI within 1-week after LT was evaluated using the area under receiver operating characteristic curve (AUC).
RESULTS. 54 patients (12.7 %) were diagnosed AKI within 1-week after LT. The mPNI has the highest predictive accuracy (AUC = 0.810, Table 1.). The MELD score and PNI were 0.793 and 0.712, respectively. The INR and serum bilirubin were 0.705 and 0.637, respectively. The mPNI was the highest predictive value for development of AKI within 1-week after LT.
CONCLUSION. The mPNI is the highest prognostic model for AKI within 1-week in patients who underwent LT (AUC = 0.810).

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000953

INTRODUCTION. Intensive care unit (ICU) acquired hypernatremia is a highly prevalent condition in critically ill patients and is associated with increased mortality and length of stay. (1) The kidneys play an important role in the volume and osmolality regulation, and are therefore a possible key player in sodium derangements. Approximately 30% of ICU admissions is complicated by acute kidney injury (AKI). (2) Therefore, this study focused on AKI in the development of hypernatremia.
OBJECTIVES. This study aimed to provide insight in the effect of AKI on the development of ICU acquired hypernatremia.
METHODS. A retrospective comparative analysis was performed using prospectively collected data of ICU patients in a tertiary referral hospital. All adult patients requiring ICU admission more than 48hours were identified and included between April and December 2018. Urine samples were collected and analyzed for electrolytes and osmolality. Additional serum osmolality analyses were performed. Further data collection consisted of detailed fluid balances and medication use.
RESULTS. Of the 199 included patients, 85 (43%) developed hypernatremia. According to the RIFLE criteria, 1 (1%) patient was at **R**isk for acute kidney injury, 21 (25%) patients developed kidney **I**njury and 20 (24%) patients had acute kidney **F**ailure in the hypernatremia group. The proportion of patients with AKI was not significantly different between the two groups. However, when comparing the median maximum level of serum creatinine (128,0 µmol/L versus 92,6 µmol) and serum urea (14,0 mmol/L versus 9,7 mmol/L) between hypernatremic patients and normonatremic patients during ICU stay, a significant difference was observed (P<0,001 and P<0,001). The total median salt intake was 26 gram in the normonatremia group and 40 gram in the hypernatremia group (P=0,004). A significant difference was found in median serum osmolality levels between the two groups resulting

in 298 mOsm/kg in the normonatremia group and 319 mOsml/kg in the hypernatremia group (P<0,001). The urine-osmolality of the normonatremia group was 695 mmol compared to 612 mmol in the hypernatremia group.
CONCLUSION. Patients with hypernatremia did not develop AKI more frequently than patients without hypernatremia. However, the higher levels of serum creatinine and serum urea in the hypernatremia group suggest impaired renal function. In addition, decreased urine osmolality was found in the hypernatremia group despite an (iatrogenic) increased sodium intake. Therefore, a role for the kidneys in the development of hypernatremia is not to be ruled out yet.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000963

INTRODUCTION. Deterioration of kidney function in critically ill patients is independently associated with impaired outcome. Diagnosis of acute kidney injury (AKI) is currently hampered by the lack of accurate markers for timely assessment of kidney function. Conventional creatinine-based methods to estimate glomerular filtration rate (GFR) are notoriously insensitive, late, and inaccurate. The gold standard methods to measure GFR using exogenously administered substances, such as inulin or iohexol, are not used in clinical practice because they are labour-intensive and expensive. A promising novel candidate to assess kidney function is plasma proenkephalin (PENK), a stable byproduct of the endogenous opioid enkephalin.
OBJECTIVES. 1) To determine to what extent PENK reflects the GFR in a cohort of critically ill post cardiac surgery patients that are prone to develop AKI. 2) To develop an equation to estimate the GFR using PENK plasma concentration.
METHODS. We prospectively included 180 patients undergoing cardiac surgery. Post surgery, patients received an intravenous bolus of iohexol, and plasma iohexol concentrations were determined in four samples obtained during the subsequent hours. The true GFR was determined using the slope-intercept method and the Brøchner-Mortensen correction [1]. Plasma PENK concentrations were determined using the Sphingotec immunoassay [2]. Using linear regression model, three equations were developed in a block randomized training sample of the cardiac surgery cohort. 1) PENK only; 2) age, gender and PENK; 3) age, gender, PENK and creatinine. Bias, precision and accuracy were assessed and results were compared with the currently used Modification of Diet in Renal Disease (MDRD) equation.
RESULTS. Median of the true GFR was 81 [IQR: 69-90] mL/min/1.73m^2. Results of the equations are listed in Table 1. The mean bias of the MDRD was significantly different compared to the true GFR (p<0.0001), while the mean bias of the equation of PENK was not (p=0.47). The equation using only PENK was significantly more accurate compared to the MDRD (p=0.02), when the covariates age, gender and creatinine were added, accuracy improved (p=0.0003).
CONCLUSION. Our study underscores the inaccuracy of conventional creatinine-based methods to estimate GFR in critically ill patients, causing misclassification of kidney function. Furthermore, we demonstrate that a single plasma PENK determination correlates with the true GFR in cardiac surgery patients and the PENK equation to estimate GFR performs better compared to the MDRD. Therefore, PENK has potential as an accurate and feasible marker to assess kidney function in critically ill patients. External validation in additional critically ill patient cohorts is warranted.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000984

INTRODUCTION. AKI associated with severe sepsis has a significant increase in mortality [1] and it is not known whether there is continuity of renal injury in the post sepsis recovery period. The fact is that survivors have 2.5 times more likely to be readmitted to the hospital for AKI within 90 days than patients without sepsis [2].
OBJECTIVES. Evaluate the kinetics of renal hemodynamics alterations in animals surviving from severe sepsis.
METHODS. Following DL50 sepsis model induction (2mL *E.coli* 108 CFU/mL, iv.) in adult Wistar female rats, the surviving animals were monitored to macro (MAP, HR and abdominal aorta blood flow by Transonic, TS420 transit-time flowmeter), regional (renal artery and vein by Transonic, TS420 transit-time flowmeter), and micro hemodynamics (kidney cortical microcirculation by SDF videomicroscopy). Animals were monitored at 6 hours, 1month, and 3 month post-sepsis periods. Naïve (N) animals were used as control. (n=4-5/period). All rats were euthanized at the end of experiments.
RESULTS. There was a stability of MAP at normal levels in post-sepsis periods. Only in the hypodynamic phase of acute sepsis (S-6h) did a significant reduction occur. Variations of HR (250-400 bpm) were dependent on aortic flow, being higher when the flow drop was observed in the S-6h, denoting to be a parameter more related to hemodynamic adjustment and unrelated to the post- sepsis clinical condition. Moreover, the significantly diminished renal vessels blood flow (fig.1) suggests the kidney hypoperfusion state with microcirculatory dysfunction showed by SDF (fig. 2).
CONCLUSION. In conclusion, renal damage in severe sepsis seems to improve partially in the post-sepsis period, but the persistence of the hypoperfusion may predispose to organ dysfunction in severe sepsis survivors.

INTRODUCTION. Remote ischemic preconditioning (RIPC) has demonstrated beneficial effects on acute kidney injury (AKI) and/or cardiac function after coronary angiography (CA). These protective effects have been partly explained by enhanced of the antioxidant or anti-inflammatory mechanisms. However, the effects by RIPC might be attenuated in diabetic patients, a population with enhanced of pro-inflammatory and pro-oxidant pathways.
OBJECTIVES. To evaluate the effects of RIPC on the myocardial and renal function, as measured by plasma Troponin I, N-terminal prohormone of brain natriuretic peptide (NT-proBNP), creatinine (Cre) and cystatin C (Cysc C) levels (an early marker of glomerular function), as well as plasma levels of the antioxidant enzyme Heme oxygenase-1 (HO-1), the acute phase reactants increasing during inflammation (ferritin) and protein C reactive (PCR), and the ratio of neutrofile/linfocites (NLR).
METHODS. A prospective, randomized, single-center trial was conducted at the St. Lucía University Hospital (Cartagena, Spain). Diabetic patients admitted to medical intensive care unit, with an acute coronary syndrome requiring standard CA, were enrolled and randomly assigned to an RIPC group (n = 36) or a control group without RIPC (n = 35). In the RIPC group, four cycles of 5-min of ischemia and 5-min of reperfusion were applied to the right upper limb by a cuff inflated to 50 mmHg over the systolic blood pressure. We recorded demographical, clinical and analytical data before and after 24, 48 and 72 hours of CA procedure. We analyzed qualitative variables with percentages by categories, and square Chi; quantitative variable with median ± standard deviation and T student; or median, interquartile rank and U- Mann Whitney, depending on statistical distribution
RESULTS. Patients receiving RIPC showed lower levels of NT-proBNP (pg/ml) at 72 hours (4010±6600) compared to those in the control group (6373±9600), p<0.05, without any differences in the troponin I peak. Regarding to the renal function, the increases in Cre (mg/dl) and Cysc C (mg/L) before and after 72 hours of CA were similar between groups (Cre RIPC; 1.05±0.4 vs 1.37±1 and control; 1.10±0.5 vs 1.17±0.6 and Cysc C RIPC; 1.16±0.5 vs 1.35±0.8 and control; 1.28±0.6 vs 1.38±0.6). Importantly, changes before and after 48 hours in ferritin (ng/ml) (RIPC; 175±176 vs 218±161 and control; 115±98 vs 145±92); HO-1 (ng/mL) (RIPC; 0.72±1.5 vs 1.36±1.5 and control; 0.77±1.5 vs 1.56±2.2); PCR (mg/dL) (RIPC; 4.25±4.3 vs 5.27±4.2 and control; 4.90±6.1 vs 3.96±3.7); and NLR (RIPC; 0.70±0.1 vs 0.70±0.1, control; 0.72±0.1 vs 0.70±0.1); were similar in both groups.
CONCLUSION. The RIPC maneuver before CA in diabetic patients demonstrated favorable effects on cardiac function without improving the renal parameters. These effects could not be attributed to increase in the antioxidant or inflammatory mechanisms analyzed. Alternative pathways underlying these effects merit further investigation.

A novel technique to increase extracorporeal citrate clearance to achieve regional anticoagulation of high blood flows

A. Zanella[1], L. Vivona[1], A. Galli[1], M. Battistin[2], O. Biancolilli[2], D. Dondossola[3], S. Colombo[1], C. Anzanello[1], I. Protti[1], M. Busana[1], A. Pesenti[1]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001129

INTRODUCTION. Regional anticoagulation allows to perform extracorporeal treatments avoiding the complications of systemic anticoagulation. Citrate-based regional anticoagulation is the most widespread technique but, due to limited citrate clearance, may be applied only to low extracorporeal blood flows (i.e. < 200 ml/min). We developed a novel technique to highly increase extracorporeal citrate clearance, thus achieving regional anticoagulation of higher blood flows.
METHODS. Five healthy swine (42±3 Kg) were sedated, mechanically ventilated and connected to a prototype extracorporeal circuit for continuous renal replacement therapy featuring a citrate-removal stage based on absorbent materials and replacement fluids. Blood flow was 500 ml/min. Sodium citrate was continuously infused at the circuit inlet (5 mmol/L). Heparin was continuously infused. Citrate concentration and Heparinase Kaolin thromboelastography (HK-TEG) were measured on arterial blood, extracorporeal blood downstream the citrate infusion port and downstream the citrate-removal stage.

Samples were collected at baseline, 2, 8, 15, 30, 45, 60, 90, and 120 minutes for citrate and every 30 min for HK-TEG. Calcium chloride was infused to maintain systemic ionized calcium within physiological range. The experiment lasted 2 hours.
RESULTS. Citrate concentrations in blood samples were stable within the first 30 minutes than started to slowly increase (Figure-left). The efficacy of the citrate-removal stage in removing citrate was 88% at 30 minutes and decreased down to 48% at the end of the study (Figure-right) due to loss of efficiency of the absorbent materials. During the whole experiment, HK-TEG in artery showed normal coagulation: Reaction time (R) was 8.6 ±1.3 minutes, with Maximum Amplitude (MA) of 72.2±6.2 mm. In the extracorporeal circuit, HK-TEG showed no sign of clot formation R>60 min, MA=0 mm.
CONCLUSION. The tested prototype effectively removed the infused citrate required to anticoagulate 500 ml/min of extracorporeal blood flow.

Use of cardiac biomarkers as predictors of acute renal injury in cardiac surgery: Prospective Cohort Study

P. Palacios Moguel, OE. Palacios Calderon, A. Aisa Alvarez
Intensive care unit, The American British Cowdray Medical Center, Mexico City, Mexico
Correspondence: O.E. Palacios Calderon
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001138

INTRODUCTION. Acute kidney injury is common after cardiac surgery and is associated with postoperative mortality. Cardiac biomarkers are more accessible and can help to predict this complication.
OBJECTIVES. To investigate relationship between cardiac biomarkers and postoperatively acute kidney injury (AKI) in adults undergoing cardiac surgery1.
METHODS. Prospective cohort study in post-operated cardiac surgery adults. We measured the following cardiac biomarkers in the first 6 hours of the postoperative period: B-type natriuretic peptide (BNP), ultrasensitive troponin I (usTI), creatine phosphokinase (CPK), creatine phosphokinase MB (CPK-MB) and myoglobin.
RESULTS. 63 patients evaluated, 31 (49.2%) had AKI. Patients with AKI had significantly higher levels of BNP, usTI, CPK-MB, and myoglobin. Myoglobin had a good area under the curve (AUC 0.81, 95% CI 0.66-0.95), followed by usTI (AUC 0.71, 95% CI 0.58-0.92) and BNP (AUC 0.71 IC 95% 0.53-0.88) to detect AKI. Myoglobin levels ≥731 ng/mL had a positive likelihood ratio (7.73, 95% CI 1.04-57.24). the time of extracorporeal circulation (Adjusted Odds-ratio 6.11, 95% CI 1.55 to 9.55) and myoglobin elevation (Adjusted Odds-ratio 1.00, 95% CI 1.00 to 1.01) were independent predictors of AKI.
CONCLUSION. The postoperatory levels of cardiac biomarkers are significantly higher in patients with AKI. Extracorporeal circulation (CCE) time and myoglobin elevation were shown to be predictors of AKI. These biomarkers may be suitable for identifying patients at high risk for AKI after cardiac surgery.

INTRODUCTION. Indirect calorimetry (IC) is the gold standard for estimating energy needs in critically ill children. There is no reported IC data in children receiving CRRT. The modified-Weir equation using real-time carbon dioxide production (VCO2 REE) collected via standard clinical ventilators might more accurately define energy needs without the expense of IC or the inaccuracy of predictive equations.
OBJECTIVES. This pilot feasibility study investigates whether VCO2 REE could be used in pediatric CRRT patients.
METHODS. We investigated if a detectable change in VCO2 occurs after CRRT circuit start and compared daily VCO2 REE to calculated REE. Patients were classified as hypo or hyper metabolic based on the VCO2 REE/calculated REE ratio (<0.9, >1.1, respectively). Continuous VCO2 data were obtained from the Sickbay database (Medical Informatics Corp, Houston TX). Data were sampled prior to initiation of CRRT (baseline) and then every 24 hours for a total of five days or until ventilator discontinuation.
RESULTS. There was no difference in VCO2 between baseline and first hour of CRRT. Median VCO2 REE was 903 cal/d (IQR 554-1600) and calculated REE was 874 cal/d (IQR 606-1427) (n=9). There was a moderate correlation between baseline VCO2 REE and

calculated REE (r=0.75, p=0.02) but this relationship was lost after day 2 of CRRT. Patients displayed dynamic characteristics throughout the study period transitioning between hypo and hypermetabolic. Hypometabolic patients had lower VCO2 REE (300 cal/d, 95% CI 125-475) and hypermetabolic patients higher (619 cal/d, 95% CI 440-799) than normometabolic patients. On any given day 1/3 of patients were hypermetabolic but individual patients varied daily. Longitudinal data were analyzed using mixed-effects multilevel modeling. Controlling for metabolic state (hypo or hyper) and baseline values, VCO2 REE increased daily by 44.7 cal (95%CI 20.2-69.1). Calculated REE overestimated VCO2 REE at baseline, and underestimated it after CRRT start (VCO2 REE baseline 594 cal/d (IQR 523-1299), day 5 927 cal/d (IQR 554-1251)). There was an interaction between CRRT day and metabolic state. Approximately 50% of the variation in VCO2 REE across the study population was due to patient level differences.
CONCLUSION. Pediatric CRRT patients have dynamic metabolic needs that are poorly approximated with predictive formulas. If validated in larger studies, VCO2 derived REE could bridge an important lacuna by addressing dynamic energy demands of pediatric CRRT patients, therefore, allowing for individualized nutrition prescriptions.

INTRODUCTION. Ischemia/reperfusion (I/R) is one of the main causes of acute kidney injury (AKI), which is characterized by sterile inflammation and oxidative stress leading to perturbation of the microcirculation and tissue oxygenation.
OBJECTIVES. The primary outcome of this study was to improve microcirculatory perfusion and oxygenation by use of a hemoglobin-based oxygen carrier (PEG-COHb) or a colloid (HES-RA) to provide an improved organ perfusion, oxygenation and function in I/R induced renal microcirculatory injury in the rat.
METHODS. 36 fully instrumented, mechanically ventilated and anesthetized male *Wistar albino*rats were split into 4 groups consisting of control (C), I/R (45min. aortic occlusion and 1 hour reperfusion without resuscitation), I/R group resuscitated with either PEG-COHb or HES-RA at a dose of 5 ml.kg-1h-1. Systemic and renal hemodynamic, renal oxygenation, blood gas, electrolytes and blood chemistry were measured.
RESULTS. All of the fluids used in this study improved the MAP similarly compared to the C and I/R groups (p<0.05, respectively). CVP level was significantly increased by the PEG-COHb and in the IR group (p<0.05 vs. C) (Fig 1). Plasma lactate level was normalized only by HES-RA resuscitation (p<0.05 vs. C and I/R). RBF, cortical mPO2, Clcrea and urine output was depleted after the IR insult but was improved by PEG-COHb and HES resuscitation at T3 (p<0.05 vs. IR). DO2ren and VO2ren were increased by PEG-COHb and HES at T3 (p< 0.05 vs. IR) (Fig 2). PEG-COHband HES-RA provided efficient buffer capacity to maintain the plasma HCO3- and anion gap to correct the pH (p<0.05 vs. C and IR). Additionally, plasma proADMA, inflammation markers and tissue damage score were also comparable in between the PEG-COHb and HES-RA groups (p<0.05 vs. I/R).
CONCLUSION. To conclude, PEG-COHb and HES-RA showed similar beneficial effects on the systemic hemodynamic, renal blood flow, renal oxygenation and oxygen delivery resulting in better renal function.

INTRODUCTION. Seriously ill pts receive a great spectrum of antibiotics, whose dose is usually determined by estimated creatinine clearance (CrCl). Given the bad performance of the various equations for GFR estimation, we decided to evaluate calculated CrCl as a means to more objectively adjust antibiotics in ICU pts.
METHODS. We retrospectively compared 6-hour creatinine clearance (CrCl-6h), with the Cockroft–Gault equation (Ck-G) concurrently estimated, and recorded clinical characteristics and the changes in antibiotic dosage that were attributed to abnormal values of the parameters. CrCl was calculated as [Cr urine (mg/dl)× urine volume (ml)× / Crs (mg/dl)× minutes] and the Ck-G was calculated as [(140-age)× (weight)×(0.85 females) / 72× Crs].
Results are shown as mean±SD or as median and interquartile ratio. Comparisons between groups were made by Kruskal-Wallis test, applying SPSS 21.
RESULTS. In 47 randomly selected pts (age 71.57±12.44, male 22, APACHE II score 23±8.71, SOFA score 9.02±3.08, length of stay 19.89±15.03 days, mortality 40.4%) 89 recordings were evaluated. The Ck-G was 50.49 (47.36) ml/min and the CrCl-6h was 34.4 (37.37) ml/min. The therapeutic amendment according to calculated and estimated CrCl is shown in table 1.
CONCLUSION. The use of calculated 6-h led to antibiotics' dose amendment in almost half of cases, that in the majority had to do with dose reduction. Six-hour CrCl proved more reliable of the estimated CrCl, is easily measured regularly and can be used in order to avoid nephrotoxic doses of antibiotics or undertreatment of infections.

Table 1 (abstract 001212). See text for description

	No modification N=50 (56.2%)	Dose reduction N=27 (30.3%)	Dose increase N=12 (13.5%)	p
CrCl-6h (ml/min)	37.85 (52.13)	27.93 (34.05)	35.16 (29.13)	0.03
Ck-G (ml/min)	50.18 (43.96)	56.73 (42.26)	31.52 (34.46)	0.187
Difference [(Ck-G) – (CrCl-6h)]	5.68 (24.05)	19.03 (26.55)	-9.33 (28.37)	< 0.001

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001223

INTRODUCTION. Mean perfusion pressure (MPP) is the difference between mean arterial pressure (MAP) and central venous pressure (CVP). The difference in both pressures is also related to the patient mortality rate in the ICU. Patients with low MPP were also found to have high rates of renal failure. Patients with renal failure in the ICU have a high mortality rate as well. We expacted that by maintaining a normal MPP value, incidence of acute kidney injury decrease and the mortality rate will decrease. We hoped that calculating MPP can be an effective way to manage ICU patients and early detection for acute kidney injury (AKI). By measuring blood pressure and CVP we can easier to detect patient with acute kidney injury.
OBJECTIVES. The main purpose of this study is to assess for an association between Mean Perfusion Pressure, creatinine serum, and cumulative fluid balance in Intensive Care Unit (ICU).
METHODS. A cohort study was conducted from January to December 2017 in ICU Adam Malik Hospital Medan. Patients with age over 18 years admitted to our ICU were included. The demographic data, MPP, creatinine serum, and cumulative fluid balance were compared.
RESULTS. During the study period, 74 patients were admitted. 58.1% were male with mean age 45.5 ± 17.3 years old. There was association between Mean Perfusion Pressure with increasing creatinine serum in ICU (p=0.012). But there was no association between Mean Perfusion Pressure with cumulative fluid balance in ICU (p=0.203).
CONCLUSION. There was a correlation between Mean Perfusion Pressure and increasing of creatinine serum. Mean Perfusion Pressure can be a simple sign for acute kidney injury (AKI). Further study with a bigger sample is needed to explore the accuracy of MPP in ICU.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001265

INTRODUCTION. Cardiorenal syndrome type 1 (CRS-1) refers to syndromes denoting acute renal dysfunction caused by acute cardiac dysfunction or related to cardiac procedures. Patients with CRS-1 who need renal replacement therapy may suffer from a variety risk for adverse outcomes, including mortality and increased length of stays. It is unknown the impacts of the etiologies of CRS-1 on patients' outcomes.
METHODS. This was a nationwide sampling retrospective cohort study based on a clinical trial consortium in Taiwan. Up to January of 2016, 30 hospitals have joined this consortium. We enrolled all patients with acute dialysis in these hospitals and followed them up to 90 days after dialysis. The primary outcome was 90 days' all cause mortality and the secondary outcome was free from dialysis and length of stay.
RESULTS. A total of 1075 patients were in the final analysis. The mortality rates of patients with CRS-1 were listed in Table 1. Patients who were dialyzed for reasons other than CRS-1 had a mortality rate of 59.69%. After adjusting co-morbidities and acute physiology parameters, patients with CRS-1 after cardiogenic shock have a hazard ratio (HR) of 1.76 (1.06-2.93) to die within 90 days than patients without CRS-1; patients with acute decompensated heart failure (ADHF) had a more favorable 90 days' survival than non-CRS-1 patients, with an HR of 0.66 (0.46-0.96). Patients with cardiogenic shock were more likely to be dialysis dependence, with an HR of 1.78 (1.07-2.97). Patients with CRS-1 after cardiac surgery or ADHF were more likely to be off dialysis, [HR=0.53 (0.30-0.94) and 0.65 (0.45-0.94)]
CONCLUSION. Among patients with CRS-1 needing dialysis. The outcomes differed in terms of etiologies of cardiorenal syndrome. The discussion of CRS-1 outcomes should include the etiologies.

Table 1 (abstract 001265). 90 days' Outcomes of CRS-1 needing dialysis

	90 days' Mortality	90 days' Free From RRT	Length of Stay (ICU)	Length of Stay (Hospital)
Cardiorenal Syndrome type 1	158 (40.5%)	85 (29.11%)		
Dissected aorta	7 (53.85%)	4 (30.77%)	19.69	31.00
Cardiac surgery	12 (38.71%)	14 (45.16%)	25.87	33.03
Cardiogenic shock	16 (72.73%)	4 (18.18%)	19.55	16.36
Cardiac arrest	52 (73.23%)	14 (19.72%)	16.01	20.38
Bradycardia	3 (37.5%)	8 (62.5%)	3.88	14.25
Acute decompensated heart failure	32 (41.56%)	28 (36.36%)	14.49	24.09

Early diagnosis of Acute Kidney Injury in patients with sepsis in the ED

D. Paz
Intensive Care Unit, Angeles Lomas Hospital, Mexico City, CDMX, Mexico, Mexico
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001268

INTRODUCTION. The incidence of sepsis and acute kidney injury in critical patients is gradually increasing, both indicate a poor prognosis with higher morbidity and mortality. Failure on acute diagnosis may delay the onset of an adequate therapy which may cause an unfavorable outcome, such as the need for renal replacement therapy, generating high costs to the health system. The validation of new methods that identify the presence of acute kidney injury in its early stages is needed.
OBJECTIVES. To demonstrate which is the earliest marker for the diagnosis of acute kidney injury in patients with sepsis, including creatinine, cystatin C, urinary sediment and N-GAL.
METHODS. A prospective, longitudinal and descriptive study is presented, with data obtained from patients over 18 years of age, with sepsis, who attended to the American British Cowdray Medical Center Emergency Department, between July 2017 and July 2018.
RESULTS.
Cylinders in urine and cystatin C had the same capacity to detect cases of acute kidney injury on admission (sensitivity 71.4% and specificity 77.8%).
N-GAL showed a high sensitivity (greater than 85%) and a specificity of 100% at hospital admission and also maintained a high sensitivity of 87.5%, although its specificity was reduced due to transitions between patients from sick to healthy.
CONCLUSION. In this study we found that N-GAL is the most reliable biomarker for the diagnosis and prognosis of acute kidney injury compared to creatinine, cystatin C and urinary sediment. Its urinary levels increased much earlier. Without being modified by the patient's previous condition.

The use of bioelectrical impedance vector analysis (BIVA) guide for fluid elimination in critically ill patients undergoing renal replacement therapy

P. Nuchpramool, R. Ratanarat, V. Viarasilpa
Dept of medicine, siriraj hospital, mahidol university, Division of Critical Care, Bangkok, Thailand
Correspondence: R. Ratanarat
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001299

INTRODUCTION. Fluid restriction and elimination during stabilization and de-escalation phases of fluid therapy are the keys to reduce mortality. Using bioelectrical impedance vector analysis (BIVA), the body-composition measuring equipment for excessive body fluid evaluation guiding the negative fluid balance, may reduce mortality in critically ills undergoing renal replacement therapy.
OBJECTIVES. To compare 28-day mortality between using BIVA-guided management and using standard clinical management. The secondary outcomes were ventilator-free days, ICU and hospital mortality, ICU and hospital length of stay, ventilator-associated

pneumonia occurrence, incidence of hemodynamic instability during RRT (HIRRT) and renal recovery.
METHODS. In this randomized control trial, the medical intensive care unit (MICU) patients who had stable hemodynamics and required renal replacement therapy for fluid removal, were assigned to either the BIVA and the control groups. In both groups, the rate of fluid removal and vasopressor requirement were adjusted according to hemodynamics and clinical needs. Physician's fluid management decision depended on only standard clinical data for the control group, and on additional BIVA-derived values for the BIVA group in order to achieve %BIVA hydration of 72.4-74.3% and phase-angle of more than 5.5, respectively.
RESULTS. Of 36 enrolled patients, 17 patients (47.2%) were assigned to the BIVA group. Most of the reasons for MICU admission (77.8%) were sepsis/septic shock. Baseline characteristics of the patients in the two groups were similar. Mean APACHE II score at ICU admission in both groups were not different (30.5±12.5 in BIVA,29.8±8.2 in control, p = 0.85). Before enrollment, both groups were comparable in percentage of fluid accumulation (%FA) [11.3% (6.3,21.5) in BIVA group, 10.7% (5.7,19.2) in control group, p= 0.66)]. Use of add-on BIVA to standard treatment did not provide beneficial effect in rate of fluid removal indicating by body weight and %FA. The mortality from any cause by day 28 was 47% (8/17) in BIVA and 52.6% (10/19) in control group (p = 0.78). There was no statistically significant difference between the two groups in ICU and hospital mortality, ICU and hospital length of stay, and ventilator free day. For safety and complication, HIRRT and vasopressor requirements were comparable.
CONCLUSION. Using add-on BIVA guide fluid removal to standard therapy in critically-ill patient who required renal replacement therapy does not associate with 28-day mortality. Further studies are required due to small sample size in this study.

Renal Biomarkers can predict Progression and maladaptive repair after AKI in Critically Ill Cirrhotics

R. Maiwall, P. Jain, S. Sarin
Hepatology, Institute of Liver and Biliary Sciences, New Delhi, India
Correspondence: R. Maiwall
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001345

INTRODUCTION. Bacterial infections and systemic inflammation(SIRS) are the major precipitants of organ failure including acute kidney injury (AKI) in critically ill(CIC) and predispose to increased progression to Chronic Kidney Disease(CKD). Timely identification of AKI is therefore an unmet need. Biomarkers can help in differential diagnosis and prediction of the trajectory of AKI course. We evaluated Cystatin C(CysC) and urinary neutrophil-gelatinase-associated lipocalin (NGAL) as biomarkers of glomerular and tubular injury respectively in predicting a progressive AKI and maladaptive repair in CIC.
METHODS. CIC admitted to the Liver ICU were prospectively followed up. Baseline serum creatinine, history of prior AKI (past 3 months) and precipitant for AKI was recorded at admission. Progressive AKI was defined at day 7 as an increase of serum creatinine by 0.3 mg/dl from baseline or percentage increase of more than 50% or an increase in AKI stage or requirement of dialysis.
RESULTS. A total of 519 CIC, mean age 48.4±11.4 years, 86% males were followed for 26(8-97) days. The median serum NGAL and CysC was 759(223-1230) ng/ml and 2.1(1.5-2.7)mg/l respectively. SIRS was seen in 84%, sepsis in 58%, prior AKI in 18%. AKI at admission was present in 60% (Stage 1:2:3 43%vs 14%vs 43%) of which 48% recovered and 52% had progressive AKI. Sepsis was the commonest (46%) cause of AKI. At day 7, 317(61%) patients had progressive AKI of which 51% had new onset AKI. Of these, 56% had HRS, 10% prerenal AKI and remaining had acute tubular necrosis (ATN). The levels of NGAL and CysC were higher in patients in sepsis vs non-sepsis AKI (< 0.001), correlated with the severity of AKI stage (p<0.001), response to terlipressin (p<0.001), and recovery of AKI (p<0.001) but could not differentiate HRS from ATN. On multivariate analysis (OR,95% CI), u-NGAL (2.53,1.6-4), Cyst C (1.9, 1.1-3.4) and prior AKI (3.15,1.36-7.3) significantly predicted progressive AKI which in-turn was associated with higher mortality (HR 2.32,95%CI 1.8-3.1). Further, of all patients with progressive AKI, 144(45%) had transition to chronic kidney disease which signifies maladaptive repair. The levels of NGAL(OR 1.9,1.3-2.9) and Cyst C(OR 1.9,1.3-2.5) could also predict the development of end stage renal disease (ESRD) in CIC.
CONCLUSION. Almost two-thirds of CIC have AKI at presentation, which in majority is a result of sepsis, is progressive and is associated with worse outcome. u-NGAL and CysC can accurately predict progression of AKI and maladaptive repair with development of ESRD, and can help in stratifying patients for early therapeutic intervention. Prior AKI itself predisposes to AKI progression in CIC and should be carefully assessed in readmissions.

SARF-AKI: Severe acute respiratory failure related acute kidney injury, a large retrospective analysis

L. Teresa, J. Wilson, S. Matharu, S. Ledot, J. Doyle
Adult intensive care unit, Royal Brompton, London, United Kingdom
Correspondence: J. Doyle
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001469

INTRODUCTION. Veno-venous extracorporeal membrane oxygenation (VV-ECMO) in adults is an established therapy used to treat severe acute respiratory failure (SARF). Acute Kidney injury (AKI) is a major predictor of morbidity & mortality in critical illness, indeed a single episode of AKI confers an increased long-term mortality. Recently the characteristics of AKI induced by differing conditions has been better elucidated i.e. sepsis associated-AKI. Studies suggest renal replacement therapy (RRT) is required in 60% of patients on ECMO (1). However, to date there is a paucity of evidence in this area. Some data suggests the use of RRT in ECMO patients is not associated with an increased mortality (2). Whilst other data shows higher mortality & prolonged mechanical ventilation (3). There is no doubt AKI influences ECMO patient outcomes, we hope to add significantly to this emerging body of evidence.
METHODS. Retrospective analysis of consecutive patients on VV-ECMO for SARF over a 9 year period 01/2010-02/2019. Factors contributing to AKI, the need for RRT & duration of ECMO were recorded. Outcomes included; AKI stage by both creatinine and urine output criteria (as defined by KDIGO), need for RRT during the critical illness, persistent AKI on discharge and 28, 90 day & hospital mortality. These outcomes were further stratified by age group.
RESULTS. Data was obtained from 384 patients out of a total of 447 consecutive SARF patients from 01/2010 – 02/2019. Demographics as per (table 1). **Incidence of AKI**: As calculated by creatinine criteria; AKI1 32.8%, AKI2 9.6%, AKI3 52.3%. We also report the incidence of AKI as calculated by urine output criteria; AKI1 41.4%, AKI2 3.6%, AKI3 52.3%. **Need for RRT**: 50% of patients required RRT, with higher rates in increasing age groups (40.3% in <30s, 46% in 30-50 years and 58.6% in >50s). **Persistent AKI**: Overall, of the patients who received RRT and survived, 9.3% of them had persistent versus 0% for AKI 1/2. Hospital mortality: 24.4% for the 384 patients. **Mortality:** in patients who needed RRT was 61/192 (31.8%) compared with 15/66 (22.7%) in those with AKI 1,2&3 (without RRT) and 17/126 (13.5%) in those with no AKI. Mortality rates for ECMO patients with RRT compared to those without RRT are significant (p0.05). Mortality is further classified by age (table 2).
CONCLUSION. We report on one of the largest European data sets to date for VV-ECMO patients and for the first time on AKI as defined by KDIGO urine output criteria. The incidence of SARF-AKI for patients requiring ECMO is expectedly high. However reassuringly there is a relatively low occurrence of persistent AKI amongst ECMO survivors suggesting capacity for organ recovery. Additionally, the risk of mortality for those with AKI stage 1/2 is not different to those

without AKI. RRT requirement confers a significantly increased mortality risk, this is compounded in younger age groups which is of concern given this patient population.

Does Extracorporeal Membrane Oxygenation improve prognosis of Severe Acute Respiratory Distress Syndrome: A Systematic Review and Meta-analysis

D. xu
Department of critical care medicine, Zhongnan Hospital of Wuhan University, Wuhan, China
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000193

INTRODUCTION. The effect of extracorporeal membrane oxygenation (ECMO) on mortality in patients with severe acute respiratory distress syndrome(ARDS) remains controversial. To evaluate the use of ECMO for ARDS on prognosis in critically ill patients, we systematically reviewed the literature.
OBJECTIVES. Due to the heterogeneity of the study population and ECMO treatment, the existing clinical results of current studies on the prognosis of ARDS patients are inconsistent. Therefore, we use the quantitative evaluation method of meta-analysis to increase the total sample size and improve statistical efficiency.
METHODS. Databases from Pubmed, MEDLINE, EMBASE, and Cochrane were queried for studies on ECMO in patients with ARDS from 1948 through to November 2018. Databases from Pubmed, MEDLINE, EMBASE, and Cochrane were queried for studies on ECMO in patients with ARDS from 1948 through to November 2018.
RESULTS. Ten studies (three RCTs and seven observational studies) met our inclusion criteria in this meta-analysis, 1562 patients were included. Pooled analysis suggested that ECMO does not increase mortality in patients with ARDS in both the RCTs, (RR=0.83; 95%CI, [0.66-1.03]; P=0.32; I^2=12%) and the observational studies (RR=1.21 95%CI, [0.81-1.80]; P<0.01; I^2= 79%). These findings were also consistent across all subgroup analyses from observational studies. Four studies included data for the incidence of neurologic complications in the ECMO group, in which intracranial hemorrhage is the most frequent neurologic complication.
CONCLUSION. Our meta-analysis indicates that no statistically significantly higher mortality was associated with the application of ECMO in patients with ARDS. However, this finding largely relies on data from observational studies and is potentially subject to selection bias; hence, high-quality and adequately powered RCTs are warranted. Moreover, venovenous ECMO was also associated with a moderate risk of neurologic complications, and intracranial hemorrhage is rather common among patients receiving ECMO.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000211

INTRODUCTION. Protective mechanical ventilation (low tidal volume, plateau pressure <30 cmH2O, and high positive end expiratory pressure) has been proposed as a strategy to reduce the risk of ventilator induced lung injury (VILI). Mechanical power (MP) is a relatively new concept that takes into account variables that can cause VILI and that are not included in the protective strategy. Elevated MP could have a deleterious impact on the outcome of patients, so it should be monitored.
OBJECTIVES. To determine if elevated MP increases mortality in patients with invasive mechanical ventilation (MV).
METHODS. A prospective study was conducted in patients with MV for >24 continuous hours during their stay in the Intensive Care Unit (ICU). The MP was measured four times a day for the duration of the MV and the mean MP was calculated. Elevated MP was defined as a mean value >12 J/min. Mortality in the ICU was compared between patients with normal and elevated MP. The discriminative capacity for death of the mean MP was measured by analysis of the ROC curve. We identified independent risk factors for death through bi and multivariate logistic regression analysis. A p value <0.05 was considered statistically significant.
RESULTS. Eighty-seven patients were analyzed, 51.7% were males, mean age of 54.4 years. Twenty-nine (33.3%) patients had elevated MP. Mortality was significantly higher in patients with elevated MP (44.8%) compared to those with normal MP (8.6%), with p = 0.001. The area under the ROC curve of the MP for mortality was 0.799 (95%CI 0.674 - 0.923, p = 0.001). In the multivariate analysis, elevated MP showed RR of 1.460 (95%CI 1.091 - 1.954, p = 0.011).
CONCLUSION. The frequency of elevated MP is high. Mortality of patients with elevated MP is higher than that of those with normal MP. MP has adequate discriminative capacity to predict mortality and is an independent risk factor for death in patients with MV.

INTRODUCTION. Respiratory muscle weakness frequently develops in ventilated critically ill patients and is associated with adverse outcome, including difficult weaning from mechanical ventilation. Today, no drug is approved to improve respiratory muscle function in these patients. Previously, we have shown that the calcium sensitizer levosimendan improves calcium sensitivity of human diaphragm muscle fibers (from healthy and patients with chronic obstructive pulmonary disease) *in vitro* [1] and contractile efficiency of the diaphragm in healthy subjects *in vivo* [2].
OBJECTIVES. To investigate the effects of levosimendan on diaphragm contractile efficiency in mechanically ventilated patients.
METHODS. In a double-blind randomized placebo-controlled trial mechanically ventilated patients performed two continuous positive airway pressure (CPAP) trials for 30-minutes each with 5 hour interval. After the first CPAP trial, study medication (either levosimendan 0.2 µg/kg/min continuous infusion or placebo (equal volume)) was administered. During the CPAP trials electrical activity of the diaphragm (EAdi), transdiaphragmatic pressure (Pdi) and tidal volume (TV) were continuously measured. Neuromechanical efficiency (primary outcome parameter; computed as ΔPdi/ΔEAdi) and neuroventilatory efficiency (computed as TV/ΔEAdi) were calculated.
RESULTS. Thirty-nine patients were included in the study. Neuromechanical efficiency was not different during the CPAP trial after levosimendan administration compared to the CPAP trial before study medication (Figure 1). ΔEAdi and tidal volume were higher only after levosimendan administration, therefore resulting in no difference in neuroventilatory efficiency between the CPAP trial before and after study medication (Figure 1). ΔPdi was higher in both groups in the CPAP trial after study medication compared to the CPAP trial before study medication
CONCLUSION. Levosimendan does not improve diaphragm contractile efficiency in mechanically ventilated patients. The effects of levosimendan on weaning outcome needs to be established.

INTRODUCTION. Acute respiratory failure is the leading cause for intensive care unit admission for hematological patients. High flow nasal canula devices (HFNC) can deliver oxygen up to 60 L/min with active heated humidification. HFNC was proved to be beneficial in various forms of acute respiratory failure patients.
OBJECTIVES. We hypothesized that HFNC is beneficial for mild respiratory insufficiency in hematological malignancy patients.
METHODS. The primary goal of the study to show if HFNC can decrease need for invasive and non-invasive ventilation as well as comfort VAS and dyspnea VAS. Eligible patients were hematological malignancy at our hematogy ward regardless of time from diagnosis and bone marrow transplant patients with signs of respiratory distress or labored breathing and SaO2 less than 92% for at least one hour on room air or PaO2/FiO2 less than 300 mmHg. All randomized patients were included into the final analysis. The patients were randomized to either standard medical treatment or HFNC treatment groups
RESULTS. Total of one hundred, 34 female and 66 male patients were included into the study. Mean age was 56±15. Mean APACHE II score was 17±5. The most common reason for respiratory insufficiency was pneumonia with 74 patients. HFNC group was consisted of 51 patients and standard treatment group 49 patients. Endotracheal intubation was required in 16 (33.3%) patients in standard group and 24 (48.0%) patients in HFNC group (p=0.15). A total of 20 (40.8%) patients in standard group and 21 (41.2%) patients in HFNC group received non-invasive mechanical ventilation (p=0.97). Median VAS comfort score, VAS dyspnea score and VAS thirsty score at 2nd and 24th hours were not different between groups. Baseline median P/F ratio was 276 (min-max: 190 – 295) in standard group and 257 (min-max: 209 – 295) in HFNC group (p=0.07). P/F ratios were similar between the groups

throughout the study period. Median hospital length of stay was 36 (min-max: 3 – 130) days in standard group and 28 (min-max: 3 – 126) days in HFNC group (p=0.54). Twenty-eight day mortality rate was 18 (36.7%) in standard group and 23 (45.0%) in HFNC group (p=0.42).
CONCLUSION. HFNC is not superior to standard medical treatment in respiratory insufficient of hematological malignancy patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000243

INTRODUCTION. Acute respiratory distress syndrome (ARDS) is a life-threatening condition of critically ill patients, characterized by poor oxygenation and associated with capillary endothelial injury and diffuse alveolar damage. The proposed **"Berlin Definition of ARDS",** published in 2012, predicted mortality ever-so-slightly better than the existing ARDS criteria (created at the 1994 by American-European Consensus Conference/AECC).
OBJECTIVES. The aim of this study was to find a new approach from the impact of ARDS using the Berlin Definition and to analyze APACHE II score, days of mechanical ventilation (MV), duration of ARDS and mortality in critical ill patients in an ICU of a University Hospital.
METHODS. We collected prospectively from January 2015 to December 2018 and regarded all patients undergoing MV for 48 hours or more and who met the Berlin criteria of ARDS. All patients were ventilated according to the *ARDS.Net protocol* and we focused the analysis on the **moderate** and **severe** ARDS, excluding the mild patients (corresponding to the old AECC definition of acute lung injury - ALI) with PaO2/FIO2 $\leq$ 300 mmHg. We also conducted a subgroup analysis between *survivors* and *non-survivors patients*.
RESULTS. During this period 2219 patients were admitted in the ICU, 757 were under MV for at least 48 hours and ***117 had ARDS criteria.*** Patients with **moderate ARDS** 60%: 55% male, median age 61 years, APACHE II mean 21.79 (95% CI=20.21-23.27), mean duration MV 21.84 days (95% CI=18.18-27.60), ARDS duration 10.87 days (95% CI= 7.83-13.90), average stay 26.88 days, mortality 51.4%. Patients with **severe ARDS** 40%: 66% male, median age 49 years, APACHE II mean score 23.79 (95% CI=20.62-25.75), mean duration MV 17.25 days (95% CI=13.01-24.03), ARDS duration 13.33 days (95% CI=8.72-15.58), average stay 21.65 days, mortality 48.8% with no statistically significant difference with moderate ARDS (*p*=0.72). Leading cause of death was refractory multiorgan failure (60%).
CONCLUSION. Using the Berlin criteria of our ARDS patients we found no statistically significant differences in relation to the variables of interest to analyze in the two groups. In the analysis by subgroups, patients with severe ARDS who survive at the ICU admission have a longer duration of ARDS, which means more days on MV and therefore increased ICU stay.

INTRODUCTION. Moving from ICU ventilator to transportation ventilator is commonly performed by clamping endotracheal tube (ETT) to prevent lung derecruitment. Whether or not this clamping is effective in preventing derecruitment has not previously been investigated.
OBJECTIVES. The primary objective of this bench study is to evaluate if this procedure is effective to prevent air leakage. A second objective is to evaluate the role of different clamps and ETT .
METHODS. Elysee 350 ventilator was connected via ETT cuffed inflated to a lung model set in passive condition with compliance 40 ml/cmH2O and resistance 10 cmH2O/L/s. Ventilator was set in volume-controlled mode, tidal volume 400 ml, respiratory rate 21 breaths/min and positive end expiratory pressure 15 cmH2O. Airway pressure (Paw) and flow were measured between ETT distal end and lung model and sent to Biopac 150 datalogger. Three kinds of ETT (nasal, oral, reinforced) of same 8mm internal diameter and three kinds of clamps (plastic, metallic, ECMO) were tested. A single tube was used once for each clamp. Absence of leak in the whole setup was checked. Then after 4 breaths, an end-expiratory occlusion was done during which ETT was clamped. Then, the ventilator was disconnected from the ETT whilst Paw and flow were continuously recorded for 30 sec. This procedure was repeated three times for every combination of ETT and clamp. Leak after disconnection was defined as flow in the expiratory direction and Paw drop. Primary endpoint was Paw decay during 5 sec after disconnection and secondary endpoint volume lost over this period. Data are shown as median (1st-

3rd quartiles) and analyzed by ANOVA and pairwise comparisons with Holm procedure.
RESULTS. Every ETT-clamp combination was leaky. The magnitude of leak is shown in table 1. There was a significant effect of both ETT and clamp and a significant interaction between them. ECMO clamp performed better than the two others for the nasal ETT only. For the two other ETT there were no statistical difference between ECMO and metallic clamp. Plastic clamp had the worst performance in every case.
CONCLUSION. Any clamping ETT procedure was leaky. ECMO clamp performed the best.

Changes in tracheal intubation practice and complications over a ten-year period in an Intensive Care Unit in Scotland

AA. Ahmad, S. Elawad, Y. Neil, R. David
Intensive care, Royal Infirmary Edinburgh, Edinburgh, United Kingdom
Correspondence: S. Elawad
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000295

INTRODUCTION. A nationwide study performed in Scotland in 2009 reported the practice and complications of tracheal intubation in Intensive Care Units (ICU)1. Since then new guidelines 2,3 and trials 4 have been published. Anecdotally we have noticed changes in practice in our unit related to drug choice and use of videolaryngoscopy. To determine the extent of change we performed a pilot study in the Edinburgh Royal Infirmary, Scotland (RIE).
OBJECTIVES. To determine how intubation practice has changed in our ICU since 2009 and whether such change might warrant repeating a nationwide study.
METHODS. We conducted a prospective, observational study in critically ill adult patients requiring tracheal intubation over a three month period in 2018. We used an anonymised proforma to collect data including; timing and urgency of intubation, drugs used, number of attempts and complications. We used RIE specific data from the 2009 study for comparison and the Chi-square test for statistical analysis.
RESULTS. Data from 45 intubations were analysed. Forty-three intubations (95%) were performed by doctors with more than 24 months anaesthetic experience. Intubation was successful at the first attempt in 42 (89%). There was a significant change in drugs used for induction (p<0.001) and paralysis (p=0.03); in 2009 propofol (61%) and suxamethonium (58%) were commonest, and in 2018 ketamine (36%) and rocuronium (91%) were commonest [Figure1]. Use of videolaryngoscopy increased significantly from 0.7% in 2009 (nationwide data) to 27% in 2018 [Figure2, p<0.0001]. Severe hypoxaemia (SpO2<80%) occurred in significantly fewer patients in 2018 (9.5% v 22%, p=0.03), and hypotension appeared to occur less frequently but this was not statistically significant (16% v 21%, p=0.54) [Figure3].
CONCLUSION. Drugs used for intubation and laryngoscopy technique have changed, and intubation-related morbidity has decreased significantly in our ICU in the past ten years. Our pilot study suggests that a nationwide study should be repeated.

Improving non-invasive ventilation practice in St John's Hospital

S. Elawad[1], O. Fiona[2]
[1]Intensive care, Royal Infirmary Edinburgh, Edinburgh, United Kingdom; [2]Respiratory medicine, St John's Hospital at Howden, Howden, United Kingdom
Correspondence: S. Elawad
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000296

INTRODUCTION. Acute exacerbation of chronic obstructive pulmonary disease (COPD) is one of the most common reasons for hospital admissions in the UK. Non-invasive ventilation (NIV) has revolutionised the management of acute hypercapnic respiratory failure and has become one of the major advances in medicine for the last decades given that it is used correctly with effective settings. Recently released BTS and NCEPOD guidelines showed the delivery of NIV in the acute setting is frequently sub-optimal [1,2]. This was also the case in St John's Hospital.
In St John's Hospital NIV is managed by medical staff in high dependency area which is part of the medical admission unit. Our aim was to audit the current practice in comparison with the British Thoracic Society (BTS) quality standards [2] focusing on and aiming to improve ventilator's settings. Also, we aimed to formalise a hospital protocol for NIV. We have also looked at our escalation plan in treatment failure.
METHODS. For each round, non-identifiable patient data was collected prospectively aiming for at least 20 patients. We obtained verbal consent to look in to patient's notes. We used quality improvement methodology and created an audit tool using the BTS template example. The first round was carried out between November 2017 and February 2018 where we collected the data for 20 patients and analysed the results. We presented the findings in our local hospital medical teaching day and introduced the hospital protocol. We collected the data in the second round between February and July 2018 for 18 patients and analysed the results.
RESULTS. The total number of patient's data collected in both rounds 38. In both rounds patient mix was similar. We have been consistently managing to obtain CXRs and initial blood gases before starting non-invasive ventilation 38 (100%). In the first round 13 (65%) reached recommended setting of IPAP 16-22 compared to 14 (78%) in the second round. On the other hand escalation decisions were better in the first rounds were 18 (90%) of patients had a resuscitation decisions made and 14 (80%) had clear escalation plans before starting NIV compared to 15 (83%) in the second rounds.
CONCLUSION. Having a protocol to guide the use and modification of NIV settings along with ensuring the medical and nursing staffs' familiarity with the protocol helps in providing effective care. There is still scope for improvement in escalation decisions. Also, one of the issues we encountered was effective documentation which would be a further project to undertake.

Bronchoscopy in critical care: experience in 443 procedures in Hospital Italiano de Buenos Aires

I. Carboni Bisso, C. Videla, S. Di Stefano, M. Las Heras, JM. Dianti, E. San Román
Unidad de terapia intensiva adultos, Hospital Italiano de Buenos Aires, Ciudad Autónoma de Buenos Aires, Argentina

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000310

INTRODUCTION. Bronchoscopy is frequently performed in intensive care units (ICU) for therapeutic and diagnosis purposes. The technique is relatively easy to perform bedside, poses few complications and avoids potentially dangerous patient transfer outside the ICU. As a result, bronchoscopy is presently considered to be an essential tool in critical care.
OBJECTIVES. Assessment of main indications, clinical outcomes and complications associated with bronchoscopy in critically ill patients.
METHODS. A retrospective, single-center observational study over a period of 2 years (2017- 2019) was carried out in 215 patients undergoing bronchoscopy during their stay in the ICU.
RESULTS. A total of 443 bronchoscopies were carried out. Most of the procedures (86%) were performed in mechanically ventilated patients. The average patient age was 52.1 years. The most frequent indication was flexible bronchoscopy (FB) to perform the diagnosis confirmation of initially suspected pneumonia (38.8% [172]), with positive bronchoalveolar lavage (BAL) findings in 25.3%, followed by endoscopic control of percutaneous tracheostomy confection (31.6% [140]), direct evaluation of the airway (17.6% [78]) and bronchial toilette (9.0% [40]). Other indications, such as rigid bronchoscopy in a patients with acute tumor obstruction of the bronchial tree (1.6% [7]) and pulmonary cryobiopsy (1.4% [6]) were performed. Main complication associated with the procedure was bleeding (3.6% [16]). In most of the cases it was considered mild bleeding (2.0% [9]) and did not require any particular treatment for their control. Minor complications were transient hypoxemia (0.7% [3]) and hypotension (0.5% [2]). No serious events such as pneumothorax, arrhythmias or hemodynamic collapse were recorded.
CONCLUSION. Microbiological diagnosis of pneumonia with BAL and endoscopic control of percutaneous tracheostomy are the most frequent indications in critically ill patients. FB performed by an intensivist in ICU is a safe procedure, with low incidence of complications.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000311

INTRODUCTION. Pulmonary transplantation is life changing for patients with incurable lung disease. In potential donors, several supportive interventions are performed, in order to improve the yield of lungs available for transplantation. One purpose of these interventions is to reverse pulmonary atelectasis associated with the brain death process and to improve oxygenation; PaO2/FiO2 (P/F) ratio is a key parameter in the acceptability of donor's lungs. Protective ventilation and recruitment manoeuvres are two interventions that have already shown some benefit (1,2).
OBJECTIVES. Our objective was to describe the ventilatory and recruitment interventions performed in potential lung donors in our centre and their association with P/F ratio improvement.
METHODS. We performed a retrospective study between June 2013 and May 2018 at the Sacré-Cœur Hospital organ procurement centre. For this first analysis, we included all neurologically dead donors who successfully donated their lungs. We used data from our prospective database and completed data collection retrospectively from medical records. We recorded data on interventions potentially influencing P/F ratio: duration of donor support, initial tidal volume, positive end-expiratory pressure (PEEP) applied, recruitment manoeuvres, bronchoscopies, intrapulmonary percussive ventilation, and the use of diuretics. We calculated the P/F ratio (at 100% FiO2) and static lung compliance changes for each patient, between the neurological death (ND) and the last value before lung harvesting.
RESULTS. Of 268 potential donors, 222 were declared neurologically dead and 184 had organs harvested. We included 89 patients in whom lungs were retrieved for transplantation. Mean age was 46±18 years and 37% were women. Mean duration of support was 33±20h and half of them received at least one dose of diuretic. Initial protective tidal volume (≤8mL/kg predicted body weight) was applied to 42% of patients and at least one recruitment manoeuvre (median 2 [0 -10]) was performed in 69% of them. The median PEEP was 8 (range 5-12). Median number of bronchoscopies post ND was 1 (range 1-8) and 50 patients (56%) received intrapulmonary percussive ventilation. Between the ND and harvesting, the median change in compliance was 4 mL/cmH2O (range -25 to 48) and the median change in P/F ratio was 93 (range -176 to 277). Exposure to percussive ventilation, adjusted for age, PEEP, protective ventilation and the number of recruitments, was the only intervention independently associated with P/F ratio improvement (OR: 4.5, 95% CI 1.7-11.6).
CONCLUSION. In our institution, less than half of lung donors were ventilated with protective tidal volume. Percussive ventilation was associated with significant improvement in oxygenation. Further prospective studies are needed to validate these findings.

Respiratory mechanics under paralysis and spontaneous breathing in mechanically ventilated ARDS/acute hypoxemic respiratory failure patients

WC. Lin, CC. Hsieh, JC. Lee, CW. Chen
Division of critical care medicine, department of internal medicine, National Cheng Kung University Hospital, Tainan, Taiwan
Correspondence: C.W. Chen
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000312

INTRODUCTION. Accurate measurement of respiratory mechanics is important because end-inspiratory plateau pressure (Ppla), positive end-expiratory pressure (PEEP) and tidal volume (Vt) remained the core parameters to be monitored in mechanically ventilated ARDS patients. It is easy to have reliable measurement of respiratory mechanics when patients are paralyzed but may be problemic when respiratory efforts are present. A clean Ppla was proposed to be trustable. This proposal was not validated in mechanically ventilated ARDS or acute hypoxemic respiratory failure patients under pressure control ventilation (PCV).
OBJECTIVES. A crossover study for comparison of respiratory mechanics measured during paralysis and spontaneous breathing in mechanically ventilated patients under PCV
METHODS. Twenty-four patients with ARDS or acute hypoxic respiratory failure were included in this study over a two-year period. Esophgeal pressure monitoring was placed in all cases. Tidal volume (Vt), total PEEP (PEEPt), airway driving pressure (ΔP), transpulmonary driving pressure (ΔPL), respiratory system compliance (Crs), lung compliance (CL), chest wall compliance (Ccw) were calculated with performance of end-inspiratory occlusion. A clean Ppla was defined as no steadily increasing or decreasing Ppla and Ppla with periodic oscillations less than 2–3 cmH2O. Data are presented as mean ± SD. Mann Whitney test and Spearman's rank correlation test were used for statistical analysis.
RESULTS. Fourteen patients have reliably measured respiratory mechanics during both paralysis and spontaneous breathing under PCV. Respiratory mechanics measured under paralysis and spontaneous breathing were: Vt: 468 ± 77 vs. 519 ± 90 ml, $p = 0.11$; PEEPt: 11.4 ± 3.4 vs. 10.2 ± 2.2 cmH2O, $p = 0.42$; ΔP : 12.4 ± 2.2 vs. 13.0 ± 2.0 cmH2O, $p = 0.60$; ΔPL: 8.5 ± 2.1 vs. 9.6 ± 2.7 cmH2O, $p = 0.28$; Crs: 38.9 ± 8.5 vs. 41.1 ± 9.6 ml/cmH2O, $p = 0.70$; CL: 58.8 ± 19.2 vs. 58.8 ± 19.9 ml/cmH2O, $p = 0.87$; Ccw: 130.3 ± 40.2 vs 213.1 ± 179.0 ml/cmH2O, $p = 0.12$. Spearman's rank correlation test revealed high correlation in measured Crs ($r = 0.85$, $p < 0.0001$) and CL ($r = 0.94$, $p < 0.0001$) between paralysis and spontaneous breathing in individual patient, but poor correlation for Ccw ($r = 0.433$, $p = 0.12$).
CONCLUSION. Our findings suggest a clean Ppla during PCV is reliable for measurement of Crs and CL, but not for Ccw in spontaneously breathing patients.

Patient-ventilator asynchrony in brain-injured patients: a prospective observational study

L. X-Y, H. X, JX. Zhou
Critical care medicine, Capital Medical University, Beijing, China
Correspondence: J.X. Zhou
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000314

INTRODUCTION. It has been reported that patient-ventilator asynchrony is associated with adverse clinical outcomes [1]. However, asynchrony is poorly defined in brain-injured patients. This study aimed to investigate the incidence and risk factors of asynchrony in this population.
METHODS. In this prospective observational study (NCT03212482), adult patients with brain injury and mechanical ventilation were included. Exclusion criteria were age < 18 yrs, without spontaneous breathing, and presenting with agitation. After enrollment, esophageal pressure (Pes) monitoring was established using standard method [2]. A dedicated acquisition system was used to obtain data of flow, airway pressure and Pes, which were collected for 15 min at 6-h intervals for 72 h. Four types of asynchrony were confirmed by Pes tracing according to previous reported definitions, which included ineffective-trigger, double-trigger, premature-cycle and delayed-cycle [1]. The asynchrony index was calculated as previous report [3]. Fifteen-min recording datasets with asynchrony index ≥ 10% were defined as asynchronous datasets, whereas patients with asynchrony index ≥ 10% for the sum of all datasets were defined as asynchronous subjects. Demographics data and type of injury were documented. Prior to each recording period, data of ventilator settings, blood gas, level of consciousness and the use of sedation and paralysis were collected. Clinical outcomes were followed up to hospital discharge or death. Comparisons between the asynchronous and non-asynchronous datasets and subjects were performed using t test or Mann-Whitney U test, as appropriate.
RESULTS. We enrolled 30 patients with mean age of 53 ± 17 yrs and 60% male. A total of 311 fifteen-min datasets were collected yielding 87,260 breaths, in which 11,601 (13.3%) asynchronous breaths were identified. The most common type of asynchrony was ineffective-trigger (61.8% of total asynchronous breaths), followed by delayed-cycle (21.9%), premature-cycle (12.8%) and double-trigger (3.5%). There were 91 (29.3%) datasets with asynchrony index ≥ 10%, and 11 (36.7%) patients had total asynchrony index ≥ 10%. A more severe consciousness impairment, more frequent use of synchronized intermittent mandatory ventilation, higher tidal volume and respiratory rate, and more frequent use of sedation and paralysis were found in the asynchronous datasets (Table 1). More patients with traumatic brain injury was found in the asynchronous subjects (Table 2). Adverse clinical outcomes were found in asynchronous subjects (Table 2).
CONCLUSION. Patient-ventilator asynchrony was prevalent among brain-injured patients. Level of consciousness, and the ventilator mode and settings, as well as injury type were associated with asynchrony. Clinical outcomes were worsen in asynchronous patients.

High-flow oxygen through Nasal Cannula versus Continuous Positive Airway Pressure in moderate Acute Respiratory Distress Syndrome due to pneumonia

M. Giovini, M. Barbera, E. Antonucci
Intermediate care unit, Ospedale "Guglielmo da Saliceto", Piacenza, Italy
Correspondence: E. Antonucci
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000330

INTRODUCTION. Pneumonia can progress in acute respiratory distress syndrome (ARDS) that usually shows poor outcomes in critically ill patients. If on one hand the management of severe ARDS is extensively debated in the literature, on the other hand the treatment of

moderate ARDS is not well standardized. In this perspective, oxygenation modalities (OM) such as continuous Positive Airway Pressure (C-PAP) and High Flow Oxygenation through Nasal Cannula (HFO) could be useful in adult patients with moderate ARDS due to pneumonia, but no study has ever compared helmet c-PAP and HFO in this field.

METHODS. We performed a retrospective analysis, reviewing all patients with moderate ARDS due to pneumonia and admitted to our Intermediate Care Unit (IMCU) from December 2016 to December 2018. The inclusion criteria were age ≥ 18 years old; moderate ARDS classified by Berlin definition; oxygenation with HFO or helmet C-PAP (stand-alone system) for 2 consecutive days at least. Exclusion criteria were history of chronic obstructive pulmonary disorder (COPD) or other chronic respiratory disorders; lung cancer; acute cardiogenic edema; severe neutropenia; circulatory failure. We analyzed two groups (C-PAP and HFO) matched for age, SAPS2 score, SOFA score and PaO2/FiO2 ratio before OM. We also collected demographic characteristics, settings of OM and we investigated rates of ETI, IMCU mortality and mortality at 90 days.

RESULTS. We reviewed 54 patients and 20/54 respected the inclusion criteria (10 in HFO group; 10 in CPAP group). The two groups were well matched (PaO2/FiO2 ratio before OM: 108 ± 39 (C-PAP), 119 ± 35 (HFO) p= 0.5; SAPS 2 score: 38 ± 14 (C-PAP), 30 ± 11 (HFO) p= 0.2; SOFA score: 5 ± 2 (C-PAP), 4 ± 2 (HFO) p= 0.4; age: 67 ± 14 (C-PAP), 60 ± 19 (HFO) p= 0.4). We found no significant difference in ETI rate [HFO 3/10 (30%), C-PAP 3/10 (30%)], IMCU mortality [HFO 1/10, C-PAP 2/10, OR= 2.25, 95% CI: 0.17-29.77, p= 0.5] and mortality at 90 days [HFO 2/10, C-PAP 3/10, OR = 1.7, 95% CI: 0.22-13.41, p= 0.6] (see Figure). Interestingly, C-PAP induced a higher increase of PaO2/FiO2 ratio than HFO (although not statistically significant, p=0.1) without effects on ETI and mortality rates.

CONCLUSION. In adult patients with moderate ARDS due to pneumonia, treatment with helmet C-PAP or HFO did not result in significantly different ETI and mortality rates.

INTRODUCTION. Prone positioning more than 10 hours improves oxygenation and mortality in patients with moderate to severe acute respiratory distress syndrome (ARDS). Homogenization of lung ventilation in prone positioning establishing more uniform distribution of tidal breath is the possible mechanism contributing to better outcome by alveolar recruitment and prevention of ventilator-induced lung injury. However, the time course of homogenization of ventilation has not been investigated. Electrical impedance tomography (EIT), which is the real-time monitoring tool of ventilation, has been demonstrated to be used for the evaluation of ventilation homogeneity in different body positions.

OBJECTIVES. The objective of this study was to examine the impact of prone positioning on ventilation homogeneity evaluated by EIT in ARDS patients.

METHODS. In this retrospective study, we performed off-line analysis of EIT data previously recorded before (in supine position, SP) and after taking prone position (PP) in clinical settings. In each PP session, ventilation homogeneity was evaluated using EIT measures; the proportion of ventilation distribution (ventral and dorsal lung parts, expressed in percentage to the tidal volume=100%), spatial dispersion and temporal delay in regional distribution of tidal breath (global inhomogeneity index: GI index, regional ventilation delay: RVD). These EIT measures and oxygenation were compared to the data measured in SP immediately before PP. Off-line analysis was performed by a blinded researcher. For the comparison between before and after PP, paired t-test or Wilcoxon rank sum test were used for statistical analysis as appropriate.

RESULTS. The EIT data of seven PP sessions in five patients (three primary and two secondary ARDS, mean age 66) were analyzed. Mean time to EIT measurement from the initiation of PP was 7 ± 2 hours (mean ± SD). The ventilator mode and/or pressures were changed in three PP sessions. Ventilator mode was changed from assist control to airway pressure release ventilation in one session and inspiratory pressures in assist control were increased in two sessions after taking PP. The mean proportion of ventilation in dorsal lung region increased from 44 ± 9% to 56 ± 9% (P=0.010) in PP, showing a beneficial effect of lung recruitment in dorsal part in 6 PP sessions. GI index and RVD significantly reduced after taking PP, indicating more homogeneous ventilation was achieved compared to SP. The oxygenation improved in 6 PP sessions. Significant increase in mean PaO2/FIO2 was demonstrated after taking PP (SP;130 ± 65 mmHg vs PP; 202 ± 98 mmHg, P=0.020). All patients were successfully weaned from the ventilator. Four patients have survived and discharge from the hospital.

CONCLUSION. In our cohort relatively short period application of prone positioning provided more homogeneous ventilation compared to supine position, which might result in better oxygenation.

INTRODUCTION. Lung ultrasound (LUS) score allows reliable quantification of loss of aeration[1]; it has already been applied to PEEP-induced recruitment, ARDS lung healing, weaning from mechanical ventilation and VAP recovery[2].
OBJECTIVES. To determine if LUS score early identifies responders to non-invasive respiratory support.
METHODS. Prospective observational multicenter international study (Pavia, Novara, Dijon). LUS score (from 0-normal aeration to 3-complete loss of aeration computed in 6 standard regions per hemithorax–2 anterior, 2 lateral, 2 posterior) was measured before and after 2 hours of non-invasive support (high-flow nasal cannula-HFNC, continuous positive airways pressure-CPAP, non-invasive ventilation-NIV) in hypoxemic patients (PaO2/FiO2<300). Non-responders required intubation within 48 hours.
RESULTS. 31 non-invasive supports in 29 patients (males 13, age 71.5± 13.4 yo, BMI 27.1±4.5 kg/m2, SAPS2 35.0 [29.0-47.0]), admitted to ICU from ED (15), OR (9) and medical ward (5) for acute respiratory failure (15), major surgery (9), neurological diseases (3), HELLP syndrome (1), cardiac arrest (1). They required non-invasive respiratory support for weaning failure (7), pneumonia (7), ARDS (6), derecruitment (6), pulmonary edema (5). The respiratory support was helmet CPAP (26), HFNC (3), helmet (1) and mask (1) NIV; 7 failed (22.6%).
Failing and non-failing patients didn't significantly differ before non-invasive respiratory support in term of PaO2/FiO2, respiratory rate, pH and PaCO2; LUS score similarly was not significantly different (Tab.1). After 2 hours of support, failing patients were significantly more hypoxemic and hypocapnic, despite pH and respiratory rate were not significantly different from non-failing ones. They also had significantly higher LUS score. A LUS score ≥17 predicted the failure of non-invasive respiratory support with 100% sensitivity and 83.3% specificity, while a global LUS score ≤12 predicted the success of non-invasive respiratory support with 100% sensitivity and 85.7% specificity.
CONCLUSION. LUS score early identifies responders to non-invasive respiratory support.

INTRODUCTION. In the last decade, high-flow nasal oxygen therapy (HFNO) has appeared as an intermediate alternative ventilatory support between conventional oxygen and mechanical ventilation. Its efficacy has been demonstrated in patients with respiratory failure due to different etiologies (1-2). Patients treated with HFNO rapidly showed a reduction in respiratory rate and work of breathing, associated with an improvement in functional residual capacity and gas exchange.
OBJECTIVES. To analyze the outcome of clinical and gasometric parameters during the first 24 hours of high-flow nasal oxygen therapy administration in patients with acute respiratory insufficiency with and without associated hypercapnia. Identify bad outcome predictors such as: need for mechanical ventilation and mortality.
METHODS. Prospective observational study. Adult patients admitted in the ICU to whom high-flow oxygen therapy is administered at the decision of their responsible physician. Demographic data, severity scales, treatment parameters, physiological variables and gasometry were collected.
Gasometric monitoring is performed at 1, 3, 12 and 24 hours after the start of therapy.
RESULTS. 45 patients were recruited. Mostly male (73%), the average age was 65.7 (61.7-69.7) years. APACHE II 20.5 (17.7-23.3). Among the causes of acute respiratory failure were found: heart failure (31.1%), pneumonia (22.2%), exacerbated COPD (13.3%), post extubation respiratory failure (11.1%). The therapy was initiated with FiO2 77.8% (70.6-68.5) and flow of 52.6 l/min (51-54.2). 12 (26.7%) patients required mechanical ventilation and mortality in the ICU was 18%.
A statistically significant reduction in respiratory rate was observed: -6 (-7 to -9.5) rpm and cardiac frequency: -13.6 (-7.2 to -20) bpm. An increase in SpO2 was observed: 4.4 (1.7-7)%. No significant changes were observed in pCO2. Similar changes were confirmed in the subgroup of patients with initial pCO2> 45 mmHg. The cardiac frequency was associated with mortality: area under the ROC curve: 0.72 (0.55-0.89), with an HR of 99 bpm being the cut-off point that best discriminated between patients who died and survived.
CONCLUSION. High-flow oxygen therapy improved physiological parameters of acute respiratory failure in our sample. Despite no improvement on pCO2, its use seems safe in patients with moderate hypercapnia. Persistent tachycardia could be a predictor of therapeutic failure.

INTRODUCTION. Oxygen therapy is a mainstay treatment in patients with hypoxemia or after extubation for maintaining adequate oxygenation and reducing work of breathing. Conventional low flow oxygen therapy via simple nasal cannula and oxygen rebreathing mask with bag is commonly used. However, these devices can only provide a maximum flow rate of 15 LPM which may be inadequate for patients with acute respiratory failure. High-flow nasal cannula (HFNC) is a high flow oxygen delivery system that can deliver up to 60 LPM of air-oxygen mixture gas via a wide-bore nasal cannula. It can also adjust oxygen concentration from 21-100% and provide heated and humidified gas. HFNC has been demonstrated several benefits in patients who were admitted in Intensive Care Unit (ICU) with acute hypoxemic respiratory failure and after extubation. Using HFNC outside ICU without close monitoring is growing especially in general ward and emergency department; however, the evidence in terms of efficacy and safety of HFNC in such places is scant.
OBJECTIVES. To evaluate efficacy and safety of HFNC in general internal medicine wards and factor associated with failure of HFNC.
METHODS. We performed a prospective cohort study during October 2017 to April 2018 in general internal medicine wards at Siriraj Hospital, Bangkok, Thailand. Adult patients who were admitted in general internal medicine wards and received HFNC (Airvo-2TM, Fisher & Paykel Healthcare, Auckland, New Zealand) were enrolled. All included patients were continuously monitored by multidisciplinary care team who were trained and familiar with HFNC device. The primary outcome was the rate of HFNC failure (defined by intubation or receiving non-invasive ventilation). The secondary outcomes included in-hospital mortality, 28-day mortality and factors associated with failure of HFNC.
RESULTS. A total of 88 patients were enrolled and 17 of them were patients with do-not-resuscitate (DNR) order. Mean age was 71±15 years old, APACHE II score was 18±6 and SOFA score was 6±3. Lower respiratory tract infection was the leading cause of hospital admission. The main indications of HFNC were acute hypoxemic respiratory failure (63.6%) and prophylactic after extubation (31.8%). Mean duration of HFNC use was 76.6±62.8 hours. Rate of HFNC failure was 39.8% and in-hospital and 28-day mortality were 30.7% and 36.4%, respectively. We performed subgroup analysis by excluding patients with DNR status and demonstrated that the rate of HFNC failure was 25.4% and in-hospital and 28-day mortality were 14.0% and 21.1%, respectively. The main reasons for failure of HFNC were hypoxemia and increased work of breathing. Factors associated with failure of HFNC were presence of comorbidity and respiratory rate on the first day of HFNC use ($P< 0.05$). Overall adverse event of HFNC was 6.8% and all of them were minor adverse event.
CONCLUSION. HFCN is safe and effective to use in general internal medicine wards. Presence of comorbidity and higher respiratory rate on the first day are the risk factors of HFNC failure. Appropriate patient selection and monitoring are the key for the success.

A new mask design with different ports for inflow and outflow gases reduces CO2 rebreathing in healthy volunteers during Non Invasive Ventilation

INTRODUCTION. CO2 rebreathing is known to be a cause of Non Invasive Ventilation (NIV) failure [1]. Recently we showed in a bench study that a new mask design (DiMax Zero, Dimar srl, Medolla, Italy) with different ports for inflow and outflow gases significantly reduced CO2 rebreathing in different ventilation settings [2].
OBJECTIVES. To test wheter a new mask design reduces CO2 rebreathing in healthy volunteers during NIV.
METHODS. Young adults with no pulmonary or cardiac comorbidities were eligible. Volunteers underwent NIV through two different masks: a traditional one with a single port for inflow and outflow gases (DiMax) and the new mask with separated ports (Dimax Zero). Six ventilation settings were tested: cPAP (PEEP 5 cmH2O) and Pressure Support Ventilation (PSV, PS Level 5 cmH2O) performed with mechanical ventilator and two different flow-by (8 and 20 l/min); free flow cPAP (PEEP 5 cmH2O) with two different gas flows (60 and 90 l/min). A nasal cannula was inserted in one nostril of the volunteer and connected to a gas analyzer (ADInstruments) to record CO2 concentration along the respiratory cycle (Lab Chart, ADInstruments). An EIT belt (Pulmovista, Draeger) was used to record the change in impedance during tidal breathing, to estimate tidal volume (Vt). Respiratory rate (RR) was also calculated. CO2 during inspiration, RR and and Vt were compared between the two masks in the same ventilation setting and within the same mask in different ventilation settings. ANOVA for repeated measured + post tests was used for statistical analysis. A $p<0,05$ was considered significant.
RESULTS. Seven healthy adults were enrolled in the study and gave their informed consent. CO2 during inspiration was significantly lower with DiMax Zero than with DiMax mask (Fig. 1, $p<0,001$ for DiMax Zero vs DiMax in all settings).

The maximum reduction was observed in the free-flow cPAP settings. The different ventilation settings had no influence on inspired CO2 with both masks. The difference in inspired CO2 was associated with a slight, non significant reduction in Vt during cPAP settings with DiMax Zero mask, while there were no differences in Vt during PSV settings nor in respiratory rate in any setting between the two masks (Fig. 2).

CONCLUSION. The new mask design with different ports for inhaled and exhaled gases was able to significantly reduce the amount of CO2 rebreathing in all the ventilation settings tested. The sample size has to be increased to highlight if this translate into a reduction in minute ventilation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001439

INTRODUCTION. No consensus exists regarding optimal timing for performing tracheostomy in mechanically ventilated neurocritical care patients.

OBJECTIVES. To evaluate the correlation between timing of tracheostomy and ICU mortality. Secondary end points were tracheostomy effects on: duration of sedation, duration of mechanical ventilation (MV), ventilator-associated pneumonia (VAP) incidence prior and post-tracheostomy and length of ICU stay (LOS) as well.

METHODS. Single-center study on adult neurocritical care patients (TBI, aSAH, ICH) admitted to our ICU from January to December 2018. Percutaneous elective tracheostomy was performed in all expected to need >14 days MV due to current neurological status. We assigned patients into two groups: early tracheostomy (ET ≤8 days after endotracheal intubation) and late tracheostomy (LT >8 days). Exclusion criteria were: poor prognosis, use of barbiturates, extubation failure and readmissions. Demographics, diagnosis at admission, severity of illness estimated using the APACHE II and GCS, Charlson comorbidity index (CCI) score, duration of sedation and MV, incidence of VAP, LOS and in ICU mortality were recorded. Student t-test or Mann Whitney U test were used for quantitative data and the Pearson chi-squared test or Fisher's exact test for qualitative data as necessary. The level of significance was set at P<0.05.

RESULTS. 41 patients were recorded but finally 38 (31.6%TBI, 26.3% aSAH, 42.1% ICH) were included (missing data). Each group consisted from 19 patients. The median time between ICU admission and ET or LT was 6(2-8) and 11(9-16) days respectively. Baseline characteristics (sex, age, GCS, APACHE II) were similar in both ET and LT group (p>0.05) except from CCI score (2.37±1.42 vs1.47±1.31; p =0.043) and ICU admission diagnosis (TBI:3vs9, aSAH:1vs9, ICH:15vs1 patients). Total MV and sedation duration were significantly longer in the LT-group (9vs16.1d; p<0.001 and 5.74vs10.42d; p=0.005 respectively) but post-tracheostomy there were no differences neither in sedation (p=0.682) nor in MV duration (p=0.914). Patients with LT had a higher incidence of VAP before tracheostomy (p=0.034) but no significant difference was found in post-tracheostomy MV period (p=0.547). All survivors were completely weaned from MV but none was decannulated at ICU discharge. The ICU LOS and mortality did not differ between the compared groups (p=0.075 and p=0.29 respectively).

CONCLUSION. ET reduced sedation requirements, time to wean from MV and VAP incidence in our cohort. No mortality or ICU LOS benefit was found between the compared groups. Our findings are in agreement with previous studies. It seems that tracheostomy policy in neurocritical care patients still remains a challenge and needs to be personalized.

INTRODUCTION. Spontaneous breathing (SB) efforts in acute respiratory distress syndrome patients on mechanical ventilation, has been associated with strong diaphragmatic activity and the generation of excessive strain and high regional pleural pressures in the dependent lung regions [1]. However, these mechanisms may will be present

before intubation [2]. We hypothesize that spontaneous breathing efforts during early stages of lung injury may promote high regional strain and further regional lung inflammation and that controlled mechanical ventilation is able to avoid and or reverse and control this inflammation.

OBJECTIVES. To determine the effects of spontaneous breathing efforts, during the early stage of lung injury, on regional ventilation distribution and regional inflammation.

METHODS. Six pigs (30±5kg) were anesthetized and mechanically ventilated (PEEP 5 cmH2O, VT 8 ml/kg). Lung injury was induced by 2 lavages with 30 ml/kg of warm saline. After the injury, pigs were ventilated 4 hours (T4) in pressure support ventilation (PSV for Vt of 6-8 ml/kg, PEEP between 0 and 5, and FIO2 of 1), and then switched to volume controlled ventilation (VCV) for 4 more hours (T8) using VT of 6 ml/kg, RR of 30 bpm, PEEP of 5 cmH2O, I:E ratio 1:2 and FIO2 of 1. Respiratory and hemodynamic data, as well as regional lung impedance, assessed by EIT (Pulmovista 500, Dräger), were collected at baseline, T4 and T8. BAL were performed at the anterior and posterior lung at T4 and T8 for analysis of inflammatory parameters (IL-8 and TNF-a)

RESULTS. VT increased from 8 ml/kg at baseline to 8.2 (7.1-8.8) (p= 0.03) at PSV. During T8, VT decreased to 6 ml/kg (5.4-6.7) (p= 0.001). Mean airway prressure decreases from 9 (6.7-11) to 2 (3.8-1.8) cmH2O (p= 0.001) but when switched to VCV it increased to 11 (8.8-12.8) (p=0.003). EIT analysis showed an increase in global inhomogeneity index (GI) from 1.03 (0.99-1.04) to 1.09 (1.06-1.38)(p=0.04) (Fig. 1A). In addition, when we compared T4 vs T8, tidal variation of impedance (TVI) decreased from 2227 (1520-2933) to 1137 (876-1768) (p=0.03) (Fig. 1B) and impedance ratio (IR) showed an increased from 0.75 (0.3-1.2) to 1.3 (0.5-2.0) (p= 0.03) (Fig. 1C). Regional IL-8 quantification showed greater inflammation in the dependent lung regions during PSV, situation that was reversed with VCV (3670 ± 2310 vs 1603 ± 2311 pg/uL, p= 0.02) (Fig. 2).

CONCLUSION. SB efforts during MV were associated with higher VT than controlled ventilation and lung aeration was mainly distributed in the dependent lung regions and these regions presented higher concentration of inflammatory markers, situation that was reversed during CMV.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001479

INTRODUCTION. The very elderly patients (i.e., those aged ≥ 80 years-old) represent an increasing subgroup of patients admitted to intensive care units (ICUs). Community-acquired pneumonia (CAP) is a common reason for ICU admission and how to best provide initial ventilatory support in these patients is unknown.

OBJECTIVES. To evaluate if the initial ventilatory strategy is associated with hospital mortality in very elderly patients admitted to the ICU.

METHODS. We did a retrospective multicenter cohort study of very elderly patients admitted to the ICU with a diagnosis of CAP from 2009 through 2012. Data was retrieved from the ICU quality database (Epimed Monitor) and checked for consistency. We used logistic regression to evaluate the primary outcome (hospital mortality), after adjusting sequentially for potential confounders chosen from a causal directed acyclic graph. We imputed missing data with multiple imputation by chained equations using the predictive mean matching algorithm. We evaluated ad-hoc defined subgroup effects with interaction terms in the logistic model. Sensitivity analyses were done to assess model consistency regarding the primary outcome.

RESULTS. 6,318 very elderly patients were admitted to the 11 ICUs during the study period. 1,713 admissions were due to respiratory causes, of which 678 patients were admitted for CAP. Mean age was 86.3 years (4.7); 288/678 (42.5%) were male. Mean

SAPS 3 score was 63.5 (12.8), with a median SOFA of 4 [2; 7] and a median Charlson comordity score of 1 [1; 3]. 191/678 (28.2%) patients were previouslly bedridden and 253/678 (37.3%) needed some assistance in activities of daily living. 309/678 (45.6%) did not use any MV strategy (no MV group); 232/678 (34.2%) underwent NIV first; 137/678 (20.2%) underwent IMV first. IMV patients were sicker at ICU admission when compared to both NIV and no MV groups (SAPS 3: 76.5 vs. 62.6 vs. 58.4, p-value < 0.001), with no statistically significant differences in the antecedent characteristics (burden of comorbidities and performance status). Hospital mortality was 90/309 (29 %) for no MV; 114/232 (49 %) for NIV; 90/137 (66 %) for IMV. For the comparison IMV vs. NIV, crude OR (95% CI, p-value) was 1.98 (1.28 – 3.07, p = 0.002). After adjusting for age, sex and antecedent characteristics, the aOR was 2.17 (1.38 – 3.42, p = 0.001). After including non-respiratory SOFA in the model, aOR was 1.23 (0.74 – 2.03, p = 0.419). After including respiratory variables (Pao2/Fio2; pH; Pco2) in the model, the aOR was 1.1 (0.65 – 1.85, p = 0.720). Interaction terms for the following characteristics showed no evidence of effect modification: heart failure, chronic obstructive pulmonary disease, bedridden status, non-respiratory SOFA ≥ 4, acute respiratory acidosis and Pao2/Fio2 ≤ 150. Complete case analysis (sensitivy analysis) yielded the same results.

CONCLUSION. The initial ventilatory strategy was not associated with hospital mortality in very elderly patients admitted to the ICU due to CAP, regardless of antecedent characteristics. Acuity variables were responsible for the major part of positive confounding for mortality in this population. This suggests a less invasive approach may be sufficient for most patients to provide the benefit of the doubt during an ICU trial for very elderly patients.

INTRODUCTION. The electrical activity of the diaphragm (EAdi) might be a useful parameter to quantify breathing effort in ventilated patients because it is continuously available after placing a dedicated nasogastric catheter. EAdi demonstrated a tight correlation with inspiratory muscle pressure (Pmus) in an earlier study(1). The slope of the relationship between EAdi and Pmus could be predicted by dividing the peak of EAdi by the drop in airway pressure (Paw) during an expiratory hold. However, a narrow range of respiratory muscle effort was evaluated in that study, and the gold-standard parameter for diaphragm effort (the transdiaphragmatic pressure, Pdi) was not obtained.

OBJECTIVES. To study the correlation between EAdi and Pdi in the full range of breathing effort in healthy subjects. Second, to assess whether the slope of the correlation between EAdi and Pdi could be predicted by calculating the Paw/EAdi-ratio within each subject.

METHODS. Paw, Pdi and EAdi were recorded continuously in 23 healthy subjects. Maximal Pdi against an occluded airway was measured, and subsequently different levels of inspiratory threshold loading were applied ranging from 10% to 80% of maximal Pdi.

RESULTS. All subjects successfully completed the study protocol. Four subjects were excluded from analysis for technical reasons. In the remaining 19 subjects, a total of 2327 breaths were analyzed. There was a significant, but poor linear correlation between peak EAdi and peak Pdi when pooling data from all subjects (R2=0.14, p<0.0001). Correlations between EAdi and Pdi within subjects were much stronger, especially when diaphragm effort above 60% of maximum was excluded (R2=0.80± 0.12, p<0.001). See figure 1 for a representative example. However, the ratio of Paw/EAdi was not significantly correlated to the slope of EAdi and Pdi within each subject (p = 0.51).

CONCLUSION. A strong linear correlation exists between peak EAdi and Pdi within healthy subjects, up to 60% of maximal effort. The relationship was poor at effort above 60% of maximum, possibly because of accessory muscle recruitment. The ratio of Paw/EAdi did not relate to the slope of Pdi/EAdi within each subject. Further analysis is required to determine whether a more complex model based on EAdi and Paw can reliably estimate transdiaphragmatic pressure.

INTRODUCTION. Mechanical ventilation is a life-saving intervention in critically ill patients, but may at the same time cause lung injury characterized by hyperinflammation, endothelial barrier failure, and edema formation. Yet, the exact mechanotransduction mechanisms underlying the effects of mechanical ventilation on the microvascular barrier are still unclear. In previous work, we had identified a critical role of the endothelial Ca2+ channel TRPV4 in endothelial barrier failure subsequent to mechanical overventilation. Here, we assessed the role of TRPV1 and its potential association to TRPV4-induced Ca2+ signaling *in vivo*, *ex vivo* and *in vitro*.

METHODS. Wild type, TRPV4- or TRPV1-deficient mice were ventilated for 2 h with low (7 mL/kg) and high (20 mL/kg) tidal volumes (LVT/HVT) *in vivo*. Endothelial [Ca2+]i in isolated-perfused lungs, inflated with 5 or 15 cmH2O, and in human pulmonary microvascular endothelial cells (HPMVECs) was quantified by real-time imaging with or without

inhibition of TRPV1 and TRPV4, or after activation of TRPV1 and/or TRPV4, respectively.
RESULTS. TRPV1 or TRPV4 deficiency or inhibition by either SB366791 or HC-067047, respectively, attenuated VILI, and reduced the endothelial [Ca2+]i response to high pressure inflation *ex vivo*, except SB366791, which only diminished the sustained [Ca2+]i, but not the initial Ca2+ influx. *In vitro,* [Ca2+]i measurements in HPMVECs showed a characteristic increase in endothelial [Ca2+]i response to TRPV4 agonism, in which the sustained phase could be blocked by TRPV1 inhibition. TRPV1 agonism alone induced no [Ca2+]i increase; yet, TRPV1 and TRPV4 agonism in combination amplified the TRPV4-induced [Ca2+]i response.
CONCLUSION. Here, we demonstrate a critical role for TRPV1 in amplification and sustenance of TRPV4-mediated [Ca2+]i influx. We conclude that both TRPV channels act conjointly to regulate vascular barrier integrity, with TRPV4 causing endothelial leak by triggering an initial [Ca2+]i increase and TRPV1 facilitating the sustenance of the [Ca2+]i response which ultimately results in gap formation and barrier failure. The novel TRPV1/4 signaling axis may present a putative pharmacological target for the prevention or treatment of ventilator-associated lung disease.

INTRODUCTION. Acute respiratory distress syndrome (ARDS) is a form of non-cardiogenic pulmonary edema due to alveolar injury secondary to an inflammatory process, which may be both pulmonary and systemic in origin. This syndrome presents as acute hypoxemia with bilateral pulmonary infiltrate, which can not be correlated exclusively with cardiac dysfunction. In this study, we evaluated the use of Passive Ortostatism in ARDS.
OBJECTIVES. To analyze the use of the orthostatic board as an auxiliary device for the treatment of severe ARDS by assessing its risks and benefits.
METHODS. We selected 91 patients, 43 females and 48 males, hospitalized in a Neurological ICU, between June 2014 and July 2018, in a physiotherapeutic follow-up with diagnosis of severe ARDS. The patients were submitted to orthotics assisted for 40 to 60 minutes and monitored HR, PAM, FR, SatO2 at 30 ° and 60 ° of inclination and the PaO2 / FiO2 ratio after the procedure. The mean number of sessions per patient was 6.6. All patients were undergoing anticoagulation in RASS -5, in the treatment of the cause of ARDS. The mean time of mechanical ventilation was 8.5 days.
RESULTS. Among the patients selected, 36.3% presented tachycardia above 115 bpm, requiring intervention in 12.1% and interruption of the procedure in 6.6%. PAM arterial hypotension <65 mmHg was observed in 34.1%, requiring intervention (increase of vasopressor dose and / or change of plank angulation) in 22% and interruption of the procedure in 14.3%. Hypoxemia SatO2 <92% was observed in 8.8%, without interruption, but an improvement in PaO2 / FiO2 was observed in only 95.6% of the patients
CONCLUSION. Assisted orthostatism as an auxiliary device for the treatment of severe ARDS was shown to be an alternative, with improvement of PaO2 / FiO2 in 95.6% of the patients, safe and without significant hemodynamic repercussions that could lead to interruption of the procedure

INTRODUCTION. Non-invasive ventilation (NIV) is being increasingly used in adults and children both in acute intensive care as well as for chronic home ventilation (1). NIV delivers positive pressure through an interface without endotracheal or tracheostomy tube. The success of NIV in Pediatric ICU (PICU) depends on patient selection, type of interface and close monitoring (2,3). Advantages of NIV are reduced Healthcare associated infection (HCAI), need for sedation and duration of ventilation and PICU stay. In children, acceptability of NIV remains poor due to claustrophobic nature of face masks, high pressure delivered through the interface and gastric distension. Introduction of patient friendly nasal masks, has improved the success of NIV and increased its use in PICU. In settings with limited availability of ventilators, BIPAP machines can serve as a good alternative to deliver NIV.

OBJECTIVES. To study the feasibility and outcomes of children requiring non-invasive ventilation

METHODS. Retrospective chart review from January 2018 to March 2019 (15 months) of children aged 1 month to 12 years requiring NIV and admitted to PICU of a tertiary care referral hospital. Children on indigenous CPAP and HFNC were not included. Records of children receiving NIV were analysed from patient electronic database for demographic data, primary diagnosis, indication for NIV, type of interface and ventilator used, mode, pressure settings and blood gases prior to initiation of NIV, reasons for NIV failure, sedation use, complications and final outcome (survival or death) on a pre designed proforma. The duration of NIV, need for intubation and length of PICU stay were also analysed.

RESULTS. During the study period, 1081 children were admitted to PICU, of which 530 (49%) and 32 (2.9%) required invasive and non-invasive ventilation respectively. Fourteen of the 32 who required NIV, was for post extubation. The median (IQR) age of the study group was 72 (36,108) months. Nasal interface was used in 12 and oronasal face mask in 20; 17 were ventilated using conventional ventilator and 15 through BIPAP machine. Pneumonia with ARDS (n=19) was the most common diagnosis followed by immunocompromised state (n= 6) and tropical fevers with capillary leak (n=5). The commonest indication for NIV was respiratory failure (n=26; 81%), followed by neuromuscular weakness (n=4;12.5%) and cardiac failure (n=2; 6.25%). The mean ± SD PIP/IPAP (Max) was 14.5 ±2.9 and the mean ± SD PEEP/EPAP (Max) was 6.4 ±1.4 cm H2O. The median (IQR) duration of NIV and PICU stay were 3 (2,4) and 7.5 (5,23) days respectively. The failure rate was 11/32 (34%); 6 failed in nasal mask and 5 in oronasal mask. Four (12.5%) children died. Overall survival rate was 87.5%; among survivors, 2 needed long term NIV for neuromuscular weakness and compressive lesion in thorax, 1 child underwent tracheostomy for upper airway obstruction, and 1 child was referred for cardiac transplant. Compared to year 2018, the use of NIV has tremendously increased in 2019 (17 in 12 months;1.8% vs 15 in 3 months; 8.7%) probably due to better awareness and availability of age-appropriate interface.

CONCLUSION. NIV is a good modality of ventilation in respiratory failure, cardiac failure and in post-extubation patients.

INTRODUCTION. Protective ventilation with low Tidal Volume (TV) improves outcome of acute respiratory distress syndrome (ARDS) patients [1]. Usually TV is set on ideal body weight (IBW) which reflects the size of healthy lung. However, in ARDS the amount of functional parenchyma, the "baby lung", is reduced proportionally to the severity of disease [2]. In these patients the strain applied to the lung can be determined as TV/EELV (End Expiratory Lung Volume) and an increase in strain is associated with a proinflammatory response [3]. Measuring EELV may allow to set protective TV in order to maintain strain below a safety threshold [4]
OBJECTIVES. To verify the clinical feasibility of setting TV=0,25*EELV in ARDS patients.
METHODS. ARDS patients defined according to Berlin criteria, intubated and mechanically ventilated for less than 96 hours were enrolled. Exclusion criteria were conditions precluding measurement of EELV (i.e. air leaks, extracorporeal membrane oxygenation), haemodynamic instability, history of COPD, emphysema or pulmonary fibrosis. EELV was measured with the "oxygen wash-in wash-out" technique using GE Carescape R860 ventilator. Target TV (TTV) was set as 0.25*(measured EELV–PEEP related strain), up to 8 ml/kg Ideal Body Weight and respiratory rate (RR) was adjusted to keep baseline pCO2 ±5 mmHg. TTV was maintained for 24 hours unless one of the following occurred: need to increase RR >35 bpm, desaturation requiring a FiO2 change>0,20, development of a plateau pressure >30 cmH2O, need of neuromuscular blocking agents if not already administered. One-way ANOVA for repeated measures and Pearson's linear correlation where used for statistical analysis.
RESULTS. 11 mild to moderate ARDS patients were enrolled (mean P/F ratio was 206±48mmHg). TTV was maintained for 24h in 7 out of 11 patients. 3 patients dropped out because of the shift to assisted ventilation and did not maintain the TTV; one dropped out because of calculated TV >8ml/kg. The mean TTV was 336±94 ml, comparable to clinical baseline TV 371±68 ml (Fig.1 Panel A). Mean Driving Pressure (DP) slightly decreased from 9±1,6 to 8,2±0,8 cmH2O (Fig. 1 Panel B). RR and pH were maintained within the safe limits (Fig. 1 Panel C).
Subsequent analysis revealed a strict correlation between lung strain and DP (Fig. 2, R=0,96).
CONCLUSION. These preliminary results show the feasibility of setting the TV as 0.25*(EELV-PEEP related strain) in the majority of patients enrolled. Moreover, DP is a good indicator of strain in ARDS patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001554

INTRODUCTION. Extubation readiness is normally assessed by spontaneous breathing trials (SBT) of 30-120 min (1). Tension time index (TTI) calculated from esophageal pressure (Pes) measurement is the reference technique for assessing breathing effort of a SBT, with a threshold of >0.15-0.18 following a SBT previously shown to accurately describe SBT response (2,3). However, limited data exist to explain why some patients pass a SBT despite TTI>0.15-0.18 (3).
OBJECTIVES. To investigate if metabolic measurement may explain SBT success when TTI is elevated.
METHODS. After ethical approval and informed consent, four patients (3f/1m, 65±12yrs, 85±7kg), have so far been enrolled. All were difficult to wean patients according to WIND classification (4), on pressure support (PS) ventilation, and eligible for SBT (1). Inspired oxygen fraction was set to 0.4 and a maximal inspiratory pressure effort was performed

by 20s inspiratory occlusion at baseline (5). A SBT was then performed using PS=0 cmH2O, and PEEP=5 cmH2O. The SBT was ended after 120 min. Pes, VO2 and VCO2 were measured continuously. SBT outcome was decided according to guidelines (1). Average VO2 and VCO2 were calculated across six 1 min intervals throughout the SBT duration.

RESULTS. Throughout the SBT, TTI was close to 0.18 in two cases (high TTI) and ≤0.1 in the remaining two cases (low TTI) (fig 1). Mean VO2 and VCO2 were 295 and 359 mlO2/min and 225 and 290 mlCO2/min in high TTI patients, respectively (fig 1). Mean VO2 and VCO2 were 241 and 206 mlO2/min and 210 and 169 mlCO2/min in low TTI patients, respectively (fig 1). All patients were successfully extubated within 24 hours of the SBT. Figure 1 show mean TTI and VO2 for the four patients at six different time points during a SBT.

CONCLUSION. A higher metabolic response was observed in high TTI patients which likely reflect the greater breathing effort. Regardless of the underlying physiological mechanism, these preliminary findings indicate that SBT VO2 may follow TTI, and that there may be different metabolic responses between patients with high vs low TTI during successful SBTs. Further investigation is required to explore the patient characterization potential of VO2.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001561

INTRODUCTION. Ventilator-induced diaphragm dysfunction (VIDD) is highly prevalent in patients under mechanical ventilation (MV). The study of this pathology is difficult because histological samples are difficult to obtain in critically ill patients. Recently, ultrasound measurements have been described as a good method to monitor diaphragm structure but there are no previous studies that correlates histological findings with ultrasound measurements.

OBJECTIVES. To correlate the cross-sectional area (CSA) of diaphragmatic muscle fibers of diaphragm muscle biopsy, with the ultrasound measurement of diaphragm thickness (*Tdi*) in mechanically ventilated donor patients.

METHODS. We prospectively enrolled 13 adult patients requiring mechanical ventilation (organ donor) who were admitted to the intensive care unit during 2017. Demographic data, clinical data, comorbidities, and severity scores were collected. The diaphragm thickness (*Tdi*) was determined by bedside ultrasonography previous to organ donation, as described previously in literature1. Three measurements were taken by 2 observers and average was performed. Diaphragm(DF) biopsies from DF anterior lateral costal area were obtained from ICU donor patients. Tissue was preserved immediately in alcohol-formol bath to be thereafter embedded in paraffin. Immunohistochemical and morphometric analyses were done: CSA, and proportions of type I(MHCI) and type II(MHCII) diaphragm fibers were assessed. Statistical analysis was performed using Pearson correlation coefficient, significance was set to $p<0.05$. CEIC PSMAR 2017/7183/I.

RESULTS. Muscle and ultrasound samples were obtained from 13 patients. Man were predominant (69,2%), with a mean age of 58(14) years and APACHEII score of 27(5). ICU median stay was 6(3-11) days with a median mechanical ventilation days of 6(3-14). Immunohistochemical and morphometric analyses showed a similar proportion of MHCI (50,5%) and MHCII (49,4%) diaphragm fibers with a CSA of 1480 (660) µm2 and 1722 (1031) µm2 respectively. Mean ultrasound measurement of *Tdi* was 1.68 (0.33)cm, and had a positive and significant correlation with MHCI and MHCII and Cross-sectional area (MHCI: r2 0.765 / p= 0.004; MHCII: r2 0.854 / p=0.000).

CONCLUSION. The ultrasound measurement of diaphragm thickness (Tdi) in mechanically ventilated patients has a good correlation with the cross-sectional area (CSA) of diaphragm fiber I and II (MHCI and MHCII).

INTRODUCTION. Endotracheal intubation in the critically unwell patient is a life saving procedure, which is frequently performed in the Emergency Department (1). A high level of skill and training is

needed to facilitate a controlled, safe environment in which this can be performed. The 4th National Audit Project (NAP4) of the Royal College of Anaesthetists (RCoA) and Difficult Airway Society (DAS) was designed, in part, to look at airway management in the Emergency Department and highlight any deficiencies that could lead to serious harm (2). In direct response to NAP4, the published 2018 guideline on the management of tracheal intubation in critically ill adults recommends the use of a checklist to facilitate intubations (3). Checklists have been shown to significantly reduce mortality globally in surgery and have been adopted in high-pressure environments including in pre-hospital medicine (4,5). This study describes the current practice of endotracheal intubation in a single centre emergency department in a district general hospital in Greater London.

METHODS. The study was a retrospective observational study. Using the emergency department's electronic system a search was carried out over a one-year period. Cases were identified if they had been coded as: transferred to another hospital; died in the emergency department; referred to Intensive Care Unit (ICU); admitted to ICU. A total of 1553 notes were reviewed and 94 intubations were identified. Factors studied included: age and sex; indication for intubation; checklist used; if no checklist, were any pre-defined safety measures documented; drugs used; arrival time and complications. No ethical approval was sought, as per institutional guidelines.

RESULTS. 94 intubations were identified in the one-year time period, averaging 1.8 intubations in the department per week. The most common indication for intubation was for airway protection (n=35) and 42% of the cases were due to cardiac/respiratory arrest. Only 16% of cases showed evidence of use of a checklist; in the remaining 79 patients, no patients had all the pre-defined safety measures documented. The most commonly used neuromuscular relaxant was found to be rocuronium in 45% of cases. The mean response rate time of a clinician was 10 minutes 16 seconds. There was no significant difference between the response rate times of Emergency Doctors and external physicians (p=0.0477). All intubations were successful, however, 8 complications were reported of which 100% of these were in patients without a checklist.

CONCLUSION. This study provides an overview of the intubation practices in a single-centre Emergency Department after the NAP4 recommendations. It has identified poor compliance (16%) to the use of a checklist in endotracheal intubations, despite current guidelines(2). Whilst checklists have been shown to cognitively off load the medical practitioner, there may be many barriers limiting its implementation(6). It adds to the growing call for better provision of care to patients with a deteriorating airway and for the continued auditing of practice. In response to these findings, our institution has introduced a structured teaching programme for staff and will aim to re-study and audit after one year.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001579

INTRODUCTION. Severe community pneumonia is the most frequent cause of respiratory failure and acute respiratory distress syndrome (ARDS). The mortality reported in severe forms reaches 40%. Since 2013, a mechanical ventilation protocol (MV) based on the limitation of tidal volume (VT), recruitment maneuvers and high levels of PEEP, the sequential application of neuromuscular blockade (NMB) and prone positioning, and fluid restriction have been applied in our hospital since 2013, leaving extracorporeal oxygenation (ECMO) as a rescue therapy for refractory hypoxemia.

OBJECTIVES. To present the results of the application of a protocol of respiratory failure in the management of patients with moderate and severe ARDS.

METHODS. Observational clinical study. We analyzed retrospectively from 2013 to 2015, and prospectively since 2016 to all patients admitted with moderate to severe ARDS due to community-acquired pneumonia. Demographic data, infectious agents, PaO2:FiO2 ratio (PaO2/FiO2) on admission and worst values during MV, ventilatory mechanics, treatments received (prone, NMB and/or ECMO). Main outcomes were hospital stay and hospital mortality. Data were analyzed by descriptive statistics, distribution was evaluated according to the Shapiro-Wilk test, and were expressed according to mean ± SD and/or median and p25-75, as appropriate.

RESULTS. 59 patients were included (age 49.5 years, 36 women (61%), PaO2/FiO2 at 24 hours was 162 [125 – 197] and worst PaO2/FiO2 96.4 [66.7 – 115.2). Influenza virus was identified In 49% of cases as etiology. Mean VT and PEEP during the first day were 331 [294 – 389] ml (5.7 [5.1 – 6.7] ml/kg IBW), and 13 [12-16] cmH2O, respectively. Forty five (76%) patients received NMB for 4 (1-7) days, 36 (61%) were in prone position for 3 (1-6) days, and 8 (13.5%) received ECMO therapy. From 18 patients transferred from other centers for ECMO, only 4 (22%) were connected to ECMO. The median time in MV and hospital were 15 [9 - 25] and 26 [19 - 38] days, respectively. Five (8.5%) patients died.

CONCLUSION. The implementation of a protective ventilation program allows achieving good results, using widely available and low cost therapies. Using prone positioning and NMB allow to rescue a high proportion of patients from ECMO, highlighting the importance of these cost effective therapies.

High-flow nasal cannula oxygen therapy in adult patients with acute respiratory failure: our initial experience

D. Adrião, R. Neto, AL. Rios, M. Basto, P. Castelões
Department of Intensive Care, Centro Hospitalar Vila Nova de Gaia/Espinho, Vila Nova de Gaia, Portugal

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001593

INTRODUCTION. Acute respiratory failure (ARF) is one of the leading causes for ICU admission [1]. Recently, high-flow nasal cannula (HFNC) oxygen therapy has seen increasing use in patients with ARF. The physiological benefits of HFNC include higher and more stable FiO_2 values, delivery of heated and humidified gas and reduction of the anatomical dead space and work of breathing. HFNC also generates low levels of positive pressure in the upper airways [1, 2].

OBJECTIVES. Describe our ICU initial experience with HFNC oxygen therapy in non-intubated patients with acute respiratory failure and evaluate improvement of oxygenation, the need for intubation and mortality.

METHODS. We performed an observational retrospective study involving non-intubated patients with acute respiratory failure treated with HFNC admitted to a polyvalent intensive care unit between January 2017 and March 2019. The HFNC used consisted of an air-oxygen blender with adjustable FiO_2 (0.21 to 1.0), delivering a modifiable gas flow up to 60 L/minute (Optiflow; Fisher & Paykel Healthcare, Auckland, New Zealand).
RESULTS. Twenty-four patients were included, 19 men (79%), mean age 61 ± 11 years. Mean APACHE II score and SAPS II were 19 ± 8 and 36 ± 11, respectively. The main cause of acute respiratory failure was hospital-acquired pneumonia (n = 8), followed by community-acquired pneumonia (n = 5), extrapulmonary sepsis (n = 3), pneumonia related to imunosupression (n = 2) and aspiration (n = 1).
The mean duration of HFNC oxygen therapy was 56 ± 46 hours and 3 patients received alternating periods with noninvasive ventilation. After 1 hour of therapy, PaO_2 increased from 59 ± 9.1 mmHg to 88 ± 33.7 mmHg (p = 0.005) and to 78 ± 33.7 mmHg (p = 0.018) after 6-12h. PaO_2/FiO_2 ratio increased from 107 ± 52.4 to 129 ± 76.3 after 1 hour (p = 0.159).
Despite de use of HFNC, in 13 (54%) patients intubation was unavoidable. In this group the mean duration of HFNC was 28 ± 13 hours.
Mean ICU length of stay was 8 ± 4 days and was higher for patients who required intubation (14 ± 8 days). Eight patients died in the ICU, in 7 of which was decided not to reanimate or intubate due to extensive comorbidity. The overall mortality at 90 days was 38% (n = 9). No statistical significance was found between oxygen saturation, PaO_2, $PaCO_2$, PaO_2/FiO_2 ratio or pH prior to HFNC therapy and mortality.
CONCLUSION. Few studies have examined large cohort of patients with *de novo* acute respiratory failure and the results suggesting a reduction in the intubation rate with HFNC remain controversial [3].
Although hypoxemia was improved in the first hours, a high proportion of patients still required intubation. Further studies are needed to clarify the clinical circumstances in which HFNC should be used.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001595

INTRODUCTION. Non-cardiogenic pulmonary edema and increased lung weight are hallmarks of ARDS, as a consequence lung weight and wet-to-dry ratio are often used as markers of lung damage in animal experimental models of ARDS. However, fluid management may have a profound impact on these indicators of lung damage.
OBJECTIVES. To describe the impact of different fluid administration strategies on lung weight and wet-to-dry ratio in two series of experiments on ventilator-induced lung injury in the framework of mechanical power
METHODS. In the first series of experiments, 36 healthy piglets (23.3 ± 2.3 kg) were mechanically ventilated for 52 hours with a mechanical power of 26.6 ± 12.1 J/min. In the second series, 42 healthy piglets (24.2 ± 2 kg) were mechanically ventilated for 48 hours with a mechanical power of 21.8 ± 8.3 J/min. Due to institutional policy, the sedation with propofol was increased from 6-9 mg/kg/h in the first series to 10-12 mg/Kg/h in the second series, while sufentanil (from 2-3 µg /kg/ h to 1.5-2.5 µg /kg/ h) and midazolam (from 1.5-2.5 mg/kg/h to 0.8-1.5 mg/kg/h) were reduced. Accordingly, we modified the fluid management strategy in order to attain a mean arterial pressure of 60 mmHg: the first animals received 1-2 ml/kg/h of maintenance Stereofundin 1:1 and 150 ± 232 ml/h of Gelafundin 4%, the second group received a maintenance of 3-4 ml/kg/h and 647 ± 411 ml/h of colloids. Norepinephrine was started in case of persistent hypotension, epinephrine could also be added, but only in the second group.
RESULTS. The total amount of administered fluids was 4119 ± 910 ml in the first series and 9976 ± 2376 ml in the second series (see figure 1), at the end of the experiment the pigs gained 2.4 ±1.6 kg and 5.7 ±2.7 kg respectively ($p < 0.001$ for both). There was no difference in norepinephrine (0.13 ± 0.21 vs 0.14 ± 0.21 mcg/kg/min), while epineprhine was 0.03 ± 0.07 mcg/kg/min in the second group. Lung weight and wet-to-dry ratio were higher in the second group (616.6 ±142 and 6.95± 1.1) when compared to the first group (371.2 ±105 and 6.26 ±0.6) ($p < 0.001$ for both). See figure 2. Mechanical power, instead, was higher in the first group (p = 0.049).
CONCLUSION. Propofol increase, despite decrease in other sedative and analgesic agents, lead to increased need of fluids to maintain hemodynamic stability in this animal experimental model. Lung weight and wet-to-dry ratio were increased in the group with liberal fluid strategy, despite a lower mechanical power. The assessment of lung damage via surrogates of lung edema should take into account the amount of administered fluids. Sedation policies should be standardized to allow a better comparison among different experiments.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001605

INTRODUCTION. In patients with acute respiratory distress syndrome (ARDS) lung-protective ventilationstrategies using low tidal volume

and low airway pressure ameliorated outcome although they lead tohypercapnia. Controversial effects of hypercapnia in ARDS patients are nowadays being discussed
OBJECTIVES. Evaluate the effect of hypercapnia on inflammatory response, mediators of recruitment and apoptosis in human primary alveolar cells (hATII) injured with lipopolysaccharide (LPS)
METHODS. hATII from pulmonary biopsies of patients that underwent lobectomy were isolated and incubated at 37ºC with 5% CO2 (Normocapnia) or 15% CO2 (Hypercapnia; pCO2=80 mmHg) with or without 15mM THAM buffer to maintain pH at 7.4. All groups were injured with 100 ng/ml LPS. Pro-inflammatory molecules (IL-1β, iNOS), mediators of cellular recruitment (IL-8, CCL-2) and apoptosis (caspase-3) were analyzed
RESULTS. In hATII injured with LPS the expression of mediators of neutrophils (IL-8) and monocytes (CCL-2) recruitment was decreased when cells were exposed to hypercapnia. No effects of hypercapnia were found when analyzing pro-inflammatory markers and apoptosis
CONCLUSION. Hypercapnic conditions in hATII cells injured with LPS reduced the expression of mediators of recruitment of pro-inflammatory cells but did not affect pro-inflammatory molecules nor apoptosis. There is a need to better understand the biological and physiological effects of hypercapnia

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001606

INTRODUCTION. A recent systematic review of interstitial lung disease (ILD) cases admitted to ICU found high short-term mortality, though few studies reported longer-term outcomes. We examined short- and long-term mortality in an ICU population of patients with ILD.
METHODS. To examine associations of short and longer term mortality we conducted a retrospective cohort study at two non-specialist UK ICUs (consisting of a 12-bed and a 10-bed unit) of consecutive adults admitted for respiratory failure with ILD (April 2008- January 2019).
RESULTS. 84 patients were included with median age 72 (IQR 62-78), 57% male and unit stay was 5 (2-9) days. Mechanical ventilation (MV) was performed in 43%. Median ICNARC score was 18 (14-27) and APACHE II 18 (14-23). Amongst subtypes idiopathic pulmonary fibrosis (IPF) and connective-tissue disease associated ILD (CTD-ILD) were most common (23% and 18% respectively). ICU mortality was 60% and one-year mortality 70%. MV was associated with a significant increase in ICU mortality (86.1% vs 39.6%, odds ratio (OR) 9.5 (3.1-28.6), P <0.001). Of the 4/36 MV patients (11%) alive at 1-year, 2 were classed IPF, 1 NSIP and 1 drug-induced. Of the patients who did not require MV 44% remained alive at 1-year follow-up. On Kaplan-Meier survival analysis MV was associated with a shorter duration of survival (see figure). There was no significant difference in survival between ILD subtypes.
CONCLUSION. In this dual-centre ICU cohort ILD was associated with significant short and longer-term mortality as previously described, however a small number of patients who were ventilated remained alive on longer-term follow-up.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000150

INTRODUCTION. Subarachnoid hemorrhage (SAH) is associated with high morbidity[1,2].Among all complications, infections, in particular if hospital-acquired, could represent an important cause of death in SAH patients[3]. However, few data on this issue are available.
OBJECTIVES. The aim of this study was to describe infectious complications in SAH patients and to evaluate their impact on outcome.
METHODS. Single-center cohort study including all SAH patients admitted from January 2011 to December 2016, who stayed in the ICU for at least 24 hours. Infection diagnosis was retrieved from medical files; CNS infections were not included. Multivariable logistic regression analysis was performed to identify risk factors for development of infection, for ICU mortality and unfavorable neurological outcome (UO) at 3 months, defined as a Glasgow Outcome Scale of 3-5.
RESULTS. Of the 250 SAH patients without vetriculitis treated, 70 (28%) developed at least one infection; the most frequent site of infection was respiratory (57.1%), primary blood stream (16%) and urinary tract infections (15.7%). Twenty nine patients (41.4%) had at least on episode of septic shock. ICU mortality rate was similar between infected and non-infected patients (35.7% vs. 27.2%, p=0.42 but infected patients had a higher UO rate were – 60.0% vs. 33.3%, p= 0,001. ICU length of stay [OR 1.14 (CI 95% 1.07-6.58)], WFNS score of 4-5 [OR 5.34 (CI 95% 1.40-20.33)], delayed cerebral ischemia [OR 3.75 (CI 95% 1.47-9.60)], seizures [OR 2.78 (CI 95% 1.17-6.58)] and fever [OR 8.69 (CI 95% 3.45-21.86)] were independently associated with the occurrence of infections. Infection was independently associated with ICU mortality (OR 3.93 CI 95% 1.31-11.80). The development of sepsis [OR 25.22 (CI 95% 1.75-363.19)] was independently associated with UO.
CONCLUSION. Infection is a common complication in SAH patients. Sepsis is independently associated with poor long-term neurological outcome.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000171

INTRODUCTION. Veno-arterial extracorporeal membrane oxygenation (VA ECMO) is a medical device complicated with high rates of mortality and morbidity, especially infectious complications occurring in 25% of patients (1-3).
OBJECTIVES. To study the bacterial colonization and biofilm present on VA ECMO's cannulae and oxygenator membranes and to determine the potential use of advanced techniques in daily clinical practice.
METHODS. A preliminary monocentric prospective physiological study was performed at Henri Mondor Hospital, France. Samples of both arterial and venous cannulae and oxygenator membranes were aseptically collected from patients under VA ECMO support, at the time of ECMO's weaning or immediately after patient's death. Each sample was analyzed by three different methods in order to detect bacterial colonization: standard culture, scanning electron microscopy (SEM) and 16S rRNA gene-based metagenomic analysis (next generation sequencing).
RESULTS. Overall, ten patients were included in the study. The median time of ECMO support was 10 [7-20] days. Seven (70%) patients developed an infection during VA ECMO support, including two (20%) patients with a bloodstream infection. In culture, three on nine (33%) arterial cannulae and 3/9 (33%) venous cannulae were positive. In SEM, all the oxygenator membranes had bacterial biofilm on their surface while being all negative in culture. Seven on nine (78%) arterial cannulae and 7/9 (78%) venous cannulae had also bacterial biofilm on their surfaces in SEM. In metagenomic analysis, 7/9 (78%) arterial cannulae, 4/9 (44%) venous cannulae and 8/9 (89%) membranes were positive. However, four (44%) negative venous cannulae in metagenomics analysis were considered positive in SEM. Bacterial species richness was significantly different between oxygenator membranes and arterial/venous cannulae ($p<0,01$). Indeed, Faith's phylogenetic diversity was 71 [58-78] on membranes; 112 [100-117] on arterial cannulae ($p<0,01$) and 98 [80-118] on venous cannulae ($p=0,01$). Antibiotics therapy during ECMO support did not modify Faith's phylogenetic diversity (81 [39-150] without antibiotics and 95 [77-108] with antibiotics; $p=0,79$). There was no significant difference of bacterial abundance between the different samples' types (membranes 0,63 [0,62-0,71]; arterial cannulae 0,71 [0,67-0,72]; venous cannulae 0,68 [0,62-0,70]; $p=0,53$). Bacterial colonization was mostly found on oxygenator membranes followed by arterial cannulae and then venous cannulae. SEM was the most powerful tool to detect bacterial colonization. ECMO colonization was systematically detected in patients with bloodstream infection but also in five (50%) patients without infection.
CONCLUSION. Bacterial colonization's detection by standard culture is often negative but SEM and 16S rRNA gene-based metagenomic analysis improve biofilm detection on ECMO's cannulae and oxygenator membranes, while not being used in this indication in daily clinical practice. More patients would be necessary to better define the bacterial colonization's role in the occurrence of infectious complications and to precisely describe the microorganisms responsible for colonization.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001476

INTRODUCTION. HIV is a pathology that has evolve much in the past decades with the introduction of new antiretroviral treatments.
OBJECTIVES. Compare today's Spanish HIV patients ICU admissions with the 90's ones.
METHODS. Observational and retrospective study where we included all HIV patients admitted in the ICU of Jiménez Díaz Fundation from Madrid (Spain) between 2013 and 2018 [actual sample (AS)].
We collected demographics parameters (age, sex), ICU cause of admission, time of diagnosis of HIV (before/during ICU stay), severity scores (APACHE II), lenght of ICU stay and ICU mortality.
Then we compared this information with the existing bibliography, specifically with the data published by Choperena et cols (1) from the Arantzazu Hospital in San Sebastián (Spain) between 1985 and 1997 [reference sample (RS)].
RESULTS. We collected 122 HIV patients (2% of the total admitted on ICU). The demographic characterictics are compared on the table bellow. Sexual was the most frequent mechanism of infection. 12 patients were admitted on AIDS state.
The most common causes of admission in the AS were: infections (31.2%), intoxications (27.9%) and scheduled surgery (17.1%), mostly cardiac surgery in 7.3%. However, in the RS, the vast majority of the patients were admitted for an infection.
The HIV primodiagnosis was performed in the ICU in 11.5% of the cases on the AS and the majority of this group was admitted for pneumonia due to penumocystis jirovecii (71.4% with $p=0.013$) with a longer ICU stay (5,1 vs 14,3 days, $p=0.002$) but without more mortality associated. On the contrary, in the RS the HIV diagnosis was made during ICU stay in 20% of the patients. There has been a remarkable reduction in ICU stay and mortality between the AS and the RS.
CONCLUSION. HIV is common desease in today's Spanish ICUs patients and is associated to infections and intoxications in a remarkable way. We have found that nowadays' HIV patients are admitted in ICU for causes independent from their basal disease, with a similar prognostic to the general population, except in patients with a poor control of HIV.

INTRODUCTION. Seasonal influenza causes high morbidity worldwide and high mortality in develope countries. While most influenza patients have a self-limited respiratory illness, 5-10% of hospitalized patients develop severe disease requiring Intensive Care Unit (ICU) admission (1,2).
OBJECTIVES. Describe the hospitalization rate and ICU admission rate, of patients who came to the emergency room and were diagnosed with influenza A, during Influenza Epidemic 2019. Describe the clinical characteristics of both groups.
METHODS. Descriptive analysis of patients admitted for Influenza A in two hospitals of Granada, Spain, during the Influenza Epidemic in 2019. The data have been obtained from the microbiology registry as well as from ENVIN-HELICS registry of Spanish Society of Intensive Care. We evaluated the clinical records of all the patients with positive rapid diagnostic testing of influenza A in this period, who were hospitalized. We recorded the epidemiological characteristics, comorbidities and mortality among patients admitted to the ICU and those admitted to other wards.
RESULTS. Rapid diagnostic testing on Influenza was performed in 1550 patients, 204 patients were positive for Influenza A. Finally, 111 patients required hospital admission, 51.8% were women (2.7 pregnant women) and 48.2% men with an average age of 70.24 years (27-99). In 42.7% of the cases, the patients were smokers or ex-smokers and 12.7% were obese. 69.1% of the patients suffered multiple pathologies; 10.9% had no personal medical history of interest. 24.5% of cases had onco-hematologic disease, 29.6% had corticoid therapy and 18.5% chemotherapy. In 70% of cases the clinic debut was fever and in 68.2% they also associated dysnea. 27.3% associated bacterial infection. 43.3% of the cultures insolated Streptococcus pneumoniae followed by Staphylococcus (10%) and Pseudomonas (10%). 64 patients received antibiotic treatment associated with olsentamivir, with the most commonly used combinations being ceftriaxone + azithromycin (28.12%), levofloxacin (28.12%) and ceftriaxone + levofloxacin (17.18%).
Twenty one patients required admission to Intensive Care Unit: In this group 47.6% requiered High Flow Nasal Canula or noninvasive ventilation and 43.3% required mecanic ventilation of which 90% needed muscle relaxation and 50% tracheotomy. The mean SOFA upon admission was 4.67 (1-14) and APACHE 15.86 (5-25). Of the patients admitted to ICU, 38.1% had mild Acute Respiratory Distress Syndrome (ARDS) , 33.3% had moderate ARDS and 23.8% had severe ARDS. 19 patients (80%) were suffered an infection associated with mechanic ventilation: 50% tracheobronchitis and 30% pneumonia. Two patients died during their stay in ICU.
CONCLUSION. Half of the patients who came to the emergency department for Influenza A needed hospital admission, 18.9% required admission to ICU. The rest of clinical and therapeutic characteristics are similar to those of previous years.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001502

INTRODUCTION. Invasive aspergillosis (IA) is a fungal infection that mainly affects immunocompromised patients. However, non-neutropenic patients in the Intensive Care Unit (ICU) population have shown an increasing risk profile for aspergillosis mainly due to underlying comorbidities such as chronic obstructive pulmonary disease (COPD), malignancy and prolonged corticosteroid use. In the ICU setting, IA remains difficult to diagnose and problematic to treat.
OBJECTIVES. The aim of this study was to determine the incidence, risk factors and outcome of patients with *Aspergillus* colonization or IA in our ICU.
METHODS. A 10-year retrospective study including all patients with a positive *Aspergillus* culture during ICU stay was performed. Cases were classified as *Aspergillus* colonization, putative IA and proven IA according to validated criteria. Clinical records were reviewed in order to obtain demographic, microbiological and diagnostic data as well as underlying conditions of these patients.
RESULTS. A total of 87 patients were included, 51 (58.6%) of whom were colonized, 34 (39.0%) had putative IA and 2 (2.3%) had proven IA. The lung was the most frequent site of infection (98.8%) and *Aspergillus fumigatus* the most commonly isolated species (55.2%). COPD and liver disease were the most frequent comorbidities, equally seen in both groups. Patients with IA had higher incidences

of malignancy (both solid tumors and haematological malignancy) and history of glucocorticoid treatment.
Compared with other patients, they were more frequently diagnosed with sepsis and acute respiratory distress syndrome (ARDS) on ICU admission and more frequently received renal replacement therapy (RRT) during the ICU stay.
IA patients had increased length of stay (25.2 versus 16.1 days, p< 0.05) and higher ICU mortality (31.3% among colonized patients and 44.4% in those with IA, p <0.05) but there was no difference concerning in-hospital mortality (47.1% and 50%, respectively).
CONCLUSION. IA among critically ill patients is associated with high mortality. Patients diagnosed with proven or putative IA had greater severity of illness and more frequently needed RRT than those with *Aspergillus spp* colonization.

INTRODUCTION. Influenza infection causes severe morbidity and mortality around the world. There are limited data about severe influenza infection among healthcare workers compared to the general population.
OBJECTIVES. Our aim was to determine clinical differences between health-care workers and general population with severe influenza infection admitted to the intensive care units.
METHODS. Prospective, observational, multicenter study conducted in 148 Spanish ICUs from 2009 to 2017. Healthcare workers with severe influenza infection were compared with the general population. All serotypes were confirmed using RT-PCR at ICU admission. Patients´ demographic, clinical, radiologic features, laboratory values, ICU and hospital length of stay (LOS) and outcomes were recorded. Influenza vaccination status is reported. Discrete variables are expressed as counts (percentage) and continuous variables as medians with 25th to 75th interquartile range (IQR). Differences between groups were assessed using the x2 test and the Fisher exact test for categoric variables and Mann-Whitney U test for continuous variables.
RESULTS. Of 4175 patients with confirmed influenza infection at ICU admission, 2915 of working-age adults were selected. A total of 47 healthcare workers were compared to 2864 non-healthcare professionals. There was a less proportion of male among healthcare workers (58.1% vs 36.2%, P =0.003), and less overall comorbidities (69,0% vs 53.2%, P =0.020). Healthcare workers had a higher history of asthma (21.3% vs 9.8, P=0.009) and less COPD (6.4% vs 14.4%, P=0.048), and heart failure (0% vs 7.7%, P= 0.047). There are no statistical differences in other variables related to clinical influenza infection and outcome between groups. There are no differences in MODS, mechanical ventilation, RRT, cobacterial infection or hospital-acquired pneumonia, influenza serotype (A/H1N1pdm8, 78.2% vs 76.6%, P=0.758) or proportion of vaccinated patients (4.3% vs 5.9%, P=0.917). Vaccinated rate among healthcare workers reported by Spanish Ministry of Health and Social Policy is 30%. No difference in ICU LOS, hospital LOS or mortality was observed.
CONCLUSION. The clinical characteristics, evolution and outcome of healthcare workers with severe influenza admitted to ICU is similar to the general working population.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000454

INTRODUCTION. There is little descriptive data on Stenotrophomonas maltophilia hospital-acquired pneumonia in critically ill patients. However, this non-fermenting Gram negative bacteria is one of the tenth most isolated bacteria in intensive care units. Due to its unique resistance profile to antimicrobial agents, the optimal modalities of antimicrobial therapy remain to be determined.
OBJECTIVES. Our objective was to describe the epidemiology and prognostic factors associated with Stenotrophomonas maltophilia pneumonia, focusing on antimicrobial therapy.
METHODS. This nationwide retrospective study included all patients admitted to 25 French intensive care units between 2012 and 2017 with hospital-acquired Stenotrophomonas maltophilia pneumonia. The primary endpoint was time to in-hospital death. The secondary endpoints included microbiologic effectiveness and antimicrobial therapeutic modalities such as, delay to appropriate antimicrobial

treatment, mono versus combination therapy and duration of antimicrobial therapy.
RESULTS. Of the 282 patients included, 84% were intubated at Stenotrophomonas maltophilia pneumonia diagnosis for a median duration of 11 [5-18] days. The median Simplified Acute Physiology Score II was 47 [36–63] and the in-hospital mortality was 49.7%. Underlying chronic pulmonary comorbidities were present in 14.1% of cases. Empirical antimicrobial therapy was microbiologically defined as effective on Stenotrophomonas maltophilia according to susceptibility patterns in only 30% of cases. Delay to appropriate antimicrobial treatment had, however, no significant impact on the primary endpoint. Survival analysis did not show any benefit from combination antimicrobial therapy (HR=1.27, 95%CI [0.88; 1.83]; p= 0.20) or prolonged antimicrobial therapy for more than 7 days (HR= 1.06, 95%CI [0.6; 1.86]; p=0.84).
CONCLUSION. Stenotrophomonas maltophilia hospital-acquired pneumonia occurred in severe, long-stay intensive care patients who mainly required prolonged invasive ventilation. Empirical antimicrobial therapy was barely effective while antimicrobial treatment modalities may have no significant impact on hospital survival.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000514

INTRODUCTION. Ventilator-associated tracheobronchitis (VAT) is an infective complication of mechanical ventilation. In the Intensive Care Units (ICUs), VAT is a relatively common problem but in comparison to ventilator-associated pneumonia (VAP), much less data are available on VAT and its management. The aim of this study was to determine the frequency, etiology, microbiological sensitivity and outcomes of nosocomial tracheobronchitis (NTB) in mechanically ventilated patients admitted in intensive care unit.
OBJECTIVES. To find out the incidence of ventilator associated tracheobronchitis in ventilated patients.
To map the microbiological profile of ventilator associated tracheobronchitis in the region
METHODS. A prospective observational study was conducted in two medical Intensive Care Unit (ICU), in Kolkata, India from March 2016 to April 2017. All the patients on mechanical ventilator for more than 48 hours in the ICU were evaluated according to the criteria for the diagnosis of nosocomial tracheobronchitis (NTB). Out-comes of the patients were measured in terms of development of nosocomial pneumonia after NTB, length of ICU stay, duration of mechanical ventilation and mortality in the ICU.
RESULTS. Four hundred and sixteen patients were evaluated for this study. Nosocomial tracheobronchitis was diagnosed in 48 patients. The frequency of NTB was 11.5%. Nine types of micro-organisms were identified, 42% cases were poly-microbial, while in the remaining 58% cases single organism was isolated. The most common organism was Klebsiella spp (56%), followed by Acenetobacter spp (20%) and Pseudomonas aeruginosa (8%). The majority patients who developed VAT had underlying co-morbidities. The mean time to develop VAT from the time of mechanical ventilation was 6.8 days and from time of ICU admission was 9 days, respectively. More than ninety percent of isolated GNB were multidrug resistant.
CONCLUSION. VAT is a common healthcare-associated infection caused mostly by MDR Gram-negative bacteria that significantly affects the development of pneumonia and length of ICU stay for the patients. Monitoring and active surveillance are required to detect VAT at the earliest to initiate appropriate isolation measures and therapy for better outcome.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000724

INTRODUCTION. Skin and soft tissue infections (SSTIs) are usually mild infections, but when severe, they can lead to intensive care unit (ICU) admission. There is limited published data on the epidemiology of SSTIs necessitating ICU admission.
OBJECTIVES. To describe the incidence, characteristics and outcomes of critically ill adult patients admitted to the ICU for a SSTI, as well as independent predictors of outcomes.
METHODS. A registry-based retrospective cohort study using data submitted to the Australian and New Zealand Intensive Care Society Adult Patient Database for admissions between 2006 and 2017. Inclusion criteria: primary diagnosis of SSTI and age ≥16 years. Exclusion criteria: ICU readmissions (during the same hospital admission) and transfers from ICUs from other hospitals. Primary outcome was in-hospital mortality, secondary outcomes were ICU mortality and ICU and hospital length of stay (LOS). Furthermore, independent predictors of these outcomes were determined.
RESULTS. Of 1,470,197 first admissions at ICU between 2006 and 2017, 10,962 patients (0.7%) were admitted because of SSTI. Of these, 5,706 (52.1%) were medical and 5,256 (47.9%) surgical patients. Of all medical patients, 3,682 (64.5%) had sepsis. Comorbidities were present in 25.2% of the study sample. In-hospital mortality was 9.1% (n=991), which accounted for a 0.07% SSTI in-hospital mortality rate for all first admissions at ICU between 2006-2017. Incidence of ICU admissions increased between 2006-2017 from 0.4% to 0.9%, but in-hospital mortality decreased from 16.1% to 6.8%. Median ICU LOS was 2.1 days (IQR: 3.4), median hospital LOS was 12.1 days (IQR: 20.6). ICU LOS remained stable between 2006-2017 (2.0 to 2.1 days), whereas hospital LOS decreased from 15.7 to 11.2 days. Predicting factors for in-hospital mortality were: ANZROD [1] score (OR: 1.07; CI (1.05, 1.09); $p<0.001$), any comorbidity except diabetes (OR: 2.00; CI

(1.05, 3.79); p=0.035) and admission through an emergency response call (OR: 2.07; CI (1.03, 4.16); p=0.041).
CONCLUSION. SSTIs are uncommon as primary ICU admission diagnosis. While the incidence of ICU admissions for SSTI has increased, mortality and hospital LOS have decreased over the last decade.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000861

INTRODUCTION. Pneumocystis pneumonia (PCP) often presents with severe respiratory failure leading to intensive care admission and organ support. Patterns of disease have been changing as PCP is increasingly recognized among non-HIV Immunosuppressed patients. Little is known about critical care management of these patients.
OBJECTIVES. Our aim was to evaluate intensive care management of severe PCP and to identify clinical predictors of mortality.
METHODS. A retrospective cohort study was performed that included all patients with severe PCP from 2005 to 2018 (14 years) admitted to an intensive care unit of an university hospital. Patients were characterized according to immunosuppression status into HIV-positive and HIV-negative. Clinical variables at admission and during intensive care unit stay were assessed to identify clinical predictors of in-hospital mortality.
RESULTS. Forty-three patients with PCP were included with median age 53 (41-65) years and male sex predominance (71%). HIV-negative patients were responsible for 21 (49%) cases of PCP. Between 2005-2010 HIV was responsible for all cases of PCP whereas HIV-negative represented 64% of PCP from 2011-2018 (p=0,001). Most HIV-negative patients had recognizable causes of immunosuppression: 15 patients with hematologic cancer, 3 with solid organ cancer and 3 with autoimmune disease. HIV-negative patients were significantly older (63 [56-74] vs. 43 [33-53] years, p=0,0001), presented shorter duration of symptoms (3 [2-6] vs. 15 [7-31], p=0,0002), had higher APACHEII (24 [23-30] vs. 20 [15-24], p=0,0143) and increased in-hospital mortality (61% vs. 36%, p=0,094), but equal pO2/FiO2 on admission (113 [84-133] vs. 101 [71-151] mmHg, p=0,794) and lactate (1,9 [1,3-2,6] vs. 1,6 [1,2-2,1] mmol/L, p=0,243). Non-invasive ventilation (NIV) or high-flow nasal oxygen (HFNO) were attempted on 11 (26%) patients. Failure of NIV or HFNO was high in both groups (HIV-negative 57% vs HIV-positive 75%, p=0,473). The rate of mechanical ventilation was equal in both groups (81% vs 82%). Failure of NIV or HFNO was not significantly associated with mortality.
On univariate analysis, predictors of in-hospital mortality were need for mechanical ventilation (OR 25,2 [95% CI 1,35 – 471,5], p= 0,031), renal replacement therapy (OR 6,96 [95% CI: 1,57-30,86], p=0,011) and age (OR 1,07 [95% CI 1,02-1,12], p=0,006).
CONCLUSION. Severe PCP predominantly affects HIV-negative immunosuppressed patients during last years. HIV-negative patients are older, have more abrupt disease onset and seem to have increased mortality. Increased mortality might be associated with increasing age, comorbidities and need for organ support. Need for mechanical ventilation and renal replacement therapy were the stronger predictors of mortality. Use of NIV or HFNO was associated with a high percentage of progression to mechanical ventilation but without increased mortality keeping the non invasive strategy as an option in this patients.

INTRODUCTION. Hantaviral infection is a severe disease caused primarily by inhalation of contaminated particles of infected rodents. Most deaths are caused by a combination of progressive respiratory and cardiac failure, which is called the cardiopulmonary syndrome. In 2016, our institution introduced the use of extracorporeal membrane oxygenation (ECMO) as rescue therapy in patients who developed cardiopulmonary syndrome and refractory shock or severe hypoxemia.
OBJECTIVES. The purpose of this abstract is to describe patients, complications and evaluate the outcomes of this therapy.
METHODS. Retrospective data from ECMO supported patients was analyzed. Continuous variables were expressed as mean ± standard deviation, and categorical variables were expressed as the absolute number and proportions (%). Comparisons between survivors and non-survivors were made with the Mann-Whitney U test. A descriptive analysis was performed.
RESULTS. A total of 19 patients were described. Table 1 resumes demographic characteristics and severity scores at admission, remarking SOFA 11±2,2 and APACHE II of 18,4±7. Before connection, cardiac index was 1,95±0,3, PaO2/FiO2 111±37 and lactate 3,45±2,1. Table 2 highlights other pre ECMO status. SOFA score was significantly different between survivors and non-survivors (figure 1). The most common complication was acute kidney failure. A tendency to statistical difference was seen on age, APACHE II and initial PaO2/FiO2. Cardiac output, time of ECMO and

distance to ECMO center did not show any clinical difference. In-hospital survival was 68,4%.

CONCLUSION. We described the results of a new developed ECMO program focusing on the outcomes of Hantavirus patients, showing an important survival in patients whose mortality remained extremely high before support therapy.

INTRODUCTION. Previous studies reported conflicting results regarding the impact of COPD on ventilator-associated pneumonia (VAP) incidence.
OBJECTIVES. To determine the impact of COPD on incidence, characteristics and outcomes of ventilator-associated lower respiratory tract infections (VA-LRTI).
METHODS. Retrospective analysis of prospective observational multinational TAVeM database (1). From September 2013 to July 2014, data were obtained from 2960 consecutive patients older than 18 years who received invasive mechanical ventilation (MV) for ≥48 hours. COPD patients (n=494) were compared to non COPD patients (n=2466). The diagnosis of ventilator-associated tracheobronchitis (VAT) and VAP was based on clinical, microbiological and radiological criteria.
RESULTS. VAP and VAT incidences were not significantly different between COPD and non COPD patients (12% *versus*13%, *p*=0.931, and 13% *versus*10%, *p*=0.093, respectively). Among patients with VA-LRTI, *Escherichia coli*and *Stenotrophomonas maltophilia*were significantly more frequent in COPD patients as compared with non COPD patients. The rate of multidrug-resistant bacteria was similar between the two groups. Appropriate antibiotic treatment was not significantly associated with progression from VAT to VAP among COPD patients who developed VAT, unlike non COPD patients.MV duration, ICU and hospital length of stay were significantly longer in patients with VAT or VAP as compared to patients without VA-LRTI, in both COPD and non COPD patients. Among patients who developed VAT, COPD patients exhibited significantly longer MV duration and ICU length of stay, as compared to non COPD patients (17 [9-30]) *versus*13 days [8-21], *p*= 0.042 and 24 [17-39] *versus*20 days [14-31], *p*=0.042, respectively). No significant difference regarding ICU mortality was found between COPD and non COPD groups in patients with VAT, VAP or without VA-LRTI.
CONCLUSION. Incidence of VA-LRTI was similar in both COPD and non COPD population, but VAT was associated with significantly longer duration of MV and ICU length of stay among COPD patients as compared to non COPD patients. Appropriate antibiotic treatment did not reduce the progression from VAT to VAP among COPD patients.

INTRODUCTION. A quarter of HAI's will be produced in the ICU, are an important cause of complications, prolonged ICU stay, increased costs and mortality (1-2)
OBJECTIVES. To describe the incidence and characteristics of infections associated with health care in the ICU.
METHODS. A retrospective, observational study of all patients admitted to the ICU of the Hospital Juárez de México between January 2013 and December 2018, who had a diagnosis of HAI's acquired in the ICU, was registered type of infection, pathogen and outcome.
RESULTS. We analyzed 1727 patients admitted to the ICU, of whom 479 met criteria for HAI's and 316 had at least one positive microbiological isolation. The incidence of infections associated with health care, acquired in the ICU was 44.03, 41.38, 31.50, 21.77, 20.81, 15.01% during 2013, 2014, 2015, 2016, 2017 and 2018 respectively, observing an increase in the number of patients attended in ICU with a constant and significant reduction of HAI's in ICU; the average time between admission to the ICU and the presentation of HAI's was 12 days (IQR 8-20 days). The ventilator associates pmneumonia had incidence of 60.12%, other pneumonias 9.39% and non cathether related bacteriemia 8.97%. It was found that A. baumannii (n = 128 cases) as a risk factor for mortality in ICU with OR = 1.0215 (95% CI 0.5455 to 1.9127, p = 0.9470) and of Pseudomonas sp. There were 91 cases OR 1.1250 (95% CI 0.5639 to 2.2445, p = 0.7382) in comparison to other pathogens.
CONCLUSION. VAPs are the most common cause of HAIs in ICU, pathogens such as A. baumannii and Pseudomonas are common in our environment, however, they do not seem to increase mortality in relation to other pathogens (1-3).

INTRODUCTION. The timing, severity and treatment of healthcare-associated CDI are not well described in critically ill patients.
OBJECTIVES. The objectives of this nested cohort study are: 1) the incidence of CDI and timing of CDI (pre-ICU, in ICU, post-ICU); 2) severity of CDI based on the Infectious Diseases Society of American/Society for Healthcare Epidemiology of American (IDSA/SHEA), American College of Gastroenterology (ACG) and European Society of Clinical Microbiology and Infectious Diseases (ESCMID) scores; 3) complications and mortality; 4) treatment for CDI in the ICU.
METHODS. This multicenter study was nested within a clinical trial testing *Lactobacillus rhamnosus* GG (Culturelle, Locin Industries Ltd) versus placebo to reduce ventilator associated pneumonia and other ICU-acquired infections. Research Coordinators completed a case report form for any patient who was suspected to have CDI. All CDI parameters were adjudicated in duplicate with respect to timing of the infection, severity, treatment, and complications; any adjudicator disagreement was resolved by a third adjudicator.
RESULTS. 64 of 1,766 patients (3.6%) developed CDI; 7 of whom (0.4%) had CDI at ICU admission (pre-ICU), while 41/1766 (2.3%) developed CDI in the ICU (ICU-acquired), and 16/1766 (0.9%) developed CDI after post-ICU discharge (post-ICU). The incidence rate of ICU-acquired CDI was 1.4/1000 patient-days. CDI severity in the ICU was mostly mild/moderate according to these criteria: 45/64 (70.3%) by IDSA/SHEA; 49/64 (76.6%) by ACG; 53/64 (82.8%) by ESCMID. Fewer patients developed severe CDI (12/64, 18.8% IDSA/SHEA; 6/64, 9.4% ACG; 11/64,17.2% ESCMID) and severe, complicated CDI was rare (7/64, 10.9% IDSA/SHEA; 9/64, 14.1% ACG). Complications attributed to CDI were frequent: 17/64 (26.6%) patients had septic shock, 12/64 (18.8%) developed new end-organ failure and 1 (1.6%) had toxic megacolon necessitating colectomy. ICU and hospital mortality was 338/1766 (22.0%) and 501/1765 (28.4%), respectively. ICU and hospital mortality based on IDSA/SHEA severity was: mild/moderate: 7/45 (15.6%), 14/45 (31.1); severe: 4/12 (33.3%), 4/12 (33.3%); severe and complicated: 3/7 (42.9%) and 4/7 (57.1%), respectively. Most patients with ICU-acquired CDI in our cohort received metronidazole [total 45/64 (70.3%)] either orally [42/64 (65.6%)] or intravenously [21/64 (32.8%)], and 40/64 (62.5%) received vancomycin orally [39/64 (60.9%)] or rectally [2/64 (3.1%)]. Fidaxomicin wasn't prescribed, but 3/64 (4.7%) patients underwent fecal transplantation.
CONCLUSION. CDI was more likely to be acquired in the ICU than to be pre-existing or develop following recovery from critical illness. Most cases were mild-moderate in severity; treatment primarily involved metronidazole, consistent with prior CDI guidelines for first episodes of non-severe CDI. CDI remains a concerning clinical problem; further research should focus on optimal risk stratification and treatment.

INTRODUCTION. Hand hygiene is the most important infection control intervention that has proved to decrease the risk of hospital-acquired infections in intensive care units or hospitals. However,

proper hand hygiene implementation in healthcare institutions still faces various challenges in many developing countries due to limited resources and non-availability of hand hygiene infrastructure.
OBJECTIVES. We aimed to assess the effectiveness of environmental and behavioral changes before and after the implementation of a hand hygiene promotion program in a rural public hospital in Cambodia.
METHODS. This project was operated the cooperation by Kaohsiung Veterans General Hospital (KVGH), Taiwan, and carried out in a regional public hospital, namely, Bati Referral Hospital (BRH), in Bati District, Takeo Province, Cambodia during May 2017 to December 2018. A baseline survey was conducted before the implementation andcontinuous quality improvement program were used to analyze and solve the problems.
RESULTS. A total of 42 health care workers participated in the project, among these ten were chosen as auditors. The rate of technical practice of hand hygiene was 0% at baseline and rose to 95.6% ($p< 0.001$) in the follow up assessment. The rate of auditors was from 0% to 100%. Compliance rates of moment one (before touching patients) and moment four (after touching patient) of hand hygiene improved from 0% to 100%. The prevalence ratesof diarrhea and pneumonia decreased from 4.15% to 3.78% and 4.8% to 4.4%, respectively. The length of admission decreased from 3 to 2.7 days.
CONCLUSION. This program showed continuous quality improvement program could establish a pilot hand hygiene promotion program and system in a rural hospital in where hand hygiene program was never implemented in a developing country. Availability of hand hygiene equipment, periodical training and evaluation, and managerial empowerment are the key factors to ensure long-term sustainability. In addition, commitment and support by government and hospital authorities arealso crucial for successfulimplementation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000337

INTRODUCTION. The number of patients with cancer who receive intensive care treatment is growing. However, the prognosis of these patients remains poor with a mortality after ICU admission of around 50%. So, efforts are needed in order to improve their outcome.
OBJECTIVES. Our aim was to describe the cohort of patients with solid organ cancer admitted to a tertiary hospital ICU and analyze factors that are likely to affect their survival.
METHODS. Retrospective study, including adult (+18 years) patients with solid organ cancer who required admission to ICU between 2010 and 2016. X-Square, Fisher´s test, T test, U Mann-Whitney and logistic regression were employed as required. Quantitative variables are reported as median (IQR) and categorical as frequency (%).
RESULTS. One hundred and fifty patients were included, 77 (51%) female, with a median age of 62 (52-70) years. Lung cancer was the most frequent one, being present in 34 (25%), followed by colon 20 (13%), breast 13 (9%) and ovary 13; (9%). Metastatic disease affected to 84 (58%). The functional status was ECOG 0 in 12 (8%), ECOG 1 in 74 (51%), ECOG 2 in 56 (39%) and ECOG 3 in 3 (2%). The main indications for ICU admission were respiratory failure in 55 (37%), shock in 31 (21%), post urgent surgery in 29 (20%) and central nervous system involvement in 10 (7%). SOFA score at admission was 6 (4-9) Neutropenia was present in 19 (13%). Ninety-two (62%) required vasoactive drugs (VAD), 55 (37%) high flow nasal cannula (HFNC), 66 (44%) mechanical ventilation (MV), and 13 (9%) renal replacement therapy (RRT). ICU mortality affected to 38 (26%) and hospital mortality to 66 (44%). We identified the following factors related to hospital mortality in the univariate analysis: SOFA score on admission (OR 1.1, IC95% 1-1.3, $p<0.004$), no improvement in SOFA score at day 5 (OR 6.8, IC95% 2.1-22.3, $p<0.002$), need of MV (OR=5.5, IC95%:2.7-11.2, $p< 0.0001$), VAD (OR=2.2, IC95%:1.1-4.3, $p=0.03$). We did not find any differences in mortality according to the need of RRT, ECOG status, the presence of metastatic disease or neutropenia. In the multivariate analysis, MV (OR=6.8, IC95%:1.4-32.2, $p=0.016$) and no improvement in SOFA score at day five (OR 6.7 IC95%:1.7-27: $p=0.007$) maintained statistical significance.
CONCLUSION. Despite improvement in cancer therapies and critical care management, mortality is still high in oncologic patients admitted to ICU. Organ failure and need of mechanical ventilation is related to mortality, so these patients could benefit of an earlier admission. Patients with no improvement in organ dysfunction at day 5 have a greater mortality, so this information could be useful in the decision process during an ICU trial.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001557

INTRODUCTION. Redirecting T-cell cytotoxic specificity through chimeric antigen receptor gene transfer (CAR-T cells) has become a major breakthrough in cancer immunotherapy, especially against relapsing/refractory CD19 hematologic neoplasms as acute lymphoid leukemia (ALL) or non-Hodgkin lymphoma (NHL). Significant toxicity is associated with this therapy, requiring sometimes ICU admission. The first academic pilot clinical trial (clinicaltrials.gov NCT03144583) using our fully academic (A3B1:CD8:4-1BB:CD3Z) CART-19 (ARI-0001 cells) was approved by the Spanish Agency of Medicines on May/2017

OBJECTIVES. To report the rate and characteristics of ICU admissions of patients treated with ARI-0001 cells
METHODS. Patients with NHL and ALL who had failed standard available therapy have been included in the trial. The primary objective of the study was safety, and secondary objectives were response rate and its duration. After conditioning with fludarabine (90 mg/m2) and cyclophosphamide (900 mg/m2), we infused 0.4-5 x106ARI-0001 cells /kg, either as a single infusion or in 2-3 fractions. Data are expressed in median (range) and n (percentage)
RESULTS. As of April/2018, 25 adult patients have been infused (3 of them twice and 1 three times), 14 as a single infusion and 11 as fractioned aliquots. Seven patients (28%) have been admitted to the ICU (1 patient was admitted twice). The median age was 27 years (19-54), 4/7 were men. Four had refractory ALL and three NHL, with a median of 4 previous lines of treatment (4-6). Five of them also had been treated with hematopoietic stem cell transplant (3 allogeneic). All 7 needed bridging chemotherapy between apheresis and CART-19 infusion. Five patients received the treatment as a single infusion and two as fractioned aliquots (one of them only received 40% of the planned dose). Reasons for ICU admission were cytokine releasing syndrome (CRS) (4 patients), neurotoxicity (2 patients), infection (2 patients) and non-CRS related hypotension (1 patient). One patient was admitted previously to infusion because of respiratory failure due to illness progression. Median APACHE II and SOFA were 15 (13-22) and 4 (2-8), respectively. Organ support was needed in 4/7 patients (vasopressors 4/7, mechanical ventilation 3/7, renal support therapy 3/7). Regarding CRS, severity was measured by Lee scale. One patient died (grade 5) and 2 and 1 patient had grade 3 and 2, respectively, all of them starting the day of infusion. Tocilizumab was administered in these 4 cases. Regarding neurotoxicity, the maximum grade was 3 (1 patient) and 1 (1 patient). Three patients died in the ICU, due to refractory CRS (1 patient), CRS + *Clostridium difficile* infection (1 patient) and disease progression (1 patient). The median length of stay in ICU was 4 days (2-34)
CONCLUSION. Rate of ICU admission in patients treated with ARI-0001 cells was 28%, mainly due to CRS. Fractioned infusion dose seemed associated with a lower ICU admission rate

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001078

INTRODUCTION. Current guidelines recommend to increase mean arterial pressure (MAP) in previously hypertensive septic shock patients to higher levels (80-85 mmHg) when tissue hypoperfusion has not been corrected with the initial fluid resuscitation and restoration of MAP to 65 mmHg. The impact of incremental NE titration on cardiac function depends on the balance between the effects on preload, contractibility and afterload. As NE may both increase venous return and afterload, a particular concern is a potential decrease in stroke volume (SV) in fluid-unresponsive patients.
OBJECTIVES. To determine the impact of an increase in MAP from 65 to 85 mmHg by incremental NE titration on SV and several parameters of cardiac performance in previously hypertensive fluid-unresponsive patients.
METHODS. We evaluated patients in whom the attending doctor decided to increase MAP from 65 to 85 mmHg because of persistent hypoperfusion. A comprehensive echocardiographic assessment was performed at baseline (B1), after reaching the MAP target (MAP 85), and after return to baseline MAP (B2). A SV responder was defined as patients that increased SV by >10% at MAP 85. Mean Systemic Filling Pressure (Pmsf) and pressure for venous return (Pvr) were calculated. Preload, contractility and afterload variables were assessed. Statistical analysis was performed with Wilcoxon signed-rank test, $P < 0.05$ was considered as significant.
RESULTS. Seven mechanically ventilated patients (age 71± 8 yr, APACHE II 22±7, SOFA on admission 10 ± 2) were included in this preliminary report. Hemodynamic variables are shown in table 1. No patient decreased SV after reaching MAP 85. Three patients were SV-responders this was associated with an increase in Pmsf and Pvr accompanied by a direct increase in left ventricular contractility as assessed by ventricular elastance.
CONCLUSION. In previously hypertensive and currently fluid unresponsive septic shock patients in whom MAP was increased from 65 to 85mmHg stroke volume did not decrease despite the increased afterload due to an increase in left ventricular contractility.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001108

INTRODUCTION. Despite hemodynamic stabilization after resuscitation, tissue hypoperfusion may persist in circulatory shock (CS) patients. Volume expansion (VE) and increasing mean arterial pressure (MAP) are two of the strategies to correct tissue hypoperfusion.
OBJECTIVES. We hypothesized that a VE or a change in MAP by norepinephrine (NE) titration would affect skin blood flow (SBF) and thenar muscle oxygenation (StO2).
METHODS. Hemodynamically stabilized patients with CS undergoing a VE or an adjustment of MAP were included. CS was defined as the presence of NE to maintain MAP ≥ 65 mmHg with ≥ 1 signs of tissue hypoperfusion (oliguria, alteration of consciousness, mottled skin) or lactate ≥ 2 mmol/L. VE (crystalloid solution administration at 500 ml/30 minutes infusion rate) and the adjustment of MAP (ΔNE) (an increase or decrease in NE infusion rate ≥ 20%) were decided by the attending physician.
SBF was measured (Periflux 5000, Perimed; index finger, Perfusion unit: PU) before (T0) and after (T1) VE or ΔNE. Thenar StO2 was measured at T0 and T1 by near-infrared spectroscopy (NIRS; InSpectra TM Model 325). A vaso-occlusive test (VOT) of 3 minutes was also performed at T0 and T1 to calculate the StO2 ascending slope (AscStO2) (%/min) following the end of the VOT. Hemodynamic variables and lactate levels were obtained at the same times as the measurements. The changes in SBF (ΔSBF) and AscStO2 were calculated as relative percent changes. Data are reported as medians with 25th and 75th percentiles.
RESULTS. 19 patients with CS (septic (8), cardiogenic (10), hypovolemic (1)) were studied. APACHE score at admission was 19 (17-28), SOFA score at inclusion time was 11 (8-12). At baseline there were no differences in MAP (p=0.6), cardiac index (CI) (p=0.7), lactate levels (p=0.7), StO2 (p=0.6) and AscStO2 (p=0.3) between VE patients (n = 9) and ΔNE patients (n = 10). SBF was lower in VE patients than in ΔNE patients (20 (12-121) vs 102 (64-201) p=0.04, respectively).
Hemodynamic effects of VE and ΔNE are reported in the Table. SBF and StO2 did not change, AscStO2 increased in VE patients but not in ΔNE patients (Table). Changes in CI were not correlated to ΔSBF (r=0.02; p=0.4) or ΔAscSto2 (r=0.29; p=0.5). Also, changes in MAP were not correlated to ΔSBF (r=0.05; p=0.8) or ΔAscSto2 (r=-0.04; p=0.8).
CONCLUSION. Changes in hemodynamic parameters during a VE or a change in MAP target are not correlated to changes in skin blood flow or thenar muscle tissue oxygenation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001115

INTRODUCTION. AF is the most common arrhythmia seen in Critical Care and is associated with poorer long-term outcomes and an increased incidence of permanent AF. The follow-up of patients with new-onset AF (NOAF) in Critical Care may help to determine the long-term risk of recurrence of AF.
Amiodarone and beta-blockers are commonly used to treat AF in critically ill patients. Long-term use of these medications has been associated with adverse effects. Anticoagulant therapy also has well established bleeding risks. The long-term use of these medications is currently not recommended for patients who solely develop episodes of AF as part of their critical illness.
OBJECTIVES. The primary outcome measure was the number of patients with NOAF that were started on an anti-arrhythmic and/or an anti-coagulant and discharged home on these medications.
Secondary outcome measures included the number of patients that were reviewed by cardiology as an inpatient, the number that were still in AF at discharge and the number of patients with follow-up arranged upon their discharge from hospital.
METHODS. 95 critically ill patients were found to have AF in 2017. 26 patients who were treated for NOAF in critical care and survived their admission were included in this analysis.
Electronic clinical notes, referrals and discharge summaries were reviewed to identify pre-hospital and discharge medications, AF status and follow-up arrangements at discharge.
RESULTS. No patients were discharged home on amiodarone. However, 12 patients were discharged home on bisoprolol and only 6 of these patients had follow-up arranged for AF. None of these patients were taking bisoprolol before admission to hospital. Similarly, one patient was discharged home on digoxin without follow-up.
One patient was anti-coagulated for AF and was discharged home on a Direct-Acting Oral anticoagulant (DOAC) with follow-up arranged.
8 of the 26 patients were reviewed by cardiology as inpatients, and only 7 patients were discharged from hospital with follow-up for their AF. Of the 6 patients still in AF at discharge, 4 had planned follow-up.
CONCLUSION. In contrast to previous reports, no patients were discharged home on amiodarone, However, a significant number of patients with NOAF in critical care were discharged on bisoprolol. Follow-up for AF was arranged only for two third of patients who developed NOAF during critical illness.

INTRODUCTION. Implantation of a permanent cardiac pacemaker is a surgical procedure associated with minimal patient discomfort and low percentage of complications in expert centers.
OBJECTIVES. To analyze the safety of implantation of a cardiac pacemaker as a day case procedure.
METHODS. Retrospective study in a University Hospital from February 2017 to February 2019.Inclusion criteria:over 18 years old, requiring elective pacemaker and no pacemaker dependent. Patients who did not accept the program were hospitalized in the usual way, as well as those who presented some social exclusion criteria.The Pacemaker Unit, dependent from the Critical Care Department and integrated by medical specialists in intensive medicine accredited for the implantation of pacemakers, established a program for the implantation of definitive pacemakers without hospital admission. After the implant, the patients remain under observation for 8 hours. Prior to discharge, chest radiography and pacemaker monitoring was performed. At 24 hours a patient evaluation was carried out by telephone control, at 48 hours by means of an ambulatory face-to-face visit, which repeats after 2-3 months and continuing every 6-9 months.
RESULTS. 39 patients included, all of them could be discharged following the protocol. Average age 77 (48-91) years old, 69% male. Pacing Systems: DDDR 79%-VVIR 21%. Indications: Third-degree AV block 26%, Mobitz II 21%, sick sinus syndrome 20%, Atrial fibrillation Blocked 15%. Symptom: syncope 46%, bradycardia 26%, dizziness 18% and heart failure 10%.Etiology was unknown in 95% of cases. 36% of patients were under treatment with oral anticoagulation.The most frequent placement of right ventricular electrode was the septum in a 92%. Any patient presented complications during the procedure or at discharge (table 1); only one complication at 48 hours due to hematoma in the area of the pacemaker, related to oral anticoagulation and ambulatory solved.The implant parameters were the most adequates in all cases (table 1), remaining stable in the subsequent controls. There was only one case with high capture threshold in the atrial lead but remained stable at follow-up.
CONCLUSION. Ambulatory implantation of pacemakers has proven to be a safe treatment in our experience.

INTRODUCTION. Hemodynamic optimization is a main goal in the management of critically ill patients. Right ventricular function, renal failure and fluid balance are part of this process. Our goal is to analysis those, after the initial resuscitation and the effects of mechanical ventilation over them.
METHODS. A prospective, observational study was performed with all the patients admitted to a Medical Service of Intensive Care of a Tertiary, University Hospital. All patients analyzed required mechanical ventilation as a support for their underling pathology. All consecutive patients admitted to the unit under mechanical ventilation were collected, in the absence of shock, with the expectation of remaining under mechanical ventilation for at least 24 more hours after data collection.
The incidence of right ventricular failure according to the defined parameters, renal failure, and fluid balance were described. We had described its association with mechanical ventilation and mortality.
RESULTS. A total of 30 patients were selected. Right ventricular failure was observed in 16.6% of patients (5/30). There was no statistically significant association with the need of tracheotomy, renal failure or mortality. It was not associated with longer average stay, days of mechanical ventilation or higher severity scores.
40% of the patients presented acute renal failure. Renal failure was not associated statistically significant with the need of tracheotomy or failure in scheduled extubation, however, it was associated with higher mortality. Patients requiring mechanical ventilation with normal creatinine values after initial resuscitation, had a mortality rate of 28.5% in comparison to patients who had altered values in which the mortality rate was 77.7%. ($p < 0.018$).
Regarding the post-resuscitation net fluid balance, no statistically significant differences were found in the comparison of means between survivors and non survivors, with renal failure or right ventricular failure. No even was it associated with higher mortality.
CONCLUSION. Right ventricular failure, despite not being associated with mortality, days of mechanical ventilation or failure in extubation in a statistically significant way, presents an incidence of 16.6% in patients connected to mechanical ventilation admitted to a polyvalent icu.
Acute renal failure is associated in a statistically significant way with mortality in our sample. We had not found association between fluid overload and renal failure in our sample.

INTRODUCTION. Invasive blood pressure (IBP) is the gold standard for arterial pressure (AP) monitoring in critically ill patients. Nevertheless, IBP may be affected by underdamping/resonance artifacts, that eventually lead to AP overestimation. In these cases, when a pulse contour method (PCM) is applied, wrong hemodynamic data are also delivered by the monitor. In order to overtake this issue, MostCareUp (a PCM powered by Pressure Recording Analytical Method, PRAM),

has been implemented with a dynamic electronic filter (EFMC) that automatically corrects the resonant AP waveform with two modalities: standard and advanced (i.e., higher-intensity).
OBJECTIVES. In order to test the EFMC, the electronically corrected AP, the derived cardiac output (CO) and the maximal slope of the systolic upstroke (dP/dtMAX) were compared with respective raw data corrected with the Accudynamic, an adjustable damping device specifically manufactured for normalizing the pressure waveform (in our study: the reference method).
METHODS. Systolic AP, CO and dP/dtMAX, were recorded with EFMC disabled (A), standard EFMC (B), advanced EFMC (C), Accudynamic with EFMC disabled (D).
RESULTS. Seventy patients with resonant IBP were enrolled (Table 1). According to the Bland-Altman analysis, systolic AP biases (LoAs) (mmHg) were 17.21 (-0.43; 34.87); 13.27 (-2.86; 29.4); 6.68 (-5.18;18.55) in D-A, D-B and D-C conditions respectively. CO biases (LoAs) (L/min) were 4.1 (-1;9.25); 1.19 (-1.1;3.5); 0.3 (-1.1;1.64) in in D-A, D-B and D-C conditions respectively. DP/dtMAX biases (LoAs) (mmHg/ms) were 0.88 (0.09;1.68); 0.28 (-0.04;0.6); -0.04 (-0.4;0.33) in D-A, D-B and D-C conditions respectively.
CONCLUSION. The EFMC, especially in advanced modality, efficiently corrects resonant waveforms allowing a correct measurement of AP values and contributing to improve the estimation of exact hemodynamic data.

INTRODUCTION. Although the potential ability of magnesium administration to prevent and treat arrhythmias has been recognized in clinical setting, limited evidence exists. In this study, we examined whether intravenous administration of magnesium sulfate increases successful electrical cardioversion for new-onset atrial fibrillation (AF) in critically ill patients.
METHODS. Atrial Fibrillation Treatment Evaluation Registry in the ICU (AFTER-ICU) was a multicenter, prospective cohort study of adult patient who developed new-onset AF after ICU admission, conducted from April 1, 2017 to March 31, 2018 in 31 Japanese ICUs. In this prospectively planned sub-analysis of the AFTER-ICU study, we assessed the value of magnesium sulfate in facilitating electrical cardioversion. All delivered electrical cardioversions for AF were assigned to the magnesium group (administered within 12 hours before electrical cardioversion) or the control group. The primary outcome was successful cardioversion defined as conversion to sinus rhythm after 30 seconds of electrical cardioversion.
RESULTS. Of 158 electrical cardioversions in 52 patients, 19 were assigned to the magnesium group and 139 to the control group. Compared with the control group, the magnesium group was younger (66yr vs. 70yr) and had a lower proportion of male (10.5% vs. 23.7%), but severity of critical illness was similar (APACHE II score, 29 vs. 28). Successful electrical cardioversion was more frequently observed in the magnesium group (42.1% vs. 27.3%), and there was non-significant association between magnesium pre-administration and successful electrical cardioversion (adjusted odds ratio 2.0, 95%CI 0.7-5.5).
CONCLUSION. Intravenous administration of magnesium sulfate may increase successful electrical cardioversion in patients with new-onset AF. This study was not powered to detect any associations due to the small sample size and future research is warranted.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001170

INTRODUCTION. According to European and American guidelines, intravenous (iv) thrombolysis is the primary treatment for high-risk pulmonary embolism (PE) signified by hemodynamic instability. In recent years, catheter-directed interventions (CDI) has emerged as an alternative in patients with contraindications to thrombolysis. However, there are numerous variants of CDI techniques and their effectiveness is not sufficiently studied.
OBJECTIVES. To evaluate the outcome and effectiveness of CDI, measured in terms of survival and reduction of right ventricle distension, as treatment for massive PE compared to iv thrombolysis or anticoagulation only.
METHODS. This is a retrospective study from a tertiary hospital where CDI is used for patients with high-risk PE fulfilling all three criteria: (1) distention of the right ventricle (RV); (2) systolic blood pressure <90mmHg or syncope at any time from onset of symptoms; (3) contraindication(s) to or insufficient effect from iv thrombolysis. We included patients from July 2013, when CDI with the Angiojet system as the main technique, was introduced, to December 2018. The control cohort were PE patients from 2006 to 2013, before CDI was introduced, who fulfilled the CDI criteria above but received either heparin only or iv thrombolysis, administered despite contraindications on vital indication.
RESULTS. Ninety-day survival was 60% in the CDI (n=25) and 61% (p=0.951) in the control group (n=23). The PESI score did not differ between the groups; CDI 183 ± 46 vs control 168 ± 35 (p=0.211). Median pre-treatment RV/LV ratio was 2.2 [IQR 1.6 – 2.7] in the CDI group which was higher than 1.3 [IQR 1.1 – 1.6] which was found in the control group (p<0.001). When adjusting for PESI-scores and RV/LV ratio, there was no difference between the groups as to survival at 90

days (p=0.529). There were neither any differences in long-term survival between the groups. (p=0.975, Figure). In a linear mixed model, with adjustment for timing of pre- and post-treatment imaging, the decrease of RV/LV ratio was 0.4 units higher per 24 hours in the CDI group (p=0.007).
CONCLUSION.
In this retrospective observational study of patients with high-risk PE and contraindications to thrombolysis, treatment by CDI was as efficient as treatment by iv thrombolysis or anticoagulation with regards to survival. However, CDI resulted in faster resolution of RV dilatation. The latter is to be interpreted with caution since the patients in the CDI group had higher pre-treatment RV/LV ratios.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001198

INTRODUCTION. Stress or Takotsubo cardiomyopathy(SCMP) is a syndrome characterized by transient regional left ventricular dysfunction in the absence of significant coronary artery disease. The clinical presentation of SCMP is similar to that of an acute coronary syndrome. Wall motion abnormalities in patients with SCMP are typically detected by echocardiography.
However, diagnosis of SCMP can be challenging in patients who are being treated for other diseases in the intensive care unit. And the clinical characteristics and risk factors of SCMP among patients in intensive care unit with a non-cardiac diagnosis and no prior history of cardiac disease is not known.
OBJECTIVES. The aim of study was to investigate the clinical characteristics of stress-induced cardiomyopathy in critically ill patients.
METHODS. We retrospectively assessed the medical records of patients who performed echocardiography (ECG) in the Medical intensive care unit at tertiary university hospital, from January 2015 to December 2018.
Diagnosis of SCMP was based on the following echocardiographic finding: reversible akinesia or dyskinesia of the apical and mid portions of the left ventricle beyond a single major coronary artery vascular distribution.
RESULTS. A total 62 patients were performed formal echocardiography. Of the 62 cases, 11 patients were SCMP (17.7%), and 38 patients had diagnosed a sepsis or septic shock.
There was no significant difference between the SCMP positive group and the negative group in baseline characteristics such as age, sex and other clinical features. T-wave inversion on ECG at admission day (8/11 vs. 17/51, p=0.038) was statistically different between two groups (SCMP + vs SCMP -, respectively).
And in subjects who diagnosed sepsis or septic shock (n = 38), initial T-wave inversion on ECG (7/8 vs. 13/30, p=0.045), abnormal troponin level at admission day (7/8 vs. 13/30, p=0.027), and elevated lactate even 48 hours later (3/118 vs. 3/30, p=0.026) were related with the incidence of SCMP.
CONCLUSION. In critically ill patients, T-wave inversion on ECG may be a positive SCMP suggesting clue. And also, abnormal troponin level and elevated lactate at 48 hours later could be a good clinical features for suggesting SCMP in sepsis or septic shock patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001214

INTRODUCTION. Hypovolemia is a common clinical condition in intensive care units (ICUs) and fluid resuscitation is considered the first line of therapy. Multiple studies have found that only 50% of hemodynamically unstable patients in the ICU respond to volume expansion(VE). It is therefore essential to have reliable tools to predict the efficacy of VE and ultimately distinguish patients who may benefit from VE from those who are unlikely to respond.Over the last decade, new approaches have been developed. Among the tests and indices that have been developed to predict fluid responsiveness, the end-expiratory occlusion(EEO) test has gained considerable attention, especially in mechanically ventilated patients.Following the first study demonstrating the accuracy of the EEO test by Monnet et al, conflicting results concerning the ability of EEO test have been published.
OBJECTIVES. We performed a systematic review and meta-analysis of studies investigating the EEO-induced changes in cardiac output (CO) and in arterial pressure as predictors of fluid responsiveness in adults receiving mechanical ventilation.
METHODS. MEDLINE, EMBASE, Cochrane Database and Chinese database(China National Knowledge Internet, Wanfang Database) were screened for relevant original and review articles.The meta-analysis determined the pooled area under the ROC curve, the sensitivity, specificity and threshold for the EEO test when assessed with CO and arterial pressure.
RESULTS. Thirteen studies enrolling 479 adult patients and 523 volume expansion were included. CO was measured by transpulmonary thermodilution in ten studies, echocardiography in one study, oesophageal Doppler in one study, and calibrated pulse contour analysis in one study. For the EEO-induced changes in CO, the pooled sensitivity was 0.92 (95% CI, 0.85–0.97) and the pooled specificity was 0.90 (95% CI, 0.84–0.994). The pooled AUROC was 0.96 (95% CI, 0.94–0.97). The best threshold was a EEO-induced increase in CO ≥5± 2%. For the EEO-induced changes in arterial pressure (4 studies, 149 volume expansion), the pooled sensitivity was 0.88 (95% CI, 0.63–0.97), the pooled specificity was 0.77 (95% CI, 0.58–0.89) and the pooled AUROC was 0.87 (95% CI, 0.84–0.90). Significant heterogeneity existed among the studies, and meta regression indicated that

the patients position for EEO was the major source of heterogeneity. When excluding the only one study in which EEO was performed during the prone position, the pooled sensitivity for the EEO-induced changes in CO (or surrogate) was 0.92 (0.88–0.95) and the pooled specificity was 0.89 (0.83–0.93) in semirecumbent or supine patients. **CONCLUSION.** EEO-induced changes in CO very reliably predict the response of CO to volume expansion in adults with acute circulatory failure during semirecumbent position or supine position but not during prone position. When EEO effects are assessed by changes in arterial pressure, the sensitivity of the EEO test remains acceptable but its specificity is poor.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001218

INTRODUCTION. Background: Pulse pressure variation (PPV) is a dimension-less parameter calculated from the changes in the arterial pressure curve induced by controlled mechanical ventilation CMV. PPV is a predictor of fluid responsiveness FR. Due to a potential impact of arrhythmia and spontaneous breathing on PPV, its application usually is restricted to patients with both sinus rhythm (SR) and CMV. Several other confounders and "contexts" are considered to impede the use of PPV. However, there is a lack of systematic studies investigating the exact impact of potential confounders on PPV.
OBJECTIVES. We hypothesized that PPV might be adjusted to some of these confounders ("context-sensitive indexation"). Therefore, we analyzed a large prospectively maintained database on haemodynamic monitoring (PiCCO; Pulsion; Germany). The CONSORTION I study investigated the general impact of biometrics, other haemodynamic data and contexts (e.g. type of ventilation, heart rhythm) on PPV in all measurements. The CONSORTION II study investigated the impact of ventilator setting and potential confounders on PPV in the subgroup of measurements with both SR and CMV.
METHODS. Analysis of a database including 9001 haemodynamic measurements in 513 critically ill patients. Spearman correlation. Multiple regression analysis. IBM SPSS 25.
RESULTS. Biometrics: In the totality of measurements, PPV was slightly associated with age ($r=0.162$; $p<0.001$), weight ($r=0.119$; $p<0.001$) and height ($r=0.068$; $p<0.001$). Men had slightly higher PPV compared to women (11.9±7.7 vs. 10.2±6.6; $p<0.001$). In multivariate analysis ($R^2=0.037$) regarding biometric data, all biometrics were independently associated with PPV (T-values of 10.3, 8.8, 8.8 and -2.4 for age, weight, male gender and height). Among the „contexts", there was strong impact of the heart rhythm on PPV: Patients with atrial fibrillation AF had a markedly higher PPV compared to patients with sinus rhythm SR (19.9±7.1 vs. 10.2±6.6%; $p<0.001$). Patients with mechanical ventilation MV (irrespective of assisted or controlled modality) had a lower PPV compared to spontaneously breathing patients (10.5±7.4 vs. 12.4±6.9%; $p<0.001$). Patients with controlled MV (CMV) hat a lower PPV compared to patients with assisted MV (AMV; 8.9±7.5 vs. 11.3±7.2%; $p<0.001$).
Among haemodynamic contexts, PPV was most strongly associated with high heart rate (HR; $r=0.253$; $p<0.001$), low stroke volume (SV; $r=-0.289$; $p<0.001$) and low cardiac output (CO; $r=-0.155$; $p<0.001$). There were poor associations with dPmax ($r=-0.074$; $p<0.001$), global end-diastolic volume (GEDV; $r=0.070$; $p<0.001$) and low CVP ($r=-0.027$; $p=0.023$).
In multivariate analysis ($R^2=0.333$), PPV was strongly associated with atrial fibrillation (T=19.0), heart rate (T=11.9), low SV (T=-13.1), spontaneous vs. assisted vs. controlled ventilation (T=10.4) and weight (T=9.2). Furthermore, PPV was associated to low dPmax (T=-6.5), female gender (T=4.2) and age (T=2.9; all $p<0.001$ except age ($p=0.004$)).
CONCLUSION. Among potential confounders, PPV is most strongly associated to atrial fibrillation, while the impact of assisted or even spontaneous ventilation seems to be lower. A strong association of PPV with low SV and high HR might be in line with the role of PPV as marker of fluid de-pletion. Independent association to age, sex and weight carries the potential for indexation.

INTRODUCTION. Pulse pressure variation (PPV) is a dimension-less parameter calculated from the changes in the arterial pressure curve induced by controlled mechanical ventilation CMV. PPV is a predictor of fluid responsiveness FR. Due to a potential impact of arrhythmia and spontaneous breathing on PPV, its application usually is restricted to patients with both sinus rhythm (SR) and CMV. Several other confounders and "contexts" are considered to impede the use of PPV. However, there is a lack of systematic studies investigating the exact impact of potential cofounders on PPV.
OBJECTIVES. We hypothesized that PPV might be adjusted to some of these confounders ("context-sensitive indexation"). Therefore, we analyzed a large prospectively maintained database on haemodynamic monitoring with the PiCCO-device (Pulsion; Germany). While the CONSORTION I study (Abstract 1218) investigated the general impact of biometrics, other haemodynamic data and contexts (e.g. type of ventilation, heart rhythm) on PPV in **all** measurements, CONSORTION II analyzed the impact of ventilator setting and potential confounders on PPV in the target subgroup of measurements with both SR and CMV.
METHODS. Subgroup-analysis (measurements with both SR and CMV (15.5% of all PPV-measurements)) of a database including 9001 haemodynamic measurements in 513 critically ill patients. Spearman correlation. Multiple regression analysis. IBM SPSS 25.
RESULTS. Among ventilator settings, PPV was univariately associated with low PEEP (r=-0.198; p=0.006), low mean respiratory pressure P_mean (r=-0.191; p=0.008), high Delta_P (driving pressure; r=0.180; p=0.013), high respiratory rate RR (r=0.191; p=0.008), but neither with tidal volume (TV; r=-0.002; p=0.944) nor with TV/predicted bodyweight (r=0.012; p=0.689). In multivariate analysis restricted to ventilator parameters (R^2=0.058), PPV was independently associated to high Delta_P (T=2.2; p=0.028) and low P_mean (T=-2.6; p=0.011), whereas TV/predicted bodyweight slightly failed significance (p=0.054).
In univariate analysis regarding biometric and haemodynamic data, PPV was most strongly associated to low stroke volume (SV; r=-0.427; p<0.001) and heart rate (HR; r=0.355; p<0.001). Furthermore, PPV was weakly correlated to low global end-diastolic volume (GEDV; r=-0.153; p<0.001) and low CVP (r=-0.101; p<0.001).
In a final multivariate analysis (R^2=0.363) including age, gender, weight, height, HR, SV, P_peak, P_mean, PEEP, Delta_P, RR, TV/predicted bodyweight, SV and HR, PPV was independently associated only with low P_mean (T=-3.2; p=0.001), heart rate (T=5.2; p<0.001), low SV (T=-3.9; p<0.001), young age (T=-2.9; p=0.004) and high weight (T=2.1; p=0.038), but not with any other ventilatory parameter including Delta_P and TV/predicted bodyweight.
CONCLUSION. 1.) Among ventilatory parameters, pressures were more strongly associated with PPV than TV/predicted bodyweight. 2.) PPV increased with higher Delta_P and lower P_mean. 3.) Haemodynamic parameters like high heart rate and low stroke volume as well as biometric data such as age and weight have substantial impact on PPV. Therefore, adjustment to these contexts might improve the use of PPV.

INTRODUCTION. Since multi-organ failure MOF is frequent in critically ill patients, apparative multi-organ support is intriguing. The ADVOS-device (ADVanced Organ Support) has been developed for liver support, renal replacement, CO2-elimination and modulation of the acid-base balance. To provide high efficiency, the device is equipped with two dialyzers for blood purification and ultrafiltration as well as with two dialyzers for regeneration of the albumin-containing dialysate. The standard treatment period for liver support is 8 hours. In case of treatment for CO2-elimination and/or large volume ultrafiltration, patients are treated (up to) 24h per session. Previous studies (see ESICM 2018) reported on haemodynamic effects of connection and disconnection as well as ultrafiltration (ISICEM 2019) during 8h-treatment sessions.
OBJECTIVES. This study reports on haemodynamic effects of 24h-treatment periods primarily aimed at CO2-elimination and/or high volume ultrafiltration.
METHODS. Transpulmonary thermodilution with the PiCCO-device (Pulsion; Germany) was performed immediately before and after connection (T1, T2) with the ADVOS-device and disconnection (T3; T4). The tubing was prefilled with 0.9% saline ("acute connection"). Connection, ADVOS-treatment and disconnection were performed with a blood flow of 100mL/min. Concentrate flow was 160mL/min. The vasopressor dosages were kept stable.
RESULTS. We analyzed 20 treatment sessions with a treatment-goal of 24h in 4 patients. Patients (2m; 2f), 49±14 years, APACHE-II-score 24±4, aetiology: 1 alcoholic cirrhosis, 1 non-alcoholic steato-hepatitis, 2 MOF; mechanical ventilation 20/20 (100%) treatments. Mean treatment time was 21±3h. Five of the sessions had to be terminated early (after 12h-19h) due to clotting or organizational reasons (scheduled diagnostic or therapeutic procedures outside the ICU). Net ultrafiltration was not significantly different from the pre-set ultrafiltration goal (3325±2444 vs. 3818±2508mL; p=0.182). 12 sessions were performed for high-volume ultrafiltration ≥4000mL. Also for these sessions the net ultrafiltration was not different from the pre-defined ultrafiltration goal (4621±1550 vs. 5333±778mL; p=0.139), although three of the treatments were stopped early after 15-18h.
Over up to 24h, ADVOS-therapy did not result in significant changes in heart rate (94±16 vs. 94±13/min; p=0.766), MAP (82±11 vs. 76±13mmHg; p=0.), CVP 29±9 vs. 27±9mmHg; p=0.482), SVRI 1016±297 vs. 1017±368 dyne/cm2/m4; p=0.123), dPmax (1798±727 vs. 1669±557mmHg/s; p=0.374), global end-diastolic volume index GEDVI 760±128 vs. 736±92mL/m^2; p=0.515), stroke volume variation SVV (8±3 vs. 9±6%; p=0.541), CI (4.2±0.6 vs. 4.1±0.4L/min/m^2; p=0.515), global ejection fraction GEF (29±3 vs. 29±4%; p=0.673), pulmonary vascular permeability index PVPI (2.3±0.6 vs. 2.0±0.6; p=0.068) and cardiac power index CPI (0.73±017 vs. 0.70±0.16W/m^2; p=0.493) after disconnection (T4) vs. before connection (T1). Only extravascular lung water index EVLWI slightly increased (13.7±4.8 vs. 12.1±4.9mL/kg; p=0.041). The noradrenaline dosage was comparable after (T4) vs. before connection (T1; 606±357 vs. 600±278µg; p=1.000).
CONCLUSION. 24h-treatment with high-volume ultrafiltration and/or CO2-elimination with the ADVOS-device were haemodynamically well tolerated.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001229

INTRODUCTION. Laser Speckle Contrast Imaging (LSCI) and Laser Doppler Imaging (LDI) are non-contact real-time monitoring techniques used to assess the microvascular blood flow of tissue surfaces [1]. These two techniques measure the microcirculation of different skin depth. The LSCI is used to evaluate the skin at a depth of 300 µm whereas LDI can evaluate the depth at 1-1.5 mm [2]. Measurement of different skin

depths becomes a critical step in the management of some clinical states as occurs in burn-injured patients. Currently, LDI is the most widely used and validated noninvasive technique for the assessment of burn wounds [3]. However, LDI device is rather costly, cumbersome and has a poor spatial resolution. LSCI measures perfusion in a similar way, but it provides high-quality images with a much higher spatial resolution. Moreover, the use of LSCI is much easier than using LDI [4].
OBJECTIVES. In this study, we sought to test the linearity of the LSCI device and LDI device, and assess if these two techniques can be used interchangeably.
METHODS. Fifteen healthy, non-smoker volunteers participated in the study. Iontophoresis technique with sodium nitroprusside was performed as a provocation test on the skin of the forearm. All volunteers were measured using LSCI (Perimed AB, Jarfalla, Sweden) and LDI (Moor Instruments, Devon, UK) devices at baseline and then consecutively after initiating the iontophoresis test by. Microcirculatory blood flow was analyzed by the software PIMsoft 1.5 (Perimed AB, Järfälla, Sweden) and MoorLDI2-BI Software Version 4.0. The units of each technique were reported as arbitrary units. Spearman correlation and linear regression were used to compare the values.
RESULTS. The baseline microcirculatory blood flow was 61 AU (IQR, 51-70 AU) and 34 AU (IQR, 28-37 AU) using LDI and LSCI devices, respectively. Coefficient of variance (CV) was similar within two devices (CVLDI:19% and CVLSCI: 19.8%). An excellent correlation was detected between the two LSCI devices (R2:0.88, p<0.001) (Figure-1).
CONCLUSION. Skin blood flux measured with Perimed LSCI and Moor LDI are highly correlated with each other. The higher resolution and considerably faster scan time of LSCI technique may provide an advantage if used instead of the LDI technique.

INTRODUCTION. Veno-arterial extracorporeal membrane oxygenation (VA-ECMO) is an advanced treatment for refractory cardiogenic shock (CS) and cardiac arrest (CA). VA-ECMO is used as bridge to recovery, cardiac transplantation or ventricular assist device (VAD). Successful weaning from VA-ECMO is defined as device removal without further requirement for re-cannulation over the following 30 days. There are few data available regarding timing and reliable parameters for the VA-ECMO weaning. Total isovolumic time (t-IVT) is a Pulse Wave Doppler established echocardiographic parameter of systo-diastolic interaction and ventricular efficacy (1). Along with MAPSE (mitral annular systolic plane excursion), it showed to be the most sensitive echocardiographic marker of haemodynamic profile in patients with cardiogenic shock.
OBJECTIVES. To evaluate which echocardiographic parameters are able to predict successful VA-ECMO weaning.
METHODS. Single-center retrospective observational study of patients with refractory CS and CA who underwent VA-ECMO insertion from January 2013 to December 2017. Demographic, clinical, echocardiographic and outcome data were collected. Primary endpoint was to test the predictive power of echocardiographic indices for VA-ECMO weaning. We measured left ventricular (LV) t-IVT, MAPSE (calculated as mean of septal, lateral, anterior and inferior values), ejection fraction (EF), Echo-derived stroke volume (SV) and cardiac output (CO). Data analysed: time of cannulation (t0), during the first weaning trial after 48 hours (t1) and, in those who survived, at last trial before decannulation (t2).
RESULTS. Preliminary results of 46 patients (76% male; 52±12.5 y.o.) underwent VA-ECMO cannulation. 21 (44.6%) patients died within 24 hours; 19 of them had CA. 25 patients undertook weaning trial: 18 were weaned (72%; 39% overall population) and 14 (56%; 30% overall population) were discharged alive from ICU. At time of cannulation, patients successfully weaned form VA-ECMO had shorter t-IVT (23.12 vs 33.6 sec/min, p<0.001) and greater MAPSE (5.82 vs 4.83 mm, p<0.05), SV (15.11 vs 10.42 mL, p<0.05), CO (1.36 vs 0.91 L/min, p<0.05) and EF (11.4 vs 9.04, p<0.05); heart rate between two groups was not significantly different (84.7 vs 95.4, p 0.24). In weaned patients, the variations from t0 to t2 of all these parameters (left ventricular t-IVT, MAPSE, SV, CO and EF) were significative, as shown in table 1.
CONCLUSION. The mortality of patients undertaking VA-ECMO remains exceptionally high, especially in patients with refractory cardiac arrest. Amongst all the echocardiographic parameters tested, t-IVT at the baseline was the strongest predictor of VA-ECMO weaning.

The volume of the aorta: a neglected confounding variable in transpulmonary thermodilution

A. Akohov[1], C. Barner[1], S. Grimmer[1], R. Francis[1], S. Wolf[2]
[1]Anesthesiology, Charite University Medicine, Berlin, Germany; [2]Neurosurgery, Charite University Medicine, Berlin, Germany

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001257

INTRODUCTION. Global end-diastolic volume (GEDV) derived by transpulmonary thermodilution is regarded as indicator of cardiac preload. The thermistor catheter required for measurements is usually placed in a femoral artery. A bolus of cold saline injected in a central vein travels through the right heart, arterial and venous vessels of the lung, the left heart, and finally the aorta until detection. Surprisingly, the latter is not considered in the theoretical framework of transpulmonary thermodilution (1).
OBJECTIVES. to investigate the impact of the aortic volume on measurements of GEDV.
METHODS. We screened our database of patients with transpulmonary thermodilution monitoring for subjects having additionally received a contrast-enhanced thoraco-abdominal computed tomography (CT) scan. From the CT scan we calculated the volume of the aorta, using the aortic valve and the tip of the thermodilution catheter as

longitudinal boundaries. The aortic volume was then compared to the GEDV measurement closest in temporal proximity.
RESULTS. 88 patients with 103 CT scans were identified. Median aortic volume was 193.78 ml (IQR: 147.15-248.92 ml). Median GEDV was 1305.67 ml (IQR: 1104-1568.77 ml). Average time difference between CT and GEDV measurement was 2 hours (IQR: 1-5 hours). GEDV increased linearly by 2.9 ml (95% CI: 1.8 to 4 ml, $p < 0.001$) per ml of aortic volume. The variance of thermodilution-derived GEDV explained by aortic volume was 59.3 % ($p < 0.001$), without significant further relationships to sex, age, body height or weight.
CONCLUSION. We provide evidence that the aortic volume is the main source of variance of GEDV in patients measured by single-indicator transpulmonary thermodilution, thus representing a so far unrecognized confounder. Our findings challenge the view of GEDV as preload indicator. In consequence, guiding clinical volume therapy by reference ranges of raw or indexed GEDV may be misleading.

INTRODUCTION. Mean systemic filling pressure (Pmsf) correlates with intravascular volume. Bedside estimation of Pmsf has been described in critically ill patients by three methods(1). Pmsf along with other haemodynamic variables can provide valuable information to correctly understand the cardiovascular status of critically ill patients, and their performance before and after passive leg raising (2), can facilitate the understanding of venus return (3).
OBJECTIVES. To determine the grade of correlation beween Pmsf and other haemodinamic variables during passive leg raising test (PLRt).
METHODS. observational, retrospective, cross-sectional and descriptive study in patients with continuous hemodynamic monitoring during a shock state. Pmsf analogue (4)value before and after a Passive Leg Raising test was analyzed.
RESULTS. 62 simultaneous measurements of CO, CVP and MAP were performed, Pmsf was calculated before and after a PLRt. Correlation between Pmsf and CO was Pearson's $R = 0.6064$ ($p \leq 0.00001$) that indicate a moderate to strong relationship between both variables, that support that increases in ΔPmsf will produce increases in ΔCO during PLR (and viceversa). However, Pearson's $R = 0.2486$ ($p = 0.0513$), that indicates a poor relationship between both ΔPsma and final CO (after PLRt). Correlation between CVP and CO was Pearson's $R = 0.34562$ with $p = 0.005831$, although technically a positive correlation, the relationship between ΔCVP and ΔCO is pretty low.
CONCLUSION. We found a significative positive correlation between ΔPmsf and ΔCO, but there was not significative correlation between ΔPVC and ΔCO. ΔPmsf can be useful as a volumen response indicator in selected patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000662

INTRODUCTION. Cardiac arrest (CA) is a leading cause of mortality annually in the USA and Europe. The relationship between socioeconomic status and various components of health is well established.
OBJECTIVES. The aim of this study was to investigate the relationship between socioeconomic factors and outcomes following admission to intensive care with cardiac arrest, both in hospital cardiac arrest (IHCA) and out of hospital cardiac arrest (OHCA) using deprivation measures calculated on the basis of domicile postcodes.
METHODS. All cardiac arrest cases admitted to our regional intensive care unit in South West Wales, UK between January 2007 and June 2018 were included in this analysis. Data included age, gender, domiciliary postcode, comorbidities, length of stay, follow-up time and survival status. The Welsh Index of Multiple Deprivation, 2014 (WIMD) was used to stratify cases by level of social deprivation according to domiciliary postcodes. Outcomes were investigated using multivariate regression modelling.
RESULTS. Of the 1034 (532OHCA and 502 IHCA) patients included in the study, 679 patients were deemed 'less deprived' while 355 patients 'more deprived' according to established definitions. Compared to their 'more deprived' counterparts, patients who were 'less deprived' were older on admission, 66.2 vs 62.1 ($p<0.001$) and predominantly male (473 vs 205, $p<0.001$). There were no differences at 7 and 30 days in terms of mortality, $p=0.62$ and $p=0.26$ respectively.
In the OHCA cohort, being 'more deprived' showed strong and independent correlations with mortality within the first year after admission to ICU [All: OR 1.71 (95% CI 1.14-2.61), IHCA: OR 1.81 (95% CI: 1.19 – 2.76), OHCA: OR 3.26 (95%CI: 2.12-5.07)]. Conversely, in the IHCA cohort social deprivation was not a risk factor one-year post admission to ICU.
CONCLUSION. This is the first study in which social deprivation has been investigated as a risk factor for death following admission to ICU with cardiac arrest in South West of Wales. Residing in a 'more deprived' area in South West Wales following admission an OHCA is associated with an increased risk of death compared to IHCA following one year after admission to ICU.

INTRODUCTION. There is a dearth of literature reporting cost analysis of patients admitted to intensive care unit (ICU) post out of hospital cardiac arrest especially within the UK. This is essential for assessment of cost-effectiveness of interventions necessary to allow just allocation of resources within the National Health Service.
OBJECTIVES. We aimed at performing a cost analysis of ICU stay as well as hospital stay in both in hospital (IHCA) and out of hospital (OOHCA) cardiac arrest patients admitted to ICU.
METHODS. This is a single centre retrospective observational review of Wardwatcher database. All post cardiac arrest patients admitted to a tertiary referral ICU from January 2007 until December 2017 is included. The cardiac arrest patients were grouped as out of hospital cardiac arrest (OHCA) and in hospital cardiac arrest (IHCA).
RESULTS. Of 965 consecutive patients admitted 475 were in OHCA group and 490 in IHCA group. The Trust finance department supplied ICU and hospital costs. Estimated cost of an ICU bed was £1159.00 and estimated cost of a ward bed was £327.00 according to the NHS reference costs data 2017-18. Of those patients with return of spontaneous circulation (ROSC) admitted to ICU, survival to hospital discharge in OHCA was 37% while IHCA was 35% survivors at hospital discharge. Mean length of days on mechanical ventilation was higher in the IHCA group compared to the OHCA (5.3 vs 5.1 days, $p=0.006$). Similarly mean length of ICU stay was longer in the OHCA as compared to IHCA (6.8 vs 8.4 days, $p= 0.004$) as well as mean length of total stay in hospital was longer in the OHCA as compared to IHCA (16.7 vs 15.0 days, $p= 0.03$). Total in-hospital costs was significantly higher in OHCA compared to IHCA (£12,796 vs £10,825, $p=0.02$).
CONCLUSION. The costs of in-hospital patient care and mean total length of stay in hospital for ICU admissions following ROSC after OHCA are significantly higher than those of IHCA. This might be due to the fact that OHCA patients have a longer stay in ICU compared to IHCA.

INTRODUCTION. It was demonstrated by several studies that patients admitted to hospitals on weekends have a higher mortality rate. The reasons might be multifactorial and may be limited to certain diagnostic groups and admission subtypes.
OBJECTIVES. We aimed at investigating whether the outcomes of cardiac arrest patients, both in-hospital (IHCA) and out-of-hospital (OHCA) differed between weekday and weekend admissions at our intensive care unit (ICU).
METHODS. This is a single centre retrospective observational study. The database WardWatcher is widely used in United Kingdom (UK) ICU's and the data was collected from this. Cardiac arrest patients who were admitted between January 2007 to July 2018 to a tertiary ICU were included. Death in ICU and death in hospital were used as outcome measure. Logistic regression was used to adjust for potential confounding factors.
RESULTS. Of the 1034 patients admitted with cardiac arrest, 629 patients were admitted on a weekday while 405 patients on a weekend. Patients admitted on weekday were older, 65.6 vs 63.5 years old, ($P<0.0001$), had worse creatinine function, 172.7 vs 167.2 ($P< 0.0001$). No significant differences in outcome were found between weekday and weekend admissions in rates of death in ITU and death in hospital ($P= 0.89$ and $P = 0.61$, respectively) even after adjusting for possible confounding factors.
CONCLUSION. The rate of survival to hospital discharge was similar for patients admitted with cardiac arrest on a weekday or weekend even after adjusting for many potentially confounding factors. This study demonstrates that increased mortality rates during weekend admission is limited to certain diagnostic groups and admission subtypes.

INTRODUCTION. Relationship between poverty and worse health outcomes is well established. However, studies examined the association between poverty and mortality among critically ill patients and results were contradictory. Yet, previous studies were conducted with sample size of few selected hospitals. In this study, we evaluated the association between poverty and outcomes including in-hospital mortality, re-admission of intensive care unit (ICU) and emergency room (ER) visit after discharge using national health insurance data.
METHODS. This is a retrospective cohort study using the national database from Health Insurance Review and Assessment (HIRA). We identified 1,657,218 patients who were 18 years of age or older, who had a first ICU admission between January 1, 2008 and May 31, 2015 and who was not being poor poverty status during inpatient. Poverty was defined when patients were Medical Aid beneficiaries. We used logistic regression and cox regression to evaluate risk of in-hospital death, re-admission, and ER visit among people with poverty compared to people without poverty.
RESULTS. Of total, 11.0% (n=182,091 patients) were patients with poverty. People with poverty were more likely to be female (50.7% vs. 42.2%), had more co-morbidities, and were more likely to be admitted to lower quality hospitals compared to patients without poverty. In -hospital mortality rate among patients with poverty was higher (16.5 %) than patients without poverty (12.2 %). The adjusted OR for in-hospital mortality associated with poverty was 1.20 (95% CI 1.18-1.22) and it remained significant even after matching hospital (OR 1.10; 95% CI 1.09-1.12). Among patients who were discharged without death (n= 1,411,008), patients with poverty were more likely to have re-admissions to ICU (fully-adjusted HR 1.26; 95% CI 1.23, 1.29) and ER visits (fully-adjusted HR 1.28; 95% CI 1.25, 1.32) within a year after discharge compared to patients without poverty.
CONCLUSION. Poverty was associated with an increased risk of in-hospital mortality, re-admission to ICU, and ER visits after discharge from ICU. The association was consistent even after controlling quality of hospital. It would be necessary to find out factors associated with worse outcomes among patients with poverty at ICU and ways to intervene them.

Acuity of Patient Condition Has No Affect on Critically Ill or Injured Adult Patient and Surrogate Decision Maker Opinions of Research

J. Raddatz[1], LA. Sealey[2], KW. Cunningham[3], NR. Shah[3], A. Zykova[3], MR. Nahouraii[3], CA. Becker[4], SL. Davis[4], SL. Evans[3], T. Huynh[3]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000688

INTRODUCTION. Research in the critically ill and injured population often requires time-sensitive enrollment when patients and their families are focused on making important clinical care decisions. Patients with chronic medical conditions may have the opportunity to contemplate clinical choices, and as such more readily consider participation in research trials.
OBJECTIVES. To examine if the acuity of illness correlates with patient's or surrogate decision-maker's opinions informing research participation.
METHODS. Study participants were identified by admission >24 hours to an intensive care unit (ICU) at an urban tertiary hospital. Decision makers were approached to complete an anonymous electronic survey between 3-7 days following ICU admission. Only the person providing informed consent at the time of survey was asked to participate. Surveys consisted of closed-ended questions and took 5-15 minutes to complete. A full waiver of consent was granted by the IRB. Standard statistical techniques were used for analysis.
RESULTS. There were a total of 674 subjects, of which 335 were critically ill or injured, and 339 were surrogate decision makers. Subjects completed surveys from April 2018 to January 2019. Participants were stratified as being admitted to the ICU for either an acute (372) or chronic (302) condition. There was no difference in mean age (56.8, 59.3), gender (60.8% and 60.6% male), or race of patients among the groups. Acute (68.7%) and chronic (71.9%) subjects were equally as open to consider participating in a research study. Acute (43.7%) and chronic (41.7%) subjects also had similar, but reduced interest ($p<0.001$) in co-enrolling in multiple research studies. Furthermore, both groups were equally more interested ($p<0.001$) in participating in a research study if it may potentially benefit the patient directly (79.3%, 78.8%) vs. benefiting others (57.4%, 56.6%).
CONCLUSION. Acuity of illness does not affect decision makers' opinions of research. Critically ill and injured patients and their surrogate decision makers are collectively more open to considering one research study vs. multiple research studies, suggesting that investigators should prioritize research in a manner that reduces participant burden. Further, such prioritization may include potential direct benefit to study participants. Researchers should not approach patients with acute vs. chronic conditions differently regarding research participation.

Daily Ultrasound-screening for Central Venous Catheter-related Thrombosis (DUCT) in the Critically Ill-patients: a Multicenter Prospective Study

W. Chunshuang, L. Shaoyun, Z. Mao
Department of emergency medicine, 2nd Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, China
Correspondence: Z. Mao
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000694

INTRODUCTION. Central venous catheters (CVCs) are frequently used in intensive care units (ICUs) for variety of indications. CVC-related thrombosis (CRT) is a potentially serious complication and may contribute to some adverse effects, including pulmonary embolism, CVC dysfunction, infection or loss of central venous access [1]. Preliminary observation studies showed that CRT was mostly asymptomatic, and the incidence was not low. However, there is a lack of medical literature about the incidence and characteristics of CRT in ICU [2,3].
OBJECTIVES. This is a multi-center, large-sample prospective study to identify the incidence, occurrence time, risk factors, treatment of CRT and outcome in ICU patients, so as to provide a basis for further optimization of CRT screening protocol and prevention.
METHODS. We prospectively included patients with CVCs and collected patient characteristics in 28 Chinese ICUs during 9-month study period. Compression test and duplex Doppler ultrasound screening of catheter-veins were systematically performed prior to insertion, 12h after insertion, and then, daily until removal of CVC or patient discharge. In addition, CVC characteristics, catheterization, CRT characteristics, treatment and complications of CRT were also daily recorded.
RESULTS. There were 1479 CVCs placed during the study period in 1357 subjects. Of these, 740 (50.03%) were inserted into the internal jugular veins, 413 (27.92%) in the subclavian veins, 297 (20.08%) in femoral vein, and 29 (1.97%) in axillary vein. The incidence of CVC-related thrombosis was 15.28% (n=226). Univariate and multivariate analysis demonstrated that CRT is associated with the major diagnosis, ICU length of stay, place of catheterization, length of catheterization, and the catheterization location ($p\leq0.001$). Notably, thrombosis can occur at any time from the first day after insertion to 3 days after removal, with a median of 4 days (IQR, 2-7). 88.94% of thrombosis occurred within a week after insertion. 77.43% of CVCs with CRT injected blood or blood products. In addition, the treatments of CRT were uniformity. Of these, 21.90% of patients with CRT are treated with anticoagulation, but the type, dose and duration of drugs were highly variable. 19.91% of CVCs with CRT were removed immediately, and the rest were no interventions for the thrombosis (Table 1).
CONCLUSION. Central venous catheters-related thrombosis is a relatively common complication in ICU. It is most associated with the major diagnosis, ICU length of stay, place of catheterization, length of catheterization, and the catheterization location. It may occur at any time after catheterization. Thus, a protocol of routine ultrasound screening for CRT after CVC needs to be developed.

Risk Factors for Failing Bridge Therapy with High Flow Nasal Cannula During Weaning of Invasive Mechanical Ventilation

K. Carvajal-Canizales[1], S. Cardona-Marín[1], LP. Sua[2], S. Garay[2], V. Ortiz-Perez[3], I. Chezzi-Guerra[3], P. Marcela[1], R. Buitrago[1], LF. Reyes[4]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000700

INTRODUCTION. Up to 2/3 of patients admitted to the intensive care unit (ICU) will develop acute respiratory failure (ARF) during their hospitalization, and thus, will require ventilatory support. Invasive mechanical ventilation (IMV) is the most frequently used ventilatory support strategy in the ICU. Once patients achieve clinical stability, clinicians face an important challenge when attempting ventilatory weaning; because around 13% of patients will need re-intubation, which increases morbidity and mortality. High Flow Nasal Cannula (HFNC) is a recently introduced ventilatory strategy used in patients with hypoxemic ventilatory failure. HFNC has been successfully used as initial ventilatory support and for weaning in several studies. Whereas bridge therapy with HFNC is a proved strategy, many patients will still require re-intubation within the first 48 hours of extubation; and risk factors for HFNC failure are controversial. Therefore, the goal of this study is to identify risk factors that could predict extubation failure in spite of using HFNC.
OBJECTIVES. To determine the risk factors associated with High Flow Nasal Cannula (HFNC) treatment failure during ventilatory weaning.
METHODS. This is a 2-year retrospective observational cohort study conducted in a hospital in Bogota, Colombia; between January 2016 and June 2018. All adult patients receiving IMV for more than 12 hours, who were posteriorly extubated and treated with HFNC as bridge therapy were included. HFNC failure was defined as the need for non-invasive mechanical ventilation (NIMV) or re-intubation within 48 hours after extubation. Difficult weaning group was defined as patients who had fail the extubation process or did not pass weaning tests. Descriptive statistics, parametric, non-parametric and logistic regressions were used to determine risk factors for HFNC failure. All statistical analyzes were performed using IBM SPSS statistics, version 22.0 Armonk, NY: IBM Crop.
RESULTS. A total of 109 patients were included in the study. 23 (21.1%) patients developed HFNC failure after weaning of IMV. As expected, patients who require vasopressors during ICU admission (52.2% Vs 10.5%, p=<0.01) and inotropes (34.8% Vs 10.5%, p=0.01) were more likely to present HFNC failure. Patients who fail HFNC were most likely to be in the difficult weaning group (60.9% Vs 30.2%, p=<0.01) and had higher respiratory rate before extubation (Median, Interquartile Range; 22 breaths per minute (BPM) [IQR 18-25] Vs 18 BPM [IQR 16-21], p=0.04). No differences were found among groups regarding gasometrical variables prior extubation, days of mechanical ventilation, ICU length of stay nor ICU mortality.
CONCLUSION. Bridge therapy with HFNC is a safe method for ventilatory weaning. We have identified 2 novel risk factors (weaning type and higher respiratory rate) that were independently associated with HFNC failure. Further studies are needed to confirm these findings.

Bariatric surgery and utilisation of critical care resources: a 12 year experience

J. Green[1], N. Daines[1], K. Fraser[1], C. Pring[2], M. Margarson[1]
[1]Department of Anaesthetsia and Critical Care, St Richard's Hospital, Chichester, United Kingdom; [2]Department of surgery, St Richard's Hospital, Chichester, United Kingdom

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000709

INTRODUCTION. Morbidly obese patients attending for bariatric surgery are at increased risk of complications in the peri-operative period due their associated medical co-morbidities (1) (2). Our NHS hospital has performed over 4,000 bariatric surgical procedures since the service started 12 years ago and we sought to analyse the impact that this has had on critical care.
OBJECTIVES. - To identify what proportion of all bariatric cases were admitted to the intensive care unit, along with details surrounding the support required and overall outcome.
- To compare these details to the total ICU workload and thereby demonstrate the overall impact on the service.
METHODS. We have maintained a single site bariatric anaesthesia airway database since 2006, which was checked for completeness by cross-referencing against Hospital Episode Statistics surgical codes. This was then matched against an ICU dataset of all admissions under the names of the four surgeons who admitted all bariatric surgery performed between 2007 and 2018. Cases admitted following primary bariatric surgery, or procedures related to any previous bariatric surgery, were included. Cases were individually reviewed to verify that they were genuinely associated with the inclusion criteria. Key parameters of interest including type of admission, system and level of organ support, duration of that support and the final outcome were obtained.
RESULTS. Over a 12 year period, out of a total of 4405 bariatric procedures, a cohort of 193 (4.4%) patients required admission. These cases utilised 533 bed days which accounted for 1.51% of all ICU bed days in the same period. 36 (19%) of this cohort received level 3, i.e. advanced ICU support, which utilised 0.78% of all ICU level 3 bed days in that period. 81% were level 2 only (HDU) and utilised 2.44% of all level 2 bed days. 53% were planned admissions, 32% emergency surgery and 15% were admitted from wards. APACHE II predicted 30 day mortality was 10.2 deaths; the actual was 6, giving a standardised mortality ratio of 0.59. In 2011 a new model of multi-disciplinary pre-assessment was introduced where all patients were screened by a team involving anaesthetic input before surgery was offered. Since that change, our rate of admission of level 3 patients has seen a six-fold reduction.
CONCLUSION. A mature Bariatric service is responsible for a small proportion of the overall workload in our intensive care unit, between 0.5 and 1% annually. Patients who are admitted tend to be older, predominantly male and lengths of stay are usually very short. Critical care units in a centre that is to introduce such a service may find an initial higher workload, but with agreed and sensible pre-assessment pathways the number of patients requiring advanced ICU support will be very low.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000711

INTRODUCTION. Little is known about the prevalence of critically ill patient-surrogate discordance for treatment goals in the moment, or about the clinical implications of this discordance. In a recent multicenter RCT testing a web-based personalized decision aid (DA) for surrogates of prolonged mechanical ventilation patients, the DA displayed the goal of treatment most concordant with patient values based on surrogates' reports of patient preferences.1 The unique design of the DA captured intervention surrogates' adjustment of the calculated goal of treatment option on their digital device at the moment of decision making.
OBJECTIVES. To identify characteristics of surrogates who chose discordant treatment goals and to determine the impact on patient outcomes of surrogate decisions that appeared discordant from patient preferences.
METHODS. 276 participants including all 138 primary decision makers and 138 patients ventilated for ≥10 days from the RCT's decision aid intervention group. We used chi square and t-tests to compare baseline and 1-week surrogate (Hospital Anxiety and Depression Scale, PTSS, clinician-surrogate prognostic concordance score) as well as patient outcomes (days of ventilation, ICU care, hospitalization; 6-month mortality) by decisional groups (surrogate-patient decisional discordance vs. surrogate-patient decisional concordance).
RESULTS. Of 129 (93%) surrogates witht complete data, 56 (43%) chose a goal of care that was discordant overall with patient preferences. 20 (11%) were markedly different than patient preferences (i.e., change among the three main choices [comfort, aim for survival but avoid prolonged care, aggressive care). 55 (98%) discordant decisions were related to a desire for more aggressive care than patients preferred.
We found no statistically significant associations between decisional discordance and either surrogate characteristics (age, race, gender, education, medical comprehension, employment, relation to patient, religion, distress level, amount of decisional conflict) or patient (demographics, APACHE II, diagnosis, comorbidities, medical vs. surgical ICU) factors (p >0.05).
Compared to concordant dyads, discordance was not associated with differences at 1 week in change in either prognostic discordance with physicians or symptoms of distress (depression / anxiety / PTSD symptoms; all p >0.05). Compared to concordant patients, discordant patients had numerically greater mean days of ventilation (18.0 [31.6] vs. 13.9 [15.5]), ICU care (23.2 [33.2] vs. 18.7 [16.3]), and hospitalization (45.6 [36.4] vs. 41.3 [27.8])—though identical 6-month mortality (39.3% vs. 37.0%); all p <0.05.
CONCLUSION. Surrogates commonly make goals of care decisions that are discordant with patient preferences they themselves report, yet we identified no characteristics that separated them from concordant surrogates. Patients linked to discordant surrogates had

longer use of life support and greater resource utilization, though no improvement in mortality compared to concordant patients. These exploratory findings suggest that it may be particularly important to focus future palliative care and decision support interventions on surrogate decision makers who choose goals of care that are not aligned with patient preferences.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000718

INTRODUCTION. Though ultrasonography (USG) guided central venous catheter (CVC) insertion has been advocated by critical care societies and hospitals, it has still not become the norm in 'real life' scenario in the ICUs. Lack of training in use, ability to handle, and availability of USG machines have been demonstrated to be the reasons for the same.

OBJECTIVES. We conducted a survey to assess the use of USG during CVC insertion.

METHODS. A survey comprising 10 questions was designed and mailed electronically to 386 physicians working in various ICU in our district. The questionnaire comprised queries regarding aspects of USG training, use and opinion of USG during/after CVC insertion and frequency of use, need for further training, etc.

RESULTS. Of the 190 questionnaires returned, 60% were consultant physicians, while 40% were residents. 28% were working in rural locations. About 56% of doctors reported training in the use of USG, while 46% used it routinely for CVC insertion (always 30%, almost always 66%).

The main reasons for non-use of USG during CVC insertion were i) lack of adequate training (50%), ii) no need of USG guidance during CVC insertion (54%), iii)landmark technique equally good for CVC insertion (61%),iv) other nonspecified reason (8%).

All respondents thought that landmark technique should be taught to trainee doctors.

Almost all resident doctors (96%) as compared to seniors declared that they use USG (always, almost always) for CVC insertion.

CONCLUSION. Despite various guidelines and studies demonstrating superiority of USG guidance during CVC insertion, its use is still not widespread and enough. Training and use of USG needs major improvement amongst the ICU doctors in our district.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000721

INTRODUCTION. Many patients admitted to ICU require a prolonged stay in an intensive care unit (ICU) as they recover from their critical illness. These patients have been reported to have increased mortality and morbidity.

OBJECTIVES. To study the incidence, characteristics and outcomes of prolonged stay critically ill patients admitted to our ICU.

METHODS. Retrospective analysis of patients admitted to our adult ICU (Total- 40 bedded; 20 bed medical plus cardiac ICU, 20 bed surgical ICU) during last 2 years. All patients with ICU stay > 21 days (due to mechanical ventilation and/or for hemodynamic monitoring) were included in the study. Prolonged stay critically ill patients were classified according to their location in ICU and reason for ICU admission, as medical or surgical prolonged stay critically ill patients. The main endpoints of the study were ICU and hospital length of stay (LOS), and mortality.

RESULTS. Of the total 1097 patients admitted to the ICU during the period of study, 67 patients were included in the study, for an incidence of 6.1% (Medical patients- 4.6%; Surgical patients- 7.9%). The most common diseases at ICU admission were stroke and neuromuscular disease in medical patients and intestinal diseases (obstruction or perforation) in surgical patients. Mean APACHE II score on admission in the medical and surgical patients were 17 (IQR 11-25) and 19 (IQR 14-28) (p=0.88). There was no significant difference in age, gender, tracheostomy, use of mechanical ventilation and vasopressors between the two groups of patients (p> 0.05 for all). Surgical prolonged stay critically ill patients had more episodes of hospital acquired infections as compared to medical prolonged stay critically ill patients (p<0.05).

Mean LOS in ICU for medical and surgical prolonged stay critically ill patients were 26.6 and 33.6 days, respectively (p< 0.001). Mean LOS in hospital for medical and surgical prolonged stay critically ill patients was 28.5 and 39.2 days, respectively (p< 0.001). The mortality for medical and surgical prolonged stay critically ill patients was 50% and 44%, respectively (p=0.08).

CONCLUSION. A small component of critically ill patients admitted to ICU will turn into prolonged stay critically ill patients, requiring ICU care for a longer period of time. Prolonged stay critically ill patients due to surgical indications for admission to ICU have more hospital acquired infections, longer ICU and hospital LOS but no significant increase in mortality as compared to prolonged stay critically ill patients due to medical indications for admission to ICU. More and larger studies are required to further analyse prolonged stay critically ill patients.

Feasibility and safety of bedside watershed-detection by contrast-enhanced ultrasound in patients receiving veno-arterial extracorporeal membrane oxygenation

N. Buchtele[1], M. Schwameis[2], C. Schörgenhofer[1], P. Schellongowski[3], C. Weiser[2], A. Spiel[2], T. Staudinger[3]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000723

INTRODUCTION. In veno-arterial extracorporeal membrane oxygenation (VA ECMO) with femoro-femoral cannulation the watershed is the location where retrograde ECMO-perfusion and antegrade cardiac perfusion encounter (figure 1). To date, angiography or contrast enhanced computed tomography is the only available method to determine the watershed location, which has only been described in several case reports (1-3).
OBJECTIVES. We hypothesized that contrast-enhanced ultrasound is a suitable method to detect the watershed at the bedside and examined its feasibility and safety.
METHODS. This prospective study included consecutive adult patients undergoing emergency femoro-femoral VA ECMO cannulation. The primary outcome measure was the feasibility of contrast-enhanced ultrasound for bedside detection of the watershed. The Secondary outcome was the safety of the procedure.
1ml of contrast media (Sonovue) was administered via the venous drainage ECMO cannula while transabdominal and transesophageal ultrasound was performed to concurrently display the abdominal and the thoracic aorta. Application of contrast media was repeated until the watershed was detected or the maximum volume of 4ml was reached.
Safety values obtained included hemodynamic values (mean arterial pressure, mmHg; heart rate, bpm; SpO2, %; paO2, mmHg; left and right if applicable; paCO2, mmHg), respirator settings (FiO2, %; peak pressure, mbar; tidal volume, ml), neurologic assessment (examination of pupils and computed tomography imaging of the brain if appropriate) and ECMO settings (FiO2, %; sweep gas flow, l/min; pump speed, rpm; blood flow, l/min). Patients were assessed for safety parameters as well as ventilatory demand, hemodynamic instability, arrhythmias, anaphylactic reactions or death at baseline, 5min, 15min, 2h and 6h after contrast media administration. Patients were followed up until hospital discharge or death.
RESULTS. Between October 2018 and February 2019 10 patients (90% male, mean age 52 years) were enrolled at three intensive care units at the Medical University of Vienna. The watershed was detected in the abdominal aorta in five patients (figure 2). In the remaining patients continuous blood flow was visible in all examined areas, suggesting the watershed located at the level of the aortic arch. No adverse events in close temporal relationship to contrast media administration were observed.
CONCLUSION. Contrast-enhanced ultrasound appears to be a technically feasible and safe method to determine the location of the watershed at the bedside in adult patients on VA ECMO with femoro-femoral cannulation.

Nursing Staff Experience of a Critical Care Rotation Programme

K. Russell
Critical Care, Charing Cross Hospital, London, United Kingdom
Correspondence: K. Russell
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000737

INTRODUCTION. Within healthcare many multidisciplinary teams rotate to gain wider clinical experience, develop skills and promote professional development, however within nursing in the UK rotation programmes are not as widely established. The Department of Health (2001) advocated for the introduction of rotation programmes within Critical Care, as an initiative to increase recruitment and retention. Prior studies looking into rotation programmes found that staff expressed development of their clinical skills and knowledge (Chen *et al.,* 2015; Lawton, 2006), which in turn lead to career development opportunities (Järvi and Uusitalo, 2004; Fujino and Nojima, 2005; Richardson *et al.,* 2003). However, it was also recognised that individuals can find rotating daunting when required to work in an environment or speciality in which they are unfamiliar (Richardson *et al.,* 2003). The purpose of this study was to explore nurses experience of the Critical Care Rotation Programme based in a London Trust.
OBJECTIVES. To explore nurses experience of the Critical Care Rotation Programme, specifically looking at pre-rotation preparedness, the rotation experience and post-rotation reflection.
METHODS. A phenomenological design was used to explore attitudes, experiences and opinions (Parahoo, 2006). An evaluative study was developed in the form a 'service evaluation', whereby ethical approval was sort from the Trust and the researchers University of study. A mixed-methods design was adopted to explore both qualitative and quantitative data; comprising of an electronic questionnaire and semi-structured interviews. Forty-four individuals completed the Critical Care Rotation Programme within 2018 and were invited to participate; 21 (47.7%) electronic questionnaire responses were received. A further 10 participants were interviewed to gain further narrative of their experiences. The data was evaluated using thematical analysis (Braun and Clarke, 2006).
RESULTS. The recognised benefits of the rotation programme included improving clinical knowledge and specialist skills, enhancing interdepartmental teamworking and communication, and the development of global awareness and leadership skills. Day to day support from staff and mentors was highly valued and attributed to an overall better experience. However, apprehensions prior to the rotation where common; which included fears surrounding working in a new environment and team. Disadvantages of the programme largely focused on logistical issues such as issues with security access to the rotation site and an inadequate induction period. Operational issues were reported including patient allocation and limited access to rotation mentors. However, overall all of the participants valued the experience.
CONCLUSION. The evidence from this study suggests that the Critical Care Rotation Programme is a valuable strategy for promoting learning, enhancing interdepartmental relationships which promote cross-site working, and encouraging professional development and career

progression. In order to improve the programme for 2019; a new mentoring strategy has been introduced to provide improved support. There is limited prior research in this area, and due to the small sample included in this study, more research would need to be conducted in the field before conclusions can be drawn to influence general practice.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000751

INTRODUCTION. Early identification of hospitalized patients at risk to develop clinical worsening would reduce the number of preventable deaths and admission at the Intensive Care Unit (ICU).

OBJECTIVES. To implement, in clinical practice, an early alert system based on clinical and laboratory findings aimed at establishing an effective communication between ICU physicians and the wards physicians and to evaluate its usefulness to detect and to prevent the avoidable clinical deterioration in hospitalized patients.

METHODS. Retrospective analysis of the electronic medical charts of patients older than 18 years hospitalized in any medical or surgery ward during the study period (January-December 2018). We collected, within the 6 hours prior to the consultation of the system, the following variables: age, sex, patient location, heart rate (HR) (<40 lpm; >130 lpm), respiratory rate (RR) (< 10 breaths/min;> 30 breaths/min.), systolic blood pressure (SBP) < 85 mmHg, partial oxygen saturation (SaO2)< 85%, pH < 7,30, PaCO2 > 65 mmHg and Lactate > 4 mmol/L. Patient´s charts showing alteration of one or more variables prompt a full evaluation of the clinical chart by the ICU physician and an on-site intervention with treatment reorientation or intensification or immediate transfer to ICU or participation in the decision to life support therapy limitation (LSTL).

RESULTS. 1189 records were evaluated. The mean age of patients was 71 years (SD 2.4), 52.34% were males. The hospital wards where more alerts were detected were the emergency room (n=462; 38%), internal medicine ward (n=396; 32.5%), oncology ward (n=68;5.6%), pneumology ward (n=50;4.1%), surgery (n=34;2.9%), digestive ward (n=35;2.6%), traumatology (n=31; 2.5%) and gynaecology-obstetrics (n=26;2.1%). A single altered variable was detected in 94.2% of the alerts, being the most frequent the SBP< 85mmHg (26.1%),SaO2 < 85%(23%), lactate > 4mmol/L (13%), HR> 130 lpm (12.5%), pCO2 > 65 mmHg (11.4%), RR > 30 breaths/min. (7.6%) and pH < 7.30 (5.12%). Up to 71 patients (5.8%) showed more than two altered variables being the most frequent combination pCO2/Ph (n=31). In-situ evaluation and treatment were done in 167 cases (13.74%), and only 15 patients were considered candidates to immediate admission at ICU (1.25%), being alterations in SBP and in SaO2 the main causes for ICU admission. In the remainder patients an intensification of treatment consisting in the start or adjustment of non-invasive positive pressure ventilation and initiation or intensification of fluids therapy was recommended (67.5%). In up to 5.45% of the patients the consensus decision was to not transfer to the ICU, in up to 12.75% of the patients the patient´s physician had already decided to LSTL.

CONCLUSION. This alert system allowed the early detection of patients at risk of clinical deterioration. Despite it is a consuming-time task for ICU physicians, it allows to participate, together with the patient´s physician, in the optimization of the treatment as well as in the decisions of LSTL ,and reduce the number of admissions at ICU.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000767

INTRODUCTION. Up to 60% of the patients hospitalized in the ICU require ventilatory support, being invasive mechanical ventilation (IMV) the most frequently used therapy. Patients treated with IMV are at risk of developing adverse events such as barotrauma, infections, among others. Re-intubation is needed in 13% of cases, with associated increased morbidity and mortality. Several scores and strategies have been developed to prevent reintubation. However, their efficacy and clinical utility is still being debated. HFNC is a relatively new ventilatory support therapy that allows administration of high-flow (up to 60Lts/min) humidified gas through a nasal cannula with 100% O2. This technology has shown a lower risk of complications (sedation is not required) and provides comfort to patient. HFNC has been successfully used for hypoxemic respiratory failure and during weaning of mechanical ventilation (bridge therapy). Nonetheless, there are some patients that fail HFNC therapy and require re-intubation, but these patients have not been well characterized. The respiratory rate–oxygenation (ROX) index, defined as the ratio of SpO2/FiO2 to respiratory rate, was recently validated to identify patients at risk of HFNC failure in pneumonia patients. Therefore, we hypothesize that ROX Index could accurately predict extubation failure in patients treated with postextubation HFNC.

OBJECTIVES. To investigate the accuracy of ROX Index to identify patients at risk of failing postextubation High-Flow Nasal Cannula (HFNC) therapy in intensive care unit (ICU).

METHODS. This is a 2-year retrospective observational study conducted in a reference hospital in Bogotá, Colombia. All patients in whom postextubation HFNC therapy was used as bridge to extubation were included in the study. The ROX index was calculated prior to HFNC treatment to assess the risk of postextubation HFNC failure. Secondary, we determine whether ROX index could predict ICU mortality. The cohort was stratified among patients who developed HFNC failure to compare patients characteristics and statistical analyses.

RESULTS. A total of 162 mechanical ventilated patients were included in the study, 38 patients developed HFNC failure and 28

patients died during ICU stay. After adjusting for comorbid conditions and diseases severity, ROX index was statistically lower in patients whom fail HFNC therapy (median [IQR], 10.00 [6.78] Vs 12.65 [5.47], p=0.006). However, ROX was not different in patients whom died during ICU stay (11.59 [8.70] Vs 12.37 [5.23], p=0.3).
CONCLUSION. The ROX index is an easy to calculate score that could identify patients at higher risk of HFNC failure during postextubation treatment. A prospective study is needed to confirm the utility of this index in ICU patients treated with HFNC as bridge therapy.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000152

INTRODUCTION. At many intensive care units there is need in training for decision-making for medical staff especially for the novice physicians.
OBJECTIVES. The aim of this study was therefore to develop and implement a training curriculum for novice physicians at intensive care. The training curriculum, which incorporates different medical specialities, aims to increase the physician and patient safety and reliability in decision-making.
METHODS. The present study was carried out in one of the largest German interdisciplinary intensive care and weaning centres, the Klinik Bavaria Kreischa in Saxony.
In the first step a survey was send out to all physician in intensive care to analyse job satisfaction and clinical inconveniencies with medical training.
In the second step a first concept of the training curriculum was developed and then implemented clinically for 6 months, according to principles of the PDCA-cycle (plan, do, check, act). We developed a three-level training curriculum (level A-C). Where the level A is aimed on beginners with a focus on the basics of work in intensive care and aims to achieve the knowledge level for the on-call duty. The level B is aimed on the advanced staff and wants to gain deeper specialist knowledge. The level C is specialised to expand the expertise with the goal of leading the emergency team. Each level includes a theoretical part, practical part and hands-on with medical equipment.
More than 15 months after the pilot-implementation, a follow-up survey was send out. It focused on overall job satisfaction, training in intensive care and preparation and safety and reliability in decision-making.
RESULTS. In the first round 27 physicians were surveyed with a response rate of 86%. Our first survey showed a large range of satisfaction with the training at intensive care. We concluded that there was a need in basic knowledge and technical skills for beginners (level A) and for advanced staff (level B and C) in emergency management.
In December 2018, we surveyed 20 physicians with a response rate of 83%. Although we found only a slightly higher general satisfaction (from 7.03 to 7.56 points out of 10), we showed a statistically significant improvement in the satisfaction of training at intensive care (from 6.62 to 7.19, p <0.001), better preparation for on-call duty (from 5.38 to 7.25, p <0.0031) and a small improvement in reliability and safety during on-call duty (from 6.76 to 7.00).
CONCLUSION. We conclude that our specific training curriculum is very useful for a standardized and routinely training of physicians at intensive care.

Agreement analysis of transcutaneal CO2 partial pressure in neurocritical patients with mechanical ventilation

A. Fuentes Calatayud[1], FA. López[1], LF. Guerrero[2]
[1]Intensive care, University Hospital Complex of Granada, Granada, Spain; [2]Neurocritical and trauma intensive care unit, University Hospital Complex of Granada, Granada, Spain
Correspondence: A. Fuentes Calatayud

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000545

INTRODUCTION. In neurocritical ill patients, a narrow control of the carbonic anhydride partial pressure (pCO2) must be done as a first level step to control intracraneal pressure elevation. A continuous monitoring of pCO2 would help to keep the values in optimal ranges and would reduce the necessity of arterial gasometries.
OBJECTIVES. To analyze the agreement in the values of CO2 partial pressure measured by a transcutaneal monitor (PtcCO2) with the values measured in arterial gasometries samples in patients with mechanical ventilation joined in a neurocritical ICU.
METHODS. We made an observational study in which were included 6 patients with invasive mechanical ventilation joined in our ICU. We measured PtcCO2 by SenTec® monitor and simutaneous arterial gasometry in several moments of their evolution. The continuos variables are described with averages and typical deviation. We calculated the Pearson correlation coefficient (r) and the coefficient of intraclass correlation (ICC) with a confidence interval (CI) of 95% between PaCO2 and PtcCO2 as agreement measure with Landis and Koch interpretation. We considered statistically significant $p < 0.05$. Bland and Altman analysis was applied for the dispersion data.
RESULTS. 36 samples from the 6 patients were included. The values obtained of PaCO2 were 42.05 ± 3.34 mm Hg and of PtcCO2 were 42.56 ± 3.68 mmHg. Due to correlation and concordance, the results were for PaCO2 and PtcCO2, r = 0,843 (p< 0.001) and ICC = 0,91 (CI 95% 0.83 , 0.96). In 95% of the cases the discrepancies are included between -3.48 y 4.48 mmHg. Bland and Altman analysis did not show significant dispersion data. It was showed that SenTec® monitor overvalued the values of PaCO2 in 0.5 mmHg.
CONCLUSION. The agreement between the measures of CO2 is almost perfect. The unconformities of the monitor in the measure of PtcCO2 compared with PaCO2 in arterial gasometry do not have clinical signification. The values obtained with PtcCO2 monitor seems reliables.

REFERENCE(S)
1. No grants received from any source. We thank SenTec® for lenting us the PtcCO2 monitor for make the study.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000568

INTRODUCTION. The Patient´s State Index (PSI) is a useful form of continuous neuromonitoring in the Intensive Care Unit (ICU). Suppression rate (SR) is a measurement of the suppression of brain electrical activity. Due to its good correlation with the neurological status of patients in the ICU, we believe they are associated with mortality and neurological damage in critically ill patients.
OBJECTIVES. Establish if there is a relationship between the Patient´s State Index (PSI) and Suppression rate (SR)values with mortality in intensive care patients in a given period.
METHODS. Retrospective study. From January 2016 to November 2017 all patients admitted to intensive therapy under mechanical ventilation were included, continuous qualitative electroencephalography was performed, PSI values and SR were recorded, along with epidemiological variables and SOFA score upon admission. The sample was divided into survivors and non-survivors. Primary objective: association of the PSI and SR with mortality at 28 days
RESULTS. A total of 46 patients were included, 74% of survivors. The diagnosis of septic shock was the most observed. There were no differences in the time of need for mechanical ventilation or in the use of analgesics or sedatives between the groups. The ROC curve in relation to 28-day mortality shows an AUC for PSI of 0.813 (95% CI: 0.650-0.975, p = 0.001), and for SR of 0.857 (95% CI: 0.734-0.980, p=0.001) for detection of survival. The cut point of PSI of 30.5 has a sensitivity of 88.2% and specificity of 83.3%, and the cut point of SR of 2 has 92.3% and 67% of sensitivity and specificity respectively.
CONCLUSION. Under a sedation protocol necessary to achieve minimum RASS 0 to -1, PSI values lower than 30 and SR greater than 2 are auxiliary in the analysis of the mortality risk of the patient in critical condition.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000585

INTRODUCTION. Traumatic brain injured (TBI) patients are at high risk for respiratory complications and in particular of ventilator-associated pneumonia (VAP). Aim of this study is to evaluate the occurrence of VAP after TBI and its effect on patients' outcome as well as hospital and intensive care unit (ICU) stay.
METHODS. The CENTER-TBI study (clinicaltrials.gov registration NCT02210221) is a prospective observational longitudinal cohort study including patients with TBI from 65 centers across Europe. Data were extracted from the CENTER-TBI database v1.1 with Neurobot v2.6. We focused on patients with an ICU length of stay >72 hours who were intubated (or mechanically ventilated) for at least 48 hours.
RESULTS. 4509 patients were included in the CENTER-TBI study, 2138 were admitted to the ICU and we focused on 917 patients fulfilling the inclusion criteria. Of these, 188 (20.5%) developed a VAP at a median time of 4.5 days (IQR: 3-7 days) from intubation.
Patients who developed VAP were younger (median age 39.5 vs 51 y/o, p<0.001), with a higher incidence of alcohol abuse (35% vs 28%, p=0.098), thoracic trauma (53% vs. 43.5% p=0.021), and more frequent neuroworsening episodes during ICU stay (44% vs 35%, p=0.039). VAP cohort had a longer duration of mechanical ventilation (median 15 vs 9 days, p<0.001) and ICU stay (median 20 vs 13 days, p<0.001) and a higher incidence of tracheostomies (55 vs. 34%). VAP cohort had lower ICU mortality (7.4% vs 16% p=0.004) as well as a lower six months mortality (16.4% vs 26%, p=0.012). Neurological outcome was similar in the two groups (GOSE $\leq$ 4 in 51.5% vs 58%, p= 0.154).
CONCLUSION. VAP occurs very often in intubated patients after TBI and has an important effect on ICU stay. However, the development of VAP does not seem to have a detrimental effect on mortality and neurological outcome.

INTRODUCTION. In traumatic brain injured (TBI), tracheostomy can facilitate the weaning process and can potentially result in fewer days in the intensive care unit (ICU). However, the optimal timing for tracheostomy placement remains uncertain. The aims of our study are to describe the prevalence and timing for tracheostomy in TBI patients and its effects on patients' outcome.
METHODS. The CENTER-TBI study (clinicaltrials.gov registration NCT02210221) is a prospective observational longitudinal cohort study including patients with TBI from 65 centers across Europe. Data were extracted from the CENTER-TBI database v1.1 with Neurobot v2.6. We focused on patients with an ICU stay >72h. Tracheostomy was defined as early (≤7 days from admission) or late (>7).
RESULTS. 4509 patients were included in the CENTER-TBI study, 2138 were admitted to the ICU and we focused on 1361 patients fulfilling the inclusion criteria. Of these, 436 (32%) had a tracheostomy after a median of 12 days (IQR=6-20 days). Patients who underwent tracheostomy had a more severe TBI (71.5% vs 52.7%, p<0.001) and more frequent episodes of prehospital hypoxia (19.6 vs 13%, p=0.003) and hypotension (21 vs 12.2%, p<0.001), as well as a higher number of extracranial injuries, in particular thoracic trauma (47.7% vs 36.6%, p<0.001).
The decision for late (58%) or early (42%) tracheostomy was strongly influenced by country and treating center (p<0.001). Respiratory failure (52 vs 41%, p=0.029) and ventilator associated pneumonia (40 vs 26.5%, p=0.006) were more common in patients who underwent late tracheostomy. Tracheostomy was associated with longer ICU length of stay (median 24 vs 15 days, p<0.001) and duration of mechanical ventilation (median 19 vs 12 days, p<0.001). Effect on ICU mortality (4.3 vs 7.1%, p=0.302) or 6 months neurological outcome (GOSE ≤ 4: 64.2 vs 68.4%, p=0.44) was not significant.
CONCLUSION. Tracheostomy is commonly performed after TBI. Tracheostomy policies are center dependent and are more frequent in more severe TBI and in patients with respiratory complications. The timing for tracheostomy seems to have effect on ICU length of stay and duration of mechanical ventilation, but no effect on patients' outcome.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000622

INTRODUCTION. Seizures are common entities in patients with acute brain damage which cast their prognosis. **Continuous EEG** has become a tool of increasing use for its detection but it implies an infrastructure and costs that make necessary more data that allow us to identify high risk patient who benefit most from this monitoring, making its use profitable.
OBJECTIVES. To study the **prevalence** of seizures as well as the **morbidity** and **mortality** associated with them in patients with acute brain damage. To study the relationship between the presence of seizures and different clinical and electroencephalographic variables in order to find **predictive factors** that guide us in our clinical practice.
METHODS. It is a **cross-sectional study** in 74 patients **(n = 74)** admitted to ICU with diagnosis of acute brain damage and subjected to study by continuous EEG in the period between **2015-2018**. It has been carried out a descriptive analysis of **prevalence,** main characteristics and **morbimortality** of seizures. Likewise, it has been measured the **association** of seizures with different **clinical** (sex, age, etiology, history of epilepsy, presence of clinical crises, anti-epileptic prophylaxis) and **electroencephalographic variables**(presence of periodic discharges, irritating activity and rhythmic patterns).For this purpose,-descriptive statisticians,Chi-square Test,exact Fisher Test and correlation of Spearman and Pearson have been used, with a statistical significance level p > 0.05.
RESULTS. Seizures were observed in **59%** of the analyzed patients, 77% of whom presented as an epileptic status. The average **time to the onset** of seizures is **17.9 hours** and the average **time of crisis control** is **51.8** hours. An average of **two drugs** per patient was necessary for the control of seizures, being the **most frequently used** the **Levetiracetam** (73%). Patients who present seizures had a **worse functional prognosis** at the time of hospital discharge, with a score between 4 and 6 in the Rankin scale in 80% of the cases and a significantly **higher** both **intrahospital** (48% vs 17%) **and 6-month mortality** (50% vs 20%) (p < 0.05, OR = 4 (1.4-11.7)). With regard to the presence of possible **predictor factors** we have found that seizures **prevalence** is **greater** in patients with **higher age** (Average age: 62 years vs. 53 years) or with a history of **clinical seizures** (84% vs 47%)(p = 0,002 OR 5.9) and **lower** in those who have received **anti-epileptic prophylaxis** (43% vs 70%) (P = 0.02 OR 0.32). It is worth highlighting the increased risk of seizures in patients with **periodic discharges**, considering it as the **main electroencephalographic marker**. The presence of seizures is greater when the discharges are widespread (GPLDs) and it increases proportionally to the frequency with which these periodic discharges appear.
CONCLUSION. Epileptic seizures are a common entity in patients with acute brain damage associated with an important morbimortality so that it is important their early detection and treatment. Given the average time of onset of seizures, we think that continuous EEG is a very useful tool because of its greater sensitivity but its high costs make us neccessary to guide by markers that allow to select high-risk patients. In this sense, the upper ages, the presence of clinical seizures, the absence of prophylaxis or the appearance of electroencephalographic patterns such as periodic discharges seem to have an important predictive value.

INTRODUCTION. To evaluate the presence of epileptic seizures and surgical treatment in patients with supratentorial spontaneous non-traumatic intracerebral hemorrhage (ICH) and intraventricular hemorrhage (IVH).
METHODS. During the years 2009 to 2012, ICU admitted patients from three Spanish hospitals with Neurosurgery Services with the diagnosis of supratentorial ICH and IVH were studied. The effect of the surgical intervention over these patients was studied. Using a propensity index, 26 patients who underwent surgery were paired with the same number of non-operated patients.
RESULTS. 163 patients with supratentorial and intraventricular ICH were admitted. These patients presented in the admission a Glasgow 8 + 4, APACHE-II 21.42 + 7.55 and an ICH score of 2.75 + 0.9 with a predicted mortality (30 days) of 65% and with a mortality of 59.5%. At admission, 13.5% had bilateral arreactive mydriasis. 23.3% (n=38) of patients underwent surgery. Mortality of those who underwent surgery was 34.2% and of the non-operated patients it was 67.2% (p <0.001). In the multivariate analysis, OR for surgical intervention was 0.14 (0.05-0.41).Subsequently, 26 surgically operated patients were matched with further 26 non-surgically treated patients, based on a propensity index.This index was calculated based on: age, presence of pupillary anomalies, size and location of the hematoma and Glasgow on admission. The surgical and non-surgical patients presented similar characteristics (age, Glasgow, ICH score, APACHE II, volume and location of the hematoma) and none presented bilateral mydriasis at admission.The hospital mortality of the 26 operated was 30.8% and of the 26 not operated was 65.4%, (p = 0.001) and OR 0.23; CI: 95%: 0.07-0.75.Afterwards, these 52 paired by propensity index patients were tracked for 6-9 years and mortality was 57.7% in those operated, and 73.1% in those not operated on.Of the 26 patients non-surgically treated, 6 were alive and none had epileptic seizures, and of the 26 who were surgically treated 11 were alive and had epilepsy 6 of them (54.5%), (p = 0.017).
CONCLUSION. Patients admitted to the ICU for non-traumatic cerebral hemorrhage open to ventricle who undergo surgery have lower mortality than those who have not undergone surgery, but have epileptic disorders with a frequency much higher than those who have not undergone surgery

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000756

INTRODUCTION. Brain multimodal monitoring including intracranial pressure (ICP) and brain tissue oxygen pressure ($PbtO_2$) is more accurate than ICP alone in detecting cerebral hypoperfusion after traumatic brain injury (TBI). No data are available for the role of PaO_2 changes on $PbtO_2$ in this setting.
OBJECTIVES. To examine the accuracy of ICP, brain tissue PO_2 and the oxygen ratio (OxR) in detecting cerebral hypoperfusion in patients with acute brain injury.
METHODS. Single-center study including patients with TBI, subarachnoid hemorrhage (SAH) and intracranial hemorrhage (ICH) undergoing cerebral blood flow (CBF) measurements using perfusion CT scan (CTP) concomitantly to ICP and $PbtO_2$ monitoring. Before CTP, FiO_2 was increased directly from baseline to 1.0 for a period of 20 minutes under stable conditions to test the $PbtO_2$ catheter as standard of care. The difference between $PbtO_2$ and PaO_2 at the end of test vs baseline ($\Delta PbtO_2$ and ΔPaO_2, respectively) were collected and the OxR calculated as $\Delta PbtO_2/\Delta PaO_2$. Regional CBF (rCBF) was measured using CTP in the tissue area around intracranial monitoring. The accuracy of different monitoring tools to predict cerebral hypoperfusion (i.e. CBF < 35 mL/100 g.min) was assessed using area under the receiver-operating characteristic curves (AUC).
RESULTS. 51 CTP were performed in 33 patients (age 52 [41-65] years – TBI, n=12; SAH, n=19; ICH, n=2). Median ICP, $PbtO_2$, OxR and rCBF were 13 [9–18] mmHg, 21 [19-23] mmHg, 0.25 [0.16–0.30] and 30.0 [15.8–37.4] mL/100g.min. 38 (69%) patients had cerebral hypoperfusion; rCBF correlated with ICP (r^2=0.12; p=0.01), $PbtO_2$ (r^2=0.22; p<0.001) and OxR (r^2=0.36; p<0.001). Compared with ICP alone (AUC = 0.73 [95% CI, 0.59–0.86]), monitoring ICP + PbO_2 (AUC=0.81 [0.69–0.92]) or ICP + $PbtO_2$ + OxR (AUC=0.84 [0.72–0.95]) were more accurate in predicting cerebral hypoperfusion.
CONCLUSION. The combination of ICP and $PbtO_2$ monitoring provides a better detection of cerebral hypoperfusion than ICP alone in patients with acute brain injury.

Effects of Age on Mortality in patients with Non-Traumatic Subarachnoid Haemorrhage on a Neurocritical Care Unit

J. Sokhi, V. Louma, G. Bird, S. Bapat
The national hospital for neurology and neurosurgery, University College London Hospital, London, United Kingdom
Correspondence: J. Sokhi
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000774

INTRODUCTION. Mortality rates from non-traumatic subarachnoid haemorrhage (ntSAH) in the UK are declining (9/100,000)(1). How this trend correlates with age is unclear. This observational study aimed to quantify, neurocritical care unit (NCCU) mortality, complications and functional outcome by age groups.
METHODS. A retrospective, electronic case note review of all patients admitted with ntSAH to NCCU between 2014-17. 241 patients were analysed. Functional outcome was defined as good, modified Rankin Scale (mRS 0/1/2/3) and poor (mRS 4/5/6) at 3 months. The presenting grade of ntSAH was defined by the World Federation of Neurological Surgeons scale (WFNS), good was WFNS 1/2/3 and poor

WFNS 4/5. On NCCU, the rates of acute kidney injury (AKI - KDIGO criteria), ventilation, infection and vasospasm were analysed for each age group. Data was analysed using GraphPad Prism by the $\chi 2$ test and length of stay (LOS) by the mean average.

RESULTS.

Overall NCCU mortality was 18.3% in keeping with other NCCUs (2). NCCU mortality across each age group was similar, except for the observed increase in the 80-89 year olds (p= 0.74). Hospital mortality at 6 months, increased with age but was not statistically significant (p= 0.14). The mean LOS in NCCU was 12 days, with no significant variation with age. The mean LOS in hospital was 34 days. There was a non-significant (p=0.12), increasing trend towards poor outcomes with advancing age.

CONCLUSION. Elderly patients' required more frequent mechanical ventilation (p=0.03) and had an increased risk of AKI (p=0.05). This is possibly due to reduced physiological reserve and a higher grade of ntSAH, WFNS 4/5 (p=0.03). There was no difference in the incidence of infection (p=0.17) and vasospasm (p=0.11) across age groups.

Surprisingly, advancing age showed no significant correlation with increased mortality or NCCU LOS, although the numbers in the elderly groups were smaller. Possible explanations include; centralisation of neurosurgical services with faster diagnostics, less invasive interventions, specialised multidisciplinary critical care teams and holistic critical care bundles (e.g. for ventilated patients and management of AKI). However, there was a trend towards poorer functional outcomes and increased hospital LOS with increasing age.

INTRODUCTION. Sedation is used in traumatic brain injury (TBI) patients admitted to intensive care unit (ICU) without intracranial pressure (ICP) monitoring to allow invasive treatments as mechanical ventilation and improve comfort. However, it remains unclear what the effect of prolonged sedation is and whether different sedative drugs have different effect on outcome in this population. This analysis of the CENTER-TBI study uses comparative effectiveness research to fill this knowledge gap.

METHODS. The CENTER-TBI study (clinicaltrials.gov registration NCT02210221) is a prospective observational longitudinal cohort study including patients with TBI from 65 centers across Europe. Data were extracted from the CENTER-TBI database v1.1 with Neurobot v2.6. We included all patient who were admitted to the ICU, without ICP monitoring and who had more than one day of mechanical ventilation. For every patient, the primary sedative (the sedative that the patient received most of the days) was selected. We focused on midazolam and propofol, since these were the most frequently used.

RESULTS. 4509 patients were included in the CENTER-TBI study: we selected 265 patients who received propofol and 101 patients who received midazolam as primary sedative. There was a large variation between centers in the cumulative days of sedation. Propofol increased the number of sedation days 4.00 times (95% CI: 1.62 - 9.89) when adjusted for patient characteristics. Nevertheless, unadjusted total ICU stay was 0.83 (95% CI: 0.77 - 0.90) times shorter when propofol was used, and the adjusted was 0.79 (95% CI: 0.73 - 0.86) times shorter. The unadjusted OR for a better functional outcome was 1.29 (95% CI: 0.80 - 2.09), and the adjusted was 1.15 (95% CI: 0.65 - 2.04).

CONCLUSION. There is large variation in the number of days during which TBI patients are sedated. The number of sedation days is often larger when propofol is primarily used. However, propofol is associated with a shorted length of ICU stay. This study did not find evidence that this improves outcome.

Incidence of early hyperemia post primary craniectomy in severe traumatic brain injury measured by Doppler

B. Romima, M. Victor, C. Nestor, Z. Carlos, MF. Maria, R. Avila
Critical care, Provincial Hospital Dr. José María Cullen, Santa Fe, Argentina
Correspondence: R. Avila
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000802

INTRODUCTION. The different hemodynamic phases in cerebral blood flow (CBF) after traumatic brain injury (TBI) have previously been characterized. Moreover, a hyperemic pattern by Doppler is associated with worse clinical outcomes. Some patients with severe TBI require a craniectomy as part of their treatment. It is not well understood how a craniectomy can affect CBF in this population.

OBJECTIVES. We sought to determine the cerebral blood flow velocities with transcranial Doppler during the first 24 hours in patients with severe TBI looking at how craniectomy affects these parameters.

METHODS. We retrospectively analyzed our database for transcranial Doppler procedures (TCD) performed during the first 24 hours of admission on patients with a diagnosis of severe TBI from July 2018 to March 2019. All studies measured middle cerebral artery (MCA) median blood flow velocity (MBFV) and accordingly, the results were classified in three patterns: normal, hyperemia and oligohemia. We compared the incidence of early hyperemia among patients that received primary craniectomy plus medical treatment or medical treatment alone.
RESULTS. Thirty-one patients were identified, of which 83.8% were male with a mean age 29 ± 15 years old and a median Marshall score of 2. The mean MBFV was 55 ± 17.7 cm/sec, (57.4 ±19.6 cm/sec in the left MCA and 52.7 ± 22.6 cm/sec in the right (p=0.2599)). Eleven patients (35.5%) underwent primary craniectomy. There was no difference in MBFV between patients who underwent craniectomy and those who did not (52.6 vs 56.4 cm/sec, p=0.5572). There was no difference in the incidence of early hyperemia in patient that required primary craniectomy compared to those who did not (p= 0.999)
CONCLUSION. In patients admitted with severe TBI to whom the craniectomy was performed, we found no difference in the presence of early hyperemia as well as other parameters measured by TCD.

Continuous processed EEG monitoring for sedation optimization in ICU

M. Marchesi, F. Terranova, S. Sala, M. Brognoli, GP. Nocivelli, R. Bertuetti, E. De Peri, F. Rasulo
Neuro critical care, Spedali Civili University affiliated Hospital of Brescia, Brescia, Italy

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000822

INTRODUCTION. Sedation is a significant part of medical treatment in ICU patients. Patients exposed to a too light sedation can develop agitation, pain, fear, adverse events as devices removal and respiratory distress, which can lead to post-traumatic stress disorder.A too deep sedation is associated with a longer time of mechanical ventilation and therefore of extubation, lung injury, infections, neuromuscular disease and delirium. A longer duration of ICU hospitalization and an increase of morbility incidence and mortality are also demonstrated. Many patients spend a considerable amount of time in a non-optimal sedation level. A continuous monitoring system of the sedation level is therefore necessary to improve clinical evaluation. Different pEEG analyses have been studied to monitoring sedation depth, Next Generation SedLine (Masimo) has shown a strong correlation with other monitoring systems, resulting more sensitive and less susceptible to interferences.
OBJECTIVES. The goal of our study was to evaluate the incidence of non-optimal sedation (under and over sedation) comparing the parameters expressed from NGSedLine with clinical evaluations.
METHODS. We have studied a cohort of patients admitted to the ICU of Spedali Civili of Brescia University Hospital requiring continuous sedation for more than 12 hours. In addition to standard monitoring, the patients have been studied using Next Generation Sedline (Masimo), which provides a continuous 4 channel pEEG monitoring. Derived parameters were: PSI (Patient State Index), SEFL, SEFR, EMG, ARTF, DSA and Suppression Ratio (SR). Sedation depth was evaluated through Richmond-Agitation-Sedation Scale (RASS). Non-optimal sedation has been evaluated by confronting RASS and PSI values.
RESULTS. Clinical data of our patients are shown in Table 1, while a summary of collected data is shown in Table 2.Average artefacts percentage was less than 10% in 32 of 34 patients. Accuracy is also confirmed by the analysis of EMG data: 2 patients of 34 spent more than half of the time of sedation with an EMG value of 30 or less.Collected data showed high incidence of oversedation: SR analysis showed that all patients but one had at least one episode of burst suppression and that 20 of our 34 patients spent more than 10% of total time with a high level of SR and 16 of our patients spent more than half the time with a level of PSI lower than 30, confirming an important oversedation. Also SEFL and SEFR were lower than the expected: graphic 2 shows that the average values were both lower than 10 in 18 of 34 patients.
CONCLUSION. Non-optimal sedation is an unsolved problem in ICU, affecting many patients, with a major incidence of over-sedation compared to under-sedation. Association of EEG-based monitoring systems to clinical evaluations can optimize sedation in critically-ill patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000832

INTRODUCTION. Aneurysmal subarachnoid hemorrhage (aSAH) is a devastating condition with high morbidity and mortality. Physiopathological mechanisms leading to long term outcome are still partially unexplained. Previous studies showed an association between plasma levels of Endothelial Progenitor Cells (EPC) and outcome after acute brain injury (stroke, traumatic brain injury)[1]. The link between EPC and aSAH, complicated or not of cerebral vasospasm (CVS), has not been studied yet. We previouly showed a different EPC kinetic after serious or non serious aSAH[2], and in patients with or without CVS[3].
OBJECTIVES. To compare plasma level of EPC 3 days after aSAH according to 1-year outcome.
METHODS. Prospective monocentric EVAPROPEC cohort (NCT01773200) including every adult patient admitted for aSAH, after obtaining patient's or next-of-kin's consent, or after emergency inclusion as allowed by local ethic committee. Plasma levels of CD34+/CD133+ and CD34+/CD133+/VEGFR2+ EPC (expressed as stained cells per 100 000 mononuclear cells) were measured by flow cytometry after isolation of mononuclear cells by a Ficoll gradient and surface staining on blood samples collected at admission (D0), and D3, D6, D10, D14, D21. 1-year neurologic outcome was evaluated by Glasgow Outcome Scale (GOS) assessed by a standardized questionnaire. EPC levels at D3 (principal judgement criterion), the maximal variation of EPC level between D0 and D21, and the proportion of patients with a significant mobilization of EPC (defined as an EPC level increase > 100% compared to D0 level) (secondary judgement criteria), were compared between a "bad outcome" (GOS 1-3) and a "good outcome" (GOS 4-5) group using a Mann-Whitney test (significance was defined by a p value < 0.05). Results are expressed as median [25th-75th percentiles] or n(%).
RESULTS. 90 patients: 34 with a "bad outcome" and 46 with a "good outcome" (10 lost of view). Demographical data are presented in table. D3 plasmatic level of CD34+/CD133+ EPC (46 [26-121] vs. 89 [42-143], p=0.22) or CD34+/CD133+/VEGFR2+ EPC (8 [3-31] vs. 18 [1-46], p=0.47] (figure), maximal variation of CD34+/CD133+ EPC (9 [0-48] vs. 30 [0-103], p=0.48) or CD34+/CD133+/VEGFR2+ EPC (4 [0-73] vs. 4 [0-47], p=0.89), the proportion of patients with a significant mobilization of CD34+/CD133+ EPC (29% vs. 29%, p=1) or CD34+/CD133+/VEGFR2+ EPC (38% vs. 35%, p=1) were not significantly different between both groups.
CONCLUSION. Endothelial progenitor cells level and kinetic do not seem associated with 1-year outcome after aneurysmal subarachnoid hemorrhage.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000853

INTRODUCTION. Early endovascular treatment of patients with acute ischemic stroke has changed according to the new recommendations published in 2018, mainly focused on an earlier approach over a longer period for patients with or without thrombolytic therapy

OBJECTIVES. Primary outcome: to compare the outcomes at discharge and at 90 days of patients admitted to our ICU over two periods of time (2018 and pre-2018). Secondary outcomes: 1. To discover whether global time (minutes from the beginning of the symptoms until the end of the procedure) is shorter. 2. To analyse whether any differences exist in the use of vasoactive drugs (antihypertensive therapy / amines).
METHODS. Retrospective study. Review of medical records. Patients with AIS admitted to our ICU for endovascular treatment are divided into 2 groups: G1 (year 2018); G2 (years 2015-2017). The recorded variables include (among others): demographic data, cardiovascular risk factors, previous treatment with antiplatelet agents/oral anticoagulants, outcome at discharge and after 3 months using modified Rankin Scale (mRS-d, mRS-3).
Mann-Whitney *U*-test (for independent samples) and Wilcoxon test (for related samples) were used to compare medians. The Student test was used to compare differences in time between the two groups. Pearson's chi-square test and Fisher's exact test were used to analyse differences in vasoactive drug use.
RESULTS. A total of 103 patients were included: 63 in G1 and 40 in G2. The demographic data, risk factors and NIHSS on admission did not differ, despite the difference in sample sizes.
Primary outcome: there were no statistically significant differences in mRS-d between G1 and G2, and 50% of patients have mRS-3 $\leq$ 2. Nonetheless, though the difference is not statistically significant, outcome at discharge is better in G1, given that 25% of the patients have mRS-d $\leq$1.
Outcome after three months was compared with that at discharge in each group separately (excluding patients with mRS-d=6, as improving is impossible for them). We found a statistically significant improvement in both groups, which was higher in G1. 50% of patients in G1 have mRS-3 $\leq$ 1, while 50% of those in G2 achieve mRS-3 $\leq$ 2. Furthermore, 25% of patients in G1 have mRS-3 = 0, and this is not achieved in G2.
Secondary outcomes: 1. Time is shorter, but the difference is not statistically significant. There may be external factors which bias this parameter. 2. We have used fewer vasoactive drugs in G1 than in G2, and the difference is statistically significant.
CONCLUSION. CONCLUSIONS
1.- The introduction of new recommendations for AIS endovascular treatment has improved the outcome of our patients. 2.- Thanks to early endovascular therapy, as a first line treatment for AIS, 25% of patients have no neurological sequelae. 3.- Although the time period is shorter, we have not found any statistically significant differences, probably due to several external factors. 4.-The use of vasoactive drugs has decreased upon the introduction of the new guidelines

INTRODUCTION. Controversial evidences exist concerning the effect of hyperoxia on outcome after traumatic brain injury in ICU.
OBJECTIVES. We aimed at evaluating the effect of transient and prolonged hyperoxia on outcome.
METHODS. The CENTER-TBI study is a prospective observational longitudinal cohort study including patients with TBI from centers across Europe. Data were extracted from the CENTER-TBI database v1.0 with Neurobot v2.6. We focused on patients receiving mechanical ventilation in ICU > 24 hours. We analyzed previously published predictors of outcome: age, preinjury state, ISS score, Glasgow motor score, pupils' examination, imaging results and secondary insults such as hypoxia, hypotension, unwanted hypocapnia, seizures, highest blood glucose level (BGL) at day 1, lowest hemoglobin level at day 1, raised ICP episode and length of stay.
Transient hyperoxia was defined as a single blood gas analysis (BGA) PaO2 >100 (THMild) mmHg and >300 mmHg (THsevere) and prolonged hyperoxia as the daily lowest BGA PaO2 >100 mmHg (PHmild) and 300 mmHg (PHsevere). The main outcome was a negative outcome at 6 months (Glasgow outcome scale extended, GOSe $\leq$4). Chi square tests and fisher tests were used to compare variables between good and bad outcome groups.
RESULTS. 4509 patients were included in the CENTER-TBI study, 2138 were admitted in the ICU and we focused on the 1099 receiving MV for more than 24 hours. 771/1099 (70.2%) patients were exposed at least once to PHmild whereas 2487 episodes of PHmild occurred during the entire stay, 908 (36.5%) of which during the first 48 hours. Only 26 episodes of PHsevere occurred in 23/1099 (2.1%) patients, 18 of which in the first 48 hours. 112/214 patients that died before day 4 had an episode of PHmild *vs.* 289/885 (p<.0001).
1061/1099 patients were exposed to THMild whereas 6373 episodes of THMild occurred, 1808 (26.3%) of which during the first 48 hours. 213/1099 patients presented 253 episodes of THsevere, 168(66.8%) of which in the first 48 hours. 200/214(93.4) patients that died before day 4 had an episode of THMild vs. 847/884(95.8) and 40/214 vs 136/884 (p=.280) for THsevere.
THMild or THsevere were not associated with GOSE in univariate analysis (p=0.259, p=.566) nor PHmild or PHsevere (p=.258, p=.056)
CONCLUSION. Hyperoxia is frequent in ICU after TBI but it is not associated with worse outcome.

INTRODUCTION. Severe traumatic brain injury management guidelines recommend intracranial pressure monitoring. However, the use of hospital-level intracranial pressure monitoring varies greatly, and the association between hospital-level intracranial pressure monitoring utilization and clinical outcomes remains unknown.
OBJECTIVES. To examine whether severe traumatic brain injury patients treated at hospitals with higher intracranial pressure monitoring utilization rates have better functional outcomes, based on data from the Japan Neurotrauma Data Bank Project 2015.
METHODS. In this post hoc analysis of a nationwide prospective registry of patients admitted between April 2015 and March 2017,

the primary exposure was hospital-level intracranial pressure monitoring utilization. Patients treated at hospitals where intracranial pressure monitoring was used for monitoring >80% of severe traumatic brain injury patients were assigned to a "high" group and all other patients to a "low" group. The secondary exposure was patient-level intracranial pressure monitoring utilization (intracranial pressure monitoring group vs non-intracranial pressure monitoring group). The primary endpoint was a 6-month favorable functional outcome, defined as a Glasgow Outcome Scale score of 4 or 5.
RESULTS. Intracranial pressure monitoring utilization at each hospital ranged from 0%to 100%. Overall, 459 patients from 25 hospitals were included, with 59 (12.9%) of them assigned to the high group. Multiple logistic regression model showed that patients in the high group had significantly better functional outcome than those in the low group (adjusted odds ratio 2.77; 95% confidence interval, 1.30–5.92; p = 0.009). However, patients in the intracranial pressure monitoring group at the patient-level analysis did not exhibit any clear association with a specific functional outcome.
CONCLUSION. Treatment at hospitals with higher intracranial pressure monitoring utilization for severe traumatic brain injury can be associated with better functional outcomes.

INTRODUCTION. Anemia is considered as one of the factor that could aggravate brain injuries after traumatic or non-traumatic lesions. However, the "safe" hemoglobin threshold is not clearly defined in this particular population [1].
OBJECTIVES. The objective of this study is to evaluate the association between the intensity of anemia (defined as the proportion of time spent under different hemoglobin (Hb) thresholds) and functional outcome at 3 months in brain damaged patients.
METHODS. Prospective observational study based on data from the ATLANREA cohort (traumatic or non-traumatic brain-injured patients hospitalised in intensive care), restricted to the centers of Nantes and Angers, between 2013 and 2018. From the Hb dosages of the first 8 days, an area index has been calculated by dividing the area representing the time spent with Hb values below a threshold by the total monitored time. The area below the various thresholds (10 g/dl, 9 g/dl, 8 g/dl and 7 g/dl) has been calculated using the trapezoid method (figure). Functional status at 3 months has been determined by the dichotomized GOS score (unfavourable prognosis if death, vegetative state or severe deficiency). We evaluated the judgment criterion through multivariate logistic regression by adjusting on the variables significantly associated in univariate with functional outcome (centre, age, sex, traumatic entity or not, number of pack blood cells unit transfused, initial GCS, mydriasis on admission, smoking status and SOFA score, Hb, urea, fibrinogen on admission). The statistical analyses were performed with software R (version 3.4.0).
RESULTS. Among the 585 patients studied (mean age: 49±21 years, women: 177 (30%), SOFA: 8±3; initial Hb level: 11±3 g/dl; initial GCS: 7±3), 394 (67%) had a traumatic brain injury. We recovered 4258 Hb dosages during the first 8 days (mean 0.90 ± 0.48/patient/day). During this period, 340 patients (58%) had at least one Hb value < 10 g/dl, 252 (43%) < 9 g/dl, 153 (26%) < 8 g/dl and 65 (11%) < 7 g/dl. 222 patients (38%) had an unfavourable outcome at 3 months, with a significant association for the four different hemoglobin thresholds (p-value < 0.01 for each). After adjusting for confounding factors, Hb area indexes are not associated with functional outcome at 3 months, regardless of the specified threshold (p-value: 0.746 for 10g/dl; 0.819 for 9g/dl ; 0.435 for 8g/dl ; 0.128 for 7g/dl).
CONCLUSION. There is no apparent association between the intensity of anemia during the first 8 days of resuscitation and functional development at 3 months in patients who have undergone a brain injury. A lack of power may explain the absence of any negative impact below the 7g/dl threshold.

INTRODUCTION. Circulatory shock results in impaired tissue oxygenation and brain ischemia.[1] Whether this can be alleviated with higher blood oxygen content is unknown. [2]
OBJECTIVES. We studied the interaction between the severity of circulatory shock and blood oxygen content in patients treated in the intensive care unit (ICU) with neurologic injury.
METHODS. The Finnish Intensive Care Consortium database was screened for mechanically ventilated neurologically ill adult patients treated in tertiary hospitals ICUs in years 2003–2013. Admission diagnoses included traumatic brain injury (TBI), cardiac arrest (CA), subarachnoid haemorrhage (SAH), intracerebral haemorrhage (ICH) and stroke. The primary endpoint was neurological outcome one year after intensive care admission. Independence in self-care was defined as favourable outcome and disability or death as unfavourable outcome. Patients were defined as disabled if they were granted a permanent disability allowance by the public social insurance institution at the time of data collection (September 2016). Patients already disabled before ICU admission were excluded from the study. The primary exposure of interest was arterial PaO2 recorded in connection

with the lowest measured PaO2/FiO2 ratio during the first 24 hours of ICU admission. A compromised haemodynamic state was determined by a cardiovascular SOFA subscore of 4 during the first 24 h of ICU admission. The association between outcome and predictors were analysed by multiple logistic regression. The association of oxygen exposure and haemodynamic state with outcome was inspected with interaction term PaO2*SOFA subscore of 4 as a confounding factor. Additionally, age, gender and modified APACHE II score (excluding points for oxygenation) and type of admission were included in the model.

RESULTS. The study population included a total of 10,143 cases of whom 2,788 (28%) were treated for TBI, 3,390 (33%) for CA, and 3965 (39%) for stroke (SAH 1684 [17%], ICH 1587 [15%] and, ischemic 694 [7%]). Of all cases, 4,056 (40%) survived as independent. Poor haemodynamic state (SOFA cardiovascular subscore of 4) was not an independent predictor of favourable neurological outcome (odds ratio [OR] 1.00: 95% confidence interval [CI] 0.75–1.32). We found no association between PaO2 level and favourable neurological outcome, (OR 1.01: 95% CI 0.99–1.02) and the interaction PaO2*SOFA subscore 4 remained insignificant.

CONCLUSION. In mechanically ventilated patients treated after TBI, CA or stroke (SAH, ICH or ischemic) in the ICU there was no association between arterial oxygen level and circulatory shock with long-term neurological outcome.

INTRODUCTION. Sepsis involves a dysregulated host response to infection, leading to a high mortality rate. As part of this dysregulation, CD4+CD25+ regulatory T cells (Tregs)play an essential role in sepsis-induced immunosuppression. Here, we studied the effects of interleukin (IL)-36 cytokines, which are newly described members of the IL-1 cytokine family, on CD4+CD25+ Tregs and their underlying mechanism in sepsis.

METHODS. Our study was designed to investigate the impacts of IL-36 cytokines on murine CD4+CD25+ Tregs in presence of lipopolysaccharide (LPS) and in a mouse model of sepsis induced by caecal ligation and puncture (CLP). IL-36-activated autophagy was evaluated by autophagy markers (LC3-II, Beclin1, p62), autophagosome formation and autophagic flux.

RESULTS. We provide evidence that IL-36α, IL-36β, and IL-36γ are expressed in murine CD4+CD25+ Tregs. Stimulation of CD4+CD25+ Tregs with LPS markedly upregulated the expression of these cytokines, particularly IL-36β. IL-36β strongly suppressed CD4+CD25+Tregs under LPS stimulation and in septic mice challenged with CLP, resulting in the amplification of Th1 responses and the proliferation of effector T cells. Mechanistic studies revealed that IL-36β triggered autophagy of CD4+CD25+ Tregs. These effects were significantly attenuated in the presence of the autophagy inhibitor 3-methyladenine (3-MA) or Beclin1 knockdown. Additionally, early IL-36βadministration reduced the mortality rate of CLP mice. Depletion of CD4+CD25+Tregs before the onset of sepsis obviously abrogated IL-36β-mediated protection against sepsis.

CONCLUSION. These findings suggest that IL-36β diminishes the immunosuppressive activity of CD4+CD25+ Tregs by activating the autophagic process, thereby contributing to improvement of the host immune response and prognosis in sepsis.

INTRODUCTION. Naturally occurring CD4+CD25+regulatory T cells (Tregs)are required to limit immune-induced pathology and to maintain homeostasis during the early phase of sepsis. This study aimed to investigate the role of interleukin (IL)-38, a newly described member of the IL-1 cytokine family, in mediated immune response of CD4+CD25+Tregs in sepsis.
METHODS. Primary CD4+CD25+Tregs isolated from BALB/c mice were incubated with lipopolysaccharide (LPS), recombinant murine IL-38 (rmIL-38), and anti-IL-38 antibody. A mouse septic model induced by cecal ligation and puncture (CLP) was treated with rmIL-38

or anti-IL-38 antibody. The effects of IL-38 on activity of CD4+CD25+Tregs and survival rate of mice were assessed.

RESULTS. Expressions of IL-38 and its receptor were detected in murine CD4+CD25+Tregs. Stimulation of CD4+CD25+Tregs with LPS markedly up-regulated the expression of IL-38. Treatment with rmIL-38 dramatically enhanced the immunosuppressive activity of CD4+CD25+Tregs after LPS stimulation as well as in septic mice induced by CLP, resulting in amplification of helper T cell (Th) 2 response and reduction in the proliferation of effector T cells. These effects were robustly abrogated when anti-IL-38 antibody was administered.Administrationof rmIL-38 improved the survival rate of CLP mice. In addition, CD4+CD25+Tregs depletion before the onset of sepsis obviously abolished IL-38-mediated protective response.

CONCLUSION. IL-38 enhances the immunosuppressive activity of CD4+CD25+Tregs, which might contribute to the improvement of host immune function and prognosis in the setting of sepsis.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000999

INTRODUCTION. Sepsis should be treated as medical emergencies and early management for sepsis is reported to be associated with improving patient outcomes. Patients on the ward can develop to septic shock at any time during their hospitalization. Therefore, it is very important to identify septic patient on the ward and to perform optimal treatment quickly. Rapid response systems (RRS) are providing optimal care for sepsis on the general ward. Although studies are often performed for early detection of sepsis on ward, there is a little published data on management factors of sepsis on ward.
OBJECTIVES. To study between the outcomes and bundle compliance of patient with septic shock managed by rapid response system for 10 years
METHODS. Retrospective cohort study of 935 patients with septic shock who were activated by RRS at an academic, tertiary care hospital in Korea from 2008 to 2017
RESULTS. We provided sepsis management by RRS during study period. Of the 935 enrolled patients, the compliances of each sepsis bundle were high (87.8%-99.5%) but the overall success rate of bundle was shown low (73.4%). Compliance rate for achieving overall sepsis bundle was increased and the 28 day mortality was continuously decreased for 10 years in figure 1. Of the 935 enrolled patients, 686 (73%) completed all sepsis bundle and 248(27%) were incomplete. We analyzed the two groups according to whether they completed sepsis bundle overall or not. Baseline characteristics were no difference between two groups. Bundle complete group showed lower 28-day mortality than incomplete bundle group (43.5% vs. 52.6%; p=0.001) and in the multivariate logistic regression model, 28 day mortality was significantly related to complete of all bundle (adjusted odds ratio, 0.50; 95% CI, 0.32-0.78; p=0.003).
CONCLUSION. Rapid response system provides improving sepsis bundle compliances & survival in patients with septic shock on the general ward.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001001

INTRODUCTION. Meropenem is a cornerstone in the antibiotic treatment of critically ill patients with sepsis. However, complex pathophysiologic mechanism in sepsis lead to a wide variability of plasma levels of any given drug. Subtherapeutic dosing can lead to treatment failure and antimicrobial resistance while overdosing is associated with toxic side effects. Individualized treatment guided by therapeutic drug monitoring (TDM) might be an effective means to overcome this dilemma.
OBJECTIVES. The primary aim of this study was to assess the effect of therapeutic drug monitoring on the use of meropenem in critically ill patients. The secondary aim was to assess the impact of meropenem TDM on Intensive Care Unit (ICU) length of stay and survival.
METHODS. A total of 247 septic patients treated with meropenem for at least 5 days were included. Baseline characteristics, total doses of meropenem and duration of meropenem treatment were recorded. TDM was done by an attending clinical pharmacologist. Plasma levels of meropenem were measured by use of HPLC. Dosing recommendations were based on microbiologic data were available. In all patients ICU length of stay and ICU mortality were recorded. Statistical analyses were performed by SPSS.
RESULTS. A total of 101 patients received standard doses of meropenem, 146 patients had an individualized treatment by means of TDM. In patients with TDM, meropenem doses were higher (2731.2 ± 1092.1 mg vs 2327.1 ± 652.7 mg, $p < 0.001$) and treatment duration

was longer (14.0 ± 9.7 days vs. 10.5 ± 4.7 days, p < 0.001) than in patients with standard therapy, respectively. An average of 3.2 meropenem plasma level measurements was done in the TDM group. Dose modifications were 1.6 in the TDM group vs. 0.8 in the standard group (p<0.001). ICU length of stay was similar between the two groups (14.7 ± 10.7 vs. 14.6 ± 9.8 days for TDM vs. standard group, respectively). However, ICU mortality was lower in the TDM group compared to the standard group (20 patients (14%) vs. 24 patients (24%), p=0.042).
CONCLUSION. Bearing in mind the high variability of meropenem plasma levels in critically ill patients and patients with sepsis, risk of underdosing is evident. The same is true for overdosing and unnecessary antibiotic therapy. TDM is a potent option to maximize treatment effects and to avoid resistance and toxic side effects.
In our cohort of patients with sepsis, TDM led to higher meropenem doses and longer treatment duration. Importantly, in an exploratory analysis, a lower mortality was seen in our cohort of critically ill patients within the TDM treated group when compared to a standard non-TDM group.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001002

INTRODUCTION. It is a challenging issue to reduce mortality of sepsisin intensive care units. After decades of research, and numerous preclinical and clinical trials, sepsis remains without a specific and effective pharmacotherapy.In the last few years, cell therapies gained potential as a therapeutic treatment for various diseases. However, there are still many problems that limit the therapeutic use of stem cells, including immunological rejection phenomena and unwanted cells differentiation.In recent years, researchers have found that therapeutic activity of *induced pluripotent stem cells* may be mediated by a paracrine effect.
OBJECTIVES. In this study, we investigated the potential protective effects of iPSCs-conditioned media (iPSCs-CM) on E.coli-induced lung injury in rats and LPS/IFN-g-induced inflammatory responses in murine macrophage RAW 264.7 cells, and identified the mechanisms underlying these effects.
METHODS. Rats underwent intraperitoneal inoculation with 109 CFU of Escherichia coli isolated from patient. Animals were randomized to receive (i)co-administration of conditioned medium from iPSCsin combination withceftriaxone (ii) IV administration of conditioned medium from iPSCs following 4 hr of infectionin combination with ceftriaxone; (iii) IV administration of ceftriaxone (30mg/kg)following 8 hr of infection; and (iv) IV instillation of PBS vehicle. Raw 264.7 cells were pretreated with iPSCs-CM for 2 hr prior to LPS/INF-g stimulation or were treated with iPSCs-CM after 1 hr of LPS/TNF-g treatment.Lethality; lung injury scores, including protein leakage and inflammatory cell infiltration; cell count in bronchoalveolar lavage (BAL) fluid;and chemokines and cytokines concentrations in serum were determined to evaluate the effects of iPSCs-conditioned media on sepsis-induced lung injury.
RESULTS. Administration of iPSCs-CM in combination with ceftriaxone (iPSCs-CM/ceftriaxone) has a higher survival rate than ceftriaxone treatment alone.iPSCs-CM/ceftriaxone treatment also significantly decreased the cell counts in BAL fluid in comparison to ceftriaxone treatment alone. Histological examination of lung tissue showed that the iPSCs-CM/ceftriaxone group was less than the ceftriaxone group in macrophage infiltration and MMP-9 expression.Serum levels of CXCL2, IL-1b, and IL-6 also showed decreased in E.coli-induced lung injury rat model, as well as in cells treated with LPS/INF-g.Further, expression of NLRP3, ASC, HMGB1, IL1b, IL-6, and CXCL2 mRNA was significantly decreased in iPSCs-CM/ceftriaxone group compared with no treatment. Similar effects of iPSCs-CM on LPS/INF-g-stimulated raw 264.7 cells.
CONCLUSION. Our results revealed that treatment of iPSCs-CM ameliorates lung inflammatory responses through inhibiting NLRP3 inflammasome activation, which attenuates lung injury and improves the survival rate.These data suggested that iPSCs-CM may be important in sepsis and shed light on therapeutic strategies.

INTRODUCTION. Voriconazole is an azole antifungal agent frequently used in the treatment of severely ill patients with suspected or proven fungal infection. While voriconazole has excellent in vitro susceptibility testing, it´s clinical use is limited by high interindividual variability, particularly in critically ill and septic patients.
OBJECTIVES. The primary aim of the study was to assess voriconazole plasma levels in critically ill patients with sepsis. The secondary aim was to assess whether therapeutic drug monitoring leads to dose modifications in these patients.
METHODS. A total of 92 patients with sepsis and voriconazole treatment were included. All patients received an initial dose of 400 mg voriconazole twice daily. Therapeutic drug monitoring was performed and voriconazole plasma levels were assessed at least once in all patients. Additional determination of plasma levels were ordered if deemed clinically necessary by the treating physicians. Measured patients´ voriconazole plasma levels were classified as within target range (0.5 to 5.0 mg/l depending on the underlying disease), below target range (< 0.5 to 1.0 mg/l) and above target range (>2.5 to 5.0 mg/l).
RESULTS. A total of 45 patients (49%) had voriconzole plasma levels within the predefined therapeutic range. Seven patients (8%) had voriconzole plasma levels below target range, 40 patients (43%) had voriconazole plasma levels above the therapeutic range. Thus dose modifications became necessary in more than half of the patients treated with voriconazole as a result of therapeutic drug monitoring.
CONCLUSION. Our results show high variability of voriconazole plasma levels in critically ill patients with suspected or proven fungal infection. Standard dosing of voriconazole led to plasma levels within the predefined therapeutic range in only less than half of the patients. Therapeutic drug monitoring is therefore an appropriate tool to avoid treatment failure by underdosing and at the same time toxic overdosing in patients with sepsis.

INTRODUCTION. Serum lactate has been incorporated in the new definition of septic shock as a way to identify hypotensive patients at higher risk of death (1). Hyperlactatemia at the time of admission has been shown to be a good prognostic marker (2). The usual cut-off value for hyperlactatemia is 2 mmol/L. Haas et al. (3) found a mortality approaching 80% for patients with lactate levels >10 mmol/L.
OBJECTIVES. To evaluate the influence of patient and clinical characteristics on the severity of hyperlactatemia in infected patients at ICU admission and define differences in outcomes.
METHODS. Post-hoc analysis on hyperlactatemia in the INFAUCI study, a prospective, observational, cohort, multicenter study, conducted in 14 Portuguese Intensive Care Units (ICU) with data collected between 1 May 2009 and 31 December 2010. Infected patients at admission were divided in three groups, accordingly to the severity of hyperlactatemia at admission, mild (2-3.9 mmol/L), moderate (4.0-9-9 mmol/L) and severe (>10 mmol/L).
RESULTS. Of the 3766 patients admitted to the study, 1652 (43.9%) were deemed to be infected on admission. Lactate was measured in 1640 patients, with 934 (57%) having hyperlactatemia, distributed as mild, moderate and severe in 57.0%, 34.4% and 8.7% of the cases. The degree of hyperlactatemia increased significantly with SAPS II, APACHE II score, Charlson Score, chronic liver disease as a comorbidity, presence of septic shock and secondary bacteremia. On the other hand, the degree of hyperlactatemia was significantly inversely associated with chronic respiratory disease as a comorbidity and appropriate antibiotic selection. ICU and hospital length of stay decreased with increased hyperlactatemia due to higher and earlier mortality. ICU mortality rate was 26%, 47% and 68% for mild, moderate and severe hyperlactatemia, which increased to 36%, 55% and 79% for in-hospital mortality, respectively. ICU and in-hospital mortality adjusted for age, SAPS II, APACHE II and Charlson score was correlated with moderate and severe hyperlactatemia but not with mild hyperlactatemia with an OR 2.0 [95% CI 1.4-2.8; p<0.001] and 5.4 [95% CI 2.9-9.9; p<0.001] for ICU mortality and 1.8 [95% CI 1.3-2.5; p<0.001] and 3.8 [95% CI 2.0-7-2; p<0.001] in moderate and severe hyperlactatemia, respectively.
CONCLUSION. Hyperlactatemia is a strong predictor of mortality in ICU infected patients. Lactate level correlates independently with ICU and in-hospital mortality for moderate and severe degrees of hyperlactatemia.

INTRODUCTION. Left ventricular longitudinal strain (LVLS) may be a better method for detecting systolic dysfunction in critically ill patients. However, LVLS is limited by poor feasibility, dependency on high image quality and availability of analysis in scanners. Recently Huang et al. (1) described a method for estimating LVLS using M-mode derived longitudinal wall fractional shortening (LWFS), where MAPSE is normalized to the ventricle length. LWFS is less dependent on image quality, is more feasible in critically ill patients and may be done at bedside. However, this method requires validation, especially within the setting of septic shock.
OBJECTIVES. The aim of this study is to 1) test if LVLS measured using speckle tracking (LVLSspeckle) is predicted by LWFS and MAPSE and to assess 2) agreement between LVLSspeckle & LWFS and 3) agreement between LVLS measurements as predicted by Huang's equation (LVLSHuang) & our equation (LVLSpredicted).
METHODS. We retrieved 93 TTE studies from 2 echocardiographic data repositories of patients admitted to ICU with septic shock. LVLS was measured offline (Tomtec Image-Arena Ver. 4.6.4.44) using speckle tracking from the A4C view. MAPSE was measured using the same software and the ventricle length was measured from DICOM-images, to generate LWFS.
RESULTS. The correlations between LVLSspeckle and LWFS, LVLSspeckle and MAPSE, and LWFS and MAPSE were good with r-values of 0.77, 0.68 and 0.94, see table 1.
The prediction equation demonstrated a slope close to 1 and an offset of +3.7%, very similar to those reported by Huang et al (1). The bias ±2 SD for LVLSspeckle vs. LVLSpredicted was 0 ±6.0% (see figure 1), for LVLSspeckle vs. LVLSHuang it was 3.2 ±6.2%.
CONCLUSION. LWFS is strongly correlated with LVLSspeckle measurements. The utility of LWFS for estimating LVLSspeckle is supported by its excellent accuracy and precision. This strong relationship persisted even when applying the previous equation described by Huang et al. (1) speaking for the validity of the method. Our study supports the use of the simpler LWFS method for the bedside estimation of LVLS in patients with septic shock.

INTRODUCTION. The carbapenem class of antibiotics are considered as the last resort. However, there is an increasing chance of clinical isolation of carbapenem-resistant gram-negative bacilli globally1). Although administration of broad-spectrum antibiotics, such as carbapenem, within one hour is encouraged in the treatment of sepsis, a carbapenem-sparing strategy to combat antimicrobial resistance is important2).Currently, the epidemiology of carbapenem-use in the initial antibiotic therapy for sepsis in Japanese intensive care units (ICUs) is unknown.
OBJECTIVES. To describe the epidemiology of carbapenem-use in initial antibiotic therapy for sepsis in Japanese ICUs.
METHODS. Design: Secondary descriptive study of the FORECAST study, which was a multi-center, prospective, cohort study conducted at 59 ICUs in Japan from January 2016 to March 20173).Participants: Patients ≥16 years of age with severe sepsis based on the sepsis-2 criteria were included. Patients whose antibiotic-use data was missing were excluded.Exposure: Patients were classified into two groups based on the presence or absence of carbapenem-use in initial antibiotic therapy.Variables: Patient background and prognostic data were collected for each group. The rate of use of carbapenem in ICUs, which enrolled ≥4 cases, were calculated. The log-Poisson regression mixed-effect model was used to assess the association between initial use of carbapenem and hospital mortality after adjustment for fixed effects of age, baseline SOFA score, random effects of facility, and site of infection.
RESULTS. Among the 1184 patients, information of antibiotic-use was available for 1140 patients. The number of patients who were treated with carbapenem was 627 (55.0%). Patients' characteristics and prognosis with or without carbapenem are shown in Table1. Among the 59 ICUs that participated in the study, 48 ICUs enrolled ≥4 cases. In these 48 ICUs, the median carbapenem-use rate was 43.6% [minimum: 20.0, maximum: 100.0, interquartile range: 43.6-67.2] (Fig.1). In the unadjusted and adjusted models with the log-Poisson regression analysis, there was no significant association between carbapenem-use and hospital mortality (unadjusted risk ratio [RR]: 1.25, 95% confidence interval (CI)[0.98, 1.61], p=0.078 and adjusted RR: 1.02, 95% CI [0.77, 1.35], p=0.888).
CONCLUSION. Approximately half of the patients with sepsis received a carbapenem-class antibiotic in the initial antibiotic therapy in Japanese ICUs. The rate of carbapenem-use for sepsis varied among ICUs. Carbapenem-use was not associated with hospital mortality.

The prognostic role of hyponatremia and hypernatremia in sepsis and respiratory tract infection-related sepsis (RTI-r): a sub-group analysis of the Need-Speed trial

F. Gavelli, M. Baldrighi, F. Patrucco, GC. Avanzi, LM. Castello

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001045

INTRODUCTION. Early risk stratification of septic patients presenting to the emergency department (ED) is challenging. Many biomarkers have been studied to help the emergency physician to accomplish this goal, with encouraging results. However, some biomarkers are not readily available in the ED setting. On the other hand, biochemical analyses are routinely performed, giving useful information. The aim of the study was to evaluate the prognostic value of plasma sodium concentration (pNa+) derangements at the ED presentation in a population of septic patients.
METHODS. This study is a subgroup analysis of the Need-Speed database, a multicenter observational study that included consecutive patients with suspicious of sepsis admitted to the ED of five Italian hospitals between March 2013 and March 2015 and in which several biomarkers were evaluated. The aim of this subgroup analysis was to evaluate the prognostic role of pNa+ derangements in patients with sepsis and particularly in those in which sepsis was related to respiratory tract infection (RTI-r sepsis). Mortality was evaluated at 7 and 28 days according to the presence of pNa+ derangements (hyponatremia and hypernatremia) and subsequently according to the severity of hyponatremia. Then, the same analysis was performed only in patients with RTI-r sepsis.
RESULTS. Among the 1132 patients of Need-Speed, 879 septic patients were included in this analysis. A pNa+ derangement was present in 48.7% of patients (40.3% hyponatremia, 5.7% hypernatremia). Mortality was significantly higher at 7 days in dysnatremics compared to eunatremics (11.9% vs 7.5% p=0.038) but not at 30 days (p=0.082). When patients were analyzed in terms of typology of pNa+ derangements, only hypernatremia resulted significantly associated to mortality, at both end-points (p<0.001). The Cox regression hazard model showed that both hypernatremia and hyponatremia were independent predictors of 7-day mortality (HR 3.51[1.67-7.38] and 1.80[1.02-3.18], respectively) but only hypernatremia remained significant at 30 days (HR 1.94[1.07-3.53]). Survival analysis of non-hypernatremics showed that moderate-to-severe hyponatremia independently predicted mortality both at 7 and 30 days (HR 5.92[2.83-12.39] and 1.84[1.03-3.28], respectively). In patients with RTI-r sepsis (n=549) similar results were observed as for the overall population.
CONCLUSION. Both hypernatremia and hyponatremia at ED admission are early predictors of mortality in septic patients. Thus, detection of pNa+ derangements should be part of the initial management and risk stratification of such patients in the ED.

INTRODUCTION.
Sepsis and septic shock (SS) have been shown to be associated with substantial mortality and can lead to the consumption of a significant amount of health care resources. Recognition of SS risk factors and early intervention of proper broad-spectrum antimicrobial administration may significantly improve the outcome. Selective Digestive Decontamination (SDD) has been associated with reduced ICU mortality and acquired infection rates and its use could also modify SS risk factors.
OBJECTIVES. To analyze SS risk factors in patients with nosocomial infection (NI) in an ICU after seven years of SDD.
METHODS. Prospective study. Patients with NI were included from October 1, 2010 to September 30, 2018 in a polyvalent ICU of 30 beds. SDD was applied for 7 years, from October 1, 2011 to September 30, 2018. Patients requiring mechanical ventilation for more than 48 hours , an enteral solution and a paste with colistin, tobramycin and nystatin every 8 hours until discharge were applied. Also intravenous cefotaxime were administered during the first 4 days. Rectal and pharyngeal exudates were collected on admission and weekly. The categorical variables were summarized in frequencies and percentages and the numerical variables in means and standard deviations or in medians and interquartile ranges. The percentages were compared with the X2 test or the Fisher exact test, the means with the t-test and the medians with the Wilcoxon test for independent data. A multidimensional logistic analysis was carried out. It was considered significant if $p \leq .05$.
RESULTS. Of 7240 patients admitted, 286 (56,7%) out of 504 patients with NIs developed septic shock (SS). In an univariate analysis had statistically significant SS, *Acinetobacter baumannii* NIs (p: 0.009) and multiresistant (MR) *Pseudomonas* NIs (p< 0.001). ICU stay (p: 0.003) and mortality (p< 0.001) were significantly higher in patients who developed SS (Table 1). Independent factors associated with SS were: urgent surgery, renal replacement therapy, nosocomial pneumonia, and secondary bacteremia (Table 2).
CONCLUSION.
In an ICU with SDD, factors that were independently associated with SS were: urgent surgery, renal replacement therapy, nosocomial pneumonia, and secondary bacteremia. MR *Pseudomonas* and *Acinetobacter baumannii* NIs were also associated with higher development of SS.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001068

INTRODUCTION. De-escalation (DE) is a strategy to replace empirical broad-spectrum antimicrobial treatment by using a narrower antimicrobial therapy. Some studies has no impact on mortality in patients with sepsis and/or septic shock,.We assess the appropriate use of antibiotics and their DE along 6 years, in an ICU with Selective Digestive Decontamination (SDD).
METHODS. In a 30 bed mixed ICU from October 1, 2011 to September 30, 2017 nosocomial infections were prospectively collected. Etiology, inflammatory response to infection, antibiotic treatment (ATB T) and treatment modifications according to culture results, were analyzed. SDD was applied to patients requiring endotracheal intubation over 48 hours.We performed a univariate and a logistic multidimensional DE analysis. P was significant if was $\leq$ .05.
RESULTS. DE was done in 113 out of 338 patients. Demogaphic data is shown in Table 1. Mortality was lower in patients receiving DE ATB (24.8% vs. 46.1%, p< 0.001). In the multivariate study
parenteral nutrition (PN), catheter-related bacteremia (CRB), pneumonia (NN), ICU mortality and septic shock were statistically significant (Table 2).The ATB T was inadequate in 95 infections (16,1%).Targeted therapy was performed in 254 infections (43,1%). Also 87 patients with septic shock had DE.The number of antibiotics used was 1025 and in 158 ATB DE were performed. Fifty-three patients with CRB (46.9%) and 50 with NN (44.2%) had DE. The ATB T was inadequate in 95 infections (16,1%).Targeted therapy was performed in 254 infections (43,1%). Also 87 patients with septic shock had DE. The number of antibiotics used was 1025 and in 158 ATB DE were performed. The most DE ATB were levofloxacin (22,.37%), meropenem (18.3%) and linezolid (15.38%).
CONCLUSION. ICU patients who received, compared to those that did not received DE, had a significantly lower mortality. Factors independently associated to DE were in addition to ICU mortality, PN, septic shock, CRB and NN.Inadequate ATB T was applied to 16,1% of NI. Finally, the most commonly DE ATB were levofloxacin.

Mitochondrial derangement contributes to abnormal platelet function in septic patients

E. Greco[1], O. Bosco[2], B. Vizio[2], G. Montrucchio[2], E. Lupia[1]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001118

INTRODUCTION. Abnormal platelet count and function are markers of poor prognosis in sepsis and may be involved in organ failure. However, underlying mechanisms have not been fully explained. Mitochondrial dysfunction has been widely recognized both in septic patients and laboratory models and has been shown in different organs and blood cells.

OBJECTIVES. To evaluate the role of septic plasma in modulating human platelet mitochondrial function in vitro, independently from hemodynamic alterations.
METHODS. Platelets were collected from healthy donors. Isolated mitochondria were obtained from platelet-rich plasma (PRP) and protein concentration was measured. 30-mcg samples were incubated with plasma collected from septic patients or healthy donors for 1 minutes at 37°C (N=5 or 6). Afterwards Complex I (CI) and citrate synthase (CS) activity were measured with Sinergy HT microplate reader (Bio-Tek Instruments, Winooski, VT) in duplicate. CI was calculated according to Spinazzi et al. protocol [1] and normalised to CS activity. We also analysed platelet aggregation as a marker of platelet function, with light transmission aggregometry (LTA) after incubation with either septic or control plasma.
RESULTS. Complex I activity was significantly reduced after incubation with septic plasma (Figure 1). As previously shown in burned patients [2], we confirmed the priming effect of septic plasma on different agonist involved in platelet aggregation in vitro. Inverse correlation between mitochondrial CI activity and in vitro aggregation was statistically significant (Figure 2).
CONCLUSION. Circulating factors in septic plasma affect platelet mitochondrial function. Moreover, mitochondrial derangement correlates with increased aggregation. Microthrombi formation has been suggested as a possible mechanism of organ failure. Protecting against humoral factor could improve haematologic and possibly multi-organ failure in sepsis.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001128

INTRODUCTION. Sepsis induced cardiomyopathy (SICM) is defined as a new onset myocardial dysfunction during sepsis that is reversible within days to weeks, this condition was first described in 1984 by Parker, et al. (1, 2). While the pathophysiology leading to SICM is now known to involve a complex interplay of cytokines, endotoxin, nitric oxide and autonomic dysfunction, it remains a poorly understood entity (3,4). In addition, development of SICM is also known to be a risk factor for increased mortality, yet specific management is not clear (5, 6). SICM does not include right ventricular dysfunction (RVD) in its definition and the presence of RV failure has unclear effects on patient outcomes. We aim to clarify the prevalence of RV dysfunction in SICM.
METHODS. A retrospective chart review study was designed to review patients admitted to the medical intensive care unit (ICU) with a diagnosis of sepsis from January 2016 to December 2017. Patients were included if an echocardiogram showing an ejection fraction (EF) $\leq$ 50% within 72 hours of diagnosis of sepsis was available. A comparison echocardiogram, before or after the sepsis episode, was used to characterize patients into SICM from those with preexisting reduced EF. Patients with acute coronary syndrome or significant valvular dysfunction were excluded. Descriptive statistics and multivariate logistic regression was used to analyze the data
RESULTS. We analyzed 580 patient charts, of which 38 met our inclusion criteria, with SICM being diagnosed in 19 patients. Patients with SICM had a mean age of 64 (SD 17.5) and were predominantly male (63%). The prevalence of RVD was 73.6%. Troponin leak was higher in patients with SICM and RVD 1.103 (0.143 – 1.131) vs 0.017 (0.006-0.024), p=0.006. On average, over a day had elapsed from admission

to TTE. However, the presence of RVD in patients with SICM did not have a significant effect on mortality.
CONCLUSION. Most patients with SICM have biventricular failure upon diagnosis, despite the high prevalence of RVD in our cohort we suspect that this is still underestimating the actual cases of biventricular failure due to delays in obtaining initial TTE. While the presence of RVD did not impact our patient mortality, this might be a result of our limited sample size and its presence might have important implications in management. Its inclusion into diagnostic definitions might increase its recognition and the overall diagnoses made, approaching the actual prevalence of SICM.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001142

INTRODUCTION. Recent studies have shown that the use of AI and ML techniques have improved the detection of sepsis (SE) and septic shock (SS) compared traditional models.
OBJECTIVES. Development of predictive models for the detection of sepsis using AI-ML techniques.
METHODS. We used AI-ML techniques from historical data from the Electronic Health Record (EHR) in a University Hospital with 450 beds. Retrospective asessed, but the validation of the cases with the diagnosis of SE/SS was made prospectively by the clinical experts of the Multidisciplinary Sepsis Unit within the Code Sepsis Program. We used a SEPSIS.2 definition. The predictive variables that make up the models come from different sources of structured data (clinical, analytical, pharmacological data), as well as from non-structured text from the Triage and Emergency Department (ED) reports. The Mann-Whitney-Wilcoxon test was used to identify statistically significant clinical and analytical variables, with a significance level of 0.01. And to obtain relevant unstructured data Natural Language Processing techniques. The total sample was divided into 2 groups: the 5/7 proportion of the total of randomly selected records constituted the training set and the rest of the records (2/7) formed the test set.
RESULTS. From JAN-2014 to OCT-2018, 815,170 records of the EHR have been analyzed. We included 218,562 adult patients from all areas of Hospital (78% from ED) divided into 2 groups: 1) 9301 (4.6%) had SE/SS; and 2) 209,261 (95.4%) who did NOT have sepsis. A total of 3,927 variables have been extracted from the different data sources. By relevance 244 (6.2%) variables associated with SE/SS have been selected. We have analyzed 5 predictive models: Sepsis.2, SEPSIS.2 plus qSOFA, general ML (IIC), ML + Sepsis.2 (BISEPRO), ML + Sepsis.2 + qSOFA (COMBINED), Table I and Figure 1. BISEPRO was the best approximation of the resulting prediction that offers an AUC-ROC of 0.95 (95% CI 0,94-0,96).
CONCLUSION. The use of predictive models based on AI-ML and has provided more dynamic and precision models for the detection of patients with SE/SS.

Prognostic implication and adverse events associated with very high-dose norepinephrine in septic shock patients

C. Barreiros, M. Abecasis, J. Martins, S. Fernandes
Serviço Medicina intensiva, Hospital de Santa Maria, Lisboa, Portugal
Correspondence: C. Barreiros
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001154

INTRODUCTION. Management of severe septic shock is controversial, particularly regarding the use of corticosteroids, thiamine, high-dose norepinephrine (NE) or combination with other vasopressors. Regarding the administration of NE, there is no clear recommendation for maximum dosage, although certain authors refer that doses above 2 μg/kg/min might be ineffective and associated with adverse drug events.
OBJECTIVES. To study the median dose of NE perfusion in patients diagnosed with septic shock, to evaluate the need of very high dose of NE (here defined as dose > 1 μg/kg/min) and assess it in terms of duration, adverse reactions, clinical complications and mortality.
METHODS. 31-bed level II-III Intensive Care Unit, tertiary university-affiliated urban hospital. Retrospective analysis and protocol-driven data collection from all patients admitted with a diagnosis of septic shock from 16.09.2018 to 24.01.2019: SAPS II and SOFA scores, hemodynamic variables, adequacy of antimicrobial therapy,

associated organ failure (respiratory and need for mechanical ventilation, kidney failure and need for renal replacement therapy), use of adjunctive therapies (hydrocortisone, thiamine), use of albumin and other vasopressors (epinephrine, terlipressin) or inotropes (dobutamine), lactate clearance, fluid balance and ischemic complications. Mortality was the primary clinical outcome. We performed a descriptive statistical analysis using non-parametric tests, as well as regression analysis as appropriate. Significance was defined as a p value < 0.05.

RESULTS. In a preliminary analysis we included 62 patients. Median age was 68 years (IQ range: 58-77), median SAPS II was 65 (45-81). Overall mortality was 49.2%. Median maximum dose of NE was 1.4 μg/kg/min (IQ range: 0.7-2.7), administered for a median time of 5 hours (IQ range: 2-7). In the majority of patients, maximum dose of NE was administered during the first day of disease, and titration above 0.5 μg/kg/min was used in 80% of patients. Patients who needed higher doses in order to achieve target perfusion pressure tended to be more severe (Coef. 0.04; *p< 0.001*) and younger (-0.03; *p=0.02*). Subgroup analysis revealed a mortality of 64% in patients treated with NE dose higher than 1.0 μg/kg/min and a mortality of 75% in patients treated with a NE dose higher than 2.0 μg/kg/min. We did not identify higher incidence of splanchnic (OR 1.1; p=0.947) or digital ischemia (OR 1.3, p=0.47) from high dose of NE.

CONCLUSION. Septic shock remains a condition with ominous prognosis. Although doses higher than 2.0 μg/kg/min mark a very high risk of death, we still believe that doses in this range could be used for a short period of time, during the first day of disease and with young patients, in order to revert refractory septic shock.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001156

INTRODUCTION. Prompt diagnosis and initiation of appropriate antimicrobial therapy can improve morbidity and mortality in patients affected by sepsis or septic shock. Rapid diagnostic tests that can accurately identify the pathogen causing an infection and the effective antimicrobials would increase the likelihood that patients are treated appropriately. In addition, rapid diagnostic tests can also be used to help clinicians discontinue or de-escalate antimicrobial therapy in favor of narrower-spectrum options. The Accelerate Pheno system is a new diagnostic device that can provide rapid bacterial identification and antimicrobial susceptibility test results directly from a positive blood culture.

OBJECTIVES. To evaluate the role of Accelerate Pheno system in the management of septic patients in a hospital with an antimicrobial stewardship program.

METHODS. At San Giovanni Hospital in Rome, positive blood cultures from septic patients were loaded onto the Accelerate Pheno system. The results were immediately communicated to the infectivologist for the consequent therapeutic choices. Results obtained from the Accelerate Pheno system were also compared to those of the usual standard of care.

RESULTS. Twenty positive blood cultures taken from septic patients were analyzed with Accelerate Pheno™ system from June '18 to March '19. Results were obtained from the microbiology laboratory after an average of 1.1 days versus an average of 2.95 days using conventional methods. The isolated organisms were: 6 S. aureus (3 MRSA), 6 Enterococcus spp, 5 E.coli (2 ESBL +), 2 K. pneumoniae KPC, 1 coagulase negative Staphylococcus spp. No identification errors or discrepancies in antimicrobial susceptibility test report were observed when compared to conventional methods. The infectivologist was able to establish a targeted therapy in 65% of cases, de-escalate the antibiotic therapy in 25%, and confirm empirical therapy in 10% of cases.

CONCLUSION. In septic patients, the Accelerate Pheno™ system seems to represent an effective method to obtain not only a rapid and accurate microbiological diagnosis, but also to optimize antimicrobial therapy within the context of antimicrobial stewardship principles.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001308

INTRODUCTION. Respiratory infection is a major cause of admission at Pediatric Intensive Care Unit (30-70% of admissions depending on the season). Differential diagnosis between viral and bacterial pneumonia still is a problem in pediatric population: clinical data is unspecific and Torathic X-Ray (TXR) has its limitations. Lung ultrasound (LUS) would have a better sensibility and specificity for pneumonia diagnosis, as it has been demonstrated in adult patients.

OBJECTIVES. To compare the usefulness of LUS (sensibility and specificity) with respect to TXR, for the diagnosis of severe community and nosocomial pneumonia. To analyze if LUS implementation could decrease the TXR indication.

METHODS. Prospective, randomized, blinded and interventional clinical trial, developed between June 2017-march 2019. Inclusion criteria: patients (7 days-18 years) with suspected community (CP) or nosocomial pneumonia (NP) admitted at PICU. Exclusion criteria: previous severe respiratory disease (bronchopulmonary dysplasia, cystic fibrosis…), immunodeficiency, non-acceptance of informed consent. Pneumonia diagnosis was based on clinical signs, radiological findings (group 1-experimental: LUS initial diagnosis; group 2-control: TXR initial diagnosis) and analytical data. Images were assessed by both, the paediatric investigator who was blind to the LUS or RXT, and the radiologist, blinded to clinical data. Statistics: spps 22.0. Trial design was accepted by the Institutional Research Board and the Ethical Committee.

RESULTS. There were recruited 112 cases; males 64 (57.1%), mean age: 21.14 months. Patients randomization: group1-LUS= 59 (52.7%), and group 2-TXR= 53 (47.3%).

Final diagnosis in CP suspicious (n=78) was: bacterial pneumonia in 28 patients, viral pneumonia in 22, and no pneumonia in 20. The sensitivity and specificity of LUS for CP was 98.7% and 87.2%, and 90.2% and 73.3% for TXR. LUS allowed an early diagnosis than the

TXR in 28 patients. The number of TXR in group 1-LUS resulted in 1.8/patient, with respect 2.5 in group 2-TXR, p= 0.075.
NP was confirmed in 21 of the 34 with initial suspicious. Sensitivity and specificity were also higher for group1-LUS than for TXR (96.7% and 85% vs 89.2 and 74%); with an early diagnosis for LUS in 18 patients; and lower rate of TXR in group1-LUS (2.1 vs 2.7, p= 0.084).
CONCLUSION. LUS showed better sensitivity and specificity for the diagnosis of CP and NP than TXR in this preliminary analysis. LUS seemed to allow an early diagnosis of pneumonia in some cases. LUS could lead to a lower irradiation of paediatric patients.

Ventilator Induced Diaphragmatic Dysfunction in ICU: incidence, impact on morbidity, mortality and weaning outcome

D. Panda, B. Manmohan, K. Manoj, KS. Tapas
Critical care medicine, Medanta hospital, Ranchi, India
Correspondence: D. Panda
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001331

INTRODUCTION. Diaphragmatic dysfunction (DD) has been reported to occur in 40- 60% of patients in ICU.1 This impairs the ability of respiratory pump to compensate the increased demand during acute illness resulting in increased the morbidity and mortality. Early recognition may help to optimize treatment strategy and assist in prognostication.2 Optimal timing of weaning is crucial. Clinical predictions are often incorrect. Ultrasound has emerged as an inexpensive, easily available and reproducible, bed-side tool for assessment of DD.1
OBJECTIVES. To assess incidence of DD till first spontaneous breathing trial (SBT), to identify the risk factors and to evaluate its impact on weaning outcome, mechanical ventilation (MV) days, ICU length of stay (LOS) and 28 day mortality.
METHODS. A prospective observational, study in an 18 bed multi disciplinary ICU of a tertiary care, teaching hospital between November 2018 to March 2019. All consecutive adult patients requiring MV during the period were included in the study. These patients were screened for DD on the day of intubation and then on every 3rd day till first SBT. They were followed up till 28 days or death. Patients with neuromuscular disorder, thoracic or abdominal surgery and patients extubated or died before 48 hr of MV were excluded. Data on patient demographics, ICU LOS, days on MV, 28 day mortality and result of first SBT were collected. Risk factors analyzed were sepsis on admission, duration of assist control ventilation, sedation and paralytic infusion duration, hyperglycemia requiring insulin infusion, steroid use and use of polymyxins.2,3 DD was assessed by ultrasound measurement of diaphragmatic thickness index (DTI) by a linear high frequency ultrasound probe, placed between 8-9th intercostal space near the zone of apposition of diaphragm.1 All patients were cared following standard ICU protocols and guidelines.
RESULTS. 233 patients were screened, 47 were excluded either due to extubation or death before 48 hours. 23 patients left in between the study period. The incidence of DD was 47.8% (n=78/163) using the criteria of DTI < 30%. Out of various risk factors analyzed, increased risk of DD was observed with sepsis on admission (Odds ratio 6) and use of paralytic infusion (odds ratio 16). Patients with DD had higher failure rate on their first SBT (79.4% vs. 34.1%) with relative risk of 2.32. Patients who had DD had higher ICU LOS (9.9+4.3 vs. 7.71+3.8 p=0.04). There was no significant difference in MV days in both the groups. Patients with DD had higher 28 days mortality (26 vs.16 p=0.034)
CONCLUSION. The incidence of DD was 47.8% till first SBT. Sepsis and use of paralytic infusion were found to be the significant risk factors. Patients with DD had a significantly higher failure rate on first SBT, had a significantly higher 28 days mortality and ICU LOS with no difference in MV days.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001333

INTRODUCTION. Acute pancreatitis (AP) is an inflammatory condition of the pancreas with a broad clinical spectrum that can cause local injury, systemic inflammatory response syndrome and organ failure (1). The more severe cases often require management in an intensive care unit and are associated with significant morbidity and mortality (2). The objective of the present study was to analyse the outcomes of patients admitted with AP in the last 5 years to the intermediate and intensive care units (IntCU/ICU) of a single academic medical center.
METHODS. A retrospective review of the patients admitted from January 2014 to December 2018 was undertaken. A review of the medical records for each patient was performed.
The outcomes evaluated were mortality, the presence of organ dysfunction and the need for antibiotics.
The variables collected were provenience, time of stay in the emergency department (ED) before admission and severity scores [Ranson, Bedside Index of Severity in AP (BISAP), Acute Physiology, Age Chronic Health Evaluation II (APACHE II), Sequential Organ Failure Assessment (SOFA), CT Severity Index (CTSI) score].
The collected data was analysed using SPSS.
RESULTS. Ninety-four patients (male 61, mean ± SD age = 64.6 ± 18years) with AP were admitted to the IntCU/ICU in the 5-year period. The global mortality rate was 22,3%.74.5% of patients came from the ED, 25,5% came from the wards. Patients that came from the wards had a higher mortality rate when compared to those who came from de ED [39,1% vs 18,6% (p=0.044)]. The median time in the emergency room prior to admission was 13 hours (IQR 15). We found no statistical significant difference in mortality when evaluating time of stay in the ED (p=0.530).
Severity scores had a statistically significant correlation with mortality, with the exception of CTSI [APACHE II ≥ 8 (29,4% vs 3,8%; p= 0.008); SOFA ≥ 8 (60% vs 12,2%; p<0.001); Ranson ≥ 5 (36,0% vs 11,1%; p=0.012); BISAP ≥ 3 (35,9% vs 12,7%; p=0.008); CTSI ≥ 4 (33,3% vs 17,9%; p=0.129)] and a correlation with at least one organ dysfunction [APACHE II ≥ 8 (p<0.001); SOFA ≥ 8 (p<0.001); Ranson ≥ 5 (p<0.001); BISAP ≥ 3 (p<0.001); CTSI ≥ 4 (p=0.019)].
After excluding patients that needed antibiotics for other reasons, there was no statistical significant diference in the need for antibiotics for AP complications when analysing CTSI score severity [CTSI ≥ 4 (p=0.078)].
CONCLUSION. Severity scores were statistically significantly associated with mortality and organ dysfunction. We found no statistical

significant difference in mortality when evaluating time of stay in the ED and the need for antibiotics for AP complications when correlated to CTSI score severity. Mortality was twice higher when patients came from wards when compared to those who came from ED – this should draw our attention to this group of patients who may need earlier admission and intervention.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001343

INTRODUCTION. The 6-min walk test (6MWT) is a validated measure of physical function since the walked distance can reflect the capacity to undertake daily activities after ICU stay for acute exacerbation of COPD (AECOPD). Determination of association between functional variables and health-related quality of life (HRQL) may facilitate interpretation of disease progression and impacts of therapy.
OBJECTIVES. To evaluate the association between the health-related quality of life after ICU discharge and the 6MWT in AECOPD ICU admitted patients.
METHODS. A prospective observational cohort study was performed in a Tunisian 9-beds tertiary medical ICU between February 2017 and January 2018, including all consecutive survivors of AECOPD. The 6MWT is performed the day of ICU discharge according to the international guidelines. Web-based version of the St George's Respiratory Questionnaire score (SGRQ) was used to measure HRQL. The SGRQ variables (activity, symptoms, impacts) were collected within three months of ICU discharge via phone calls. Data collected : clinical features at admission, severity of illness and ICU course. Walked and predicted distances were calculated. Spearman rank correlation was used to measure the degree of association between mean walked/predicted ratio and the SGRQ score.
RESULTS. Among 90 patients admitted for AECOPD during the study period, 62(69%) were included. General characteristics were : age, 66.4±9.5 years; sex ratio, 4,5/1; Charlson index,3.9±1.8; COPD GOLD D, 55(88%); SAPSII score, 29.8±9.9; initial invasive mechanical ventilation, 17 (27.4%); mean length of stay, 13.64±10.09. Mean walked distance, 223±96m; mean ratio walked/predicted distance, 0.41±0.17. Three months after discharge, 58(93%)patients could be interviewed via phone. SGRQ estimation was as follow: median symptoms score, 59.3[43.6-75]; median activity score, 69[53.7-84.4]; median impacts score, 49[23.8-74.2] and median total score, 56.8[63.6-77]. Compared to population norms (Symptoms, 16.1; activity, 16.3; impacts, 8.1 and total score, 12.2). 6MWD was significantly correlated with all components of the SGRQ : symptoms, -0.43(-0.64 to -0.27), p= 0.001; activity, -0.53(-0.62 to -0.19), p<0.0001; impacts, -0.46(-0.69 to-0.32), p< 0.0001 and total -0.49 (-0.62 to -0.24), p< 0.0001.
CONCLUSION. 6-min walk distance at ICU discharge was associated with HRQL among survivors of AECOPD patients admitted in a Tunisian medical ICU.

Lowest admission pH and its association with Mortality in all-cause emergency and Diabetic ketoacidosis patients in a district general Critical Care Unit

D. Wright[1], J. Morris[2], T. Samuels[1], P. Morgan[1], M. Alice[3]
[1]Intensive care, East Surrey Hospital, Redhill, United Kingdom; [2]Intensive care, Croydon University Hospital, Croydon, United Kingdom; [3]Icu, East Surrey Hospital, Redhill, United Kingdom
Correspondence: D. Wright
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001355

INTRODUCTION. Decreasing pH and advancing age are associated with increased mortality in critically ill patients. Acidosis has various etiologies and is common amongst critically ill patients. It is associated with organ dysfunction and is therefore associated with worse outcomes. Diabetic ketoacidosis (DKA) is a common complication of diabetes mellitus which infrequently requires emergency admission to the critical care unit. The outcome in these patients are better as they are young patients with a greater physiological reserve.
OBJECTIVES. The primary aim of the study was to look at mortality related to the lowest initial pH amongst all-cause emergency admissions and DKA emergency admissions to the critical care unit. Secondary outcomes looked at the age-related mortality amongst the higher risk group, that is, pH ≤7.23.
METHODS. A retrospective analysis of all-cause emergency admissions to a 16-bed mixed critical care unit between 2013 and 2019 was done using our electronic patient database. Patients aged ≥18 years with an admission pH of ≥6.8 were included in the analysis. A subset of the emergency admissions admitted with DKA were analyzed separately. Wilcoxon rank sum test was used to test for significance using R version 3.5.3 (R Foundation).
RESULTS. There was a total of 5,416 all-cause emergency admissions, 2966 (54.8%) of which were male and 1630 (30.1%) were non-survivors. Of the non-survivors, the mean lowest pH was 7.22 SD 0.16 vs 7.32 SD 0.11 in the survivor group (p=<0.0001). Non-survivors were older (mean age 69.8 vs 61.9 years p=<0.0001) than those in the surviving group.
Of those emergency admissions, 99 (1.8%) were admitted with DKA, 10(10.1%) of which were non-survivors. There was no significant difference in pH between the survivors and non-survivors (mean pH 7.15 vs 7.15 p=0.8724). The non-survivors were older than the survivors (63.8 vs 46.4 years p=0.0016).
CONCLUSION. PH and age are inversely proportional to mortality amongst all-cause emergency admissions to the critical care unit. In the DKA patients, however, there was no difference in the pH related mortality. This subset was limited by the small sample size and also the group sizes were unequal which may have led to a type II error. In both groups, the mortality was noted to be higher amongst the older patients. DKA typically presents in young patients with good physiological reserve and as such, this raises the question of whether Hyperosmolar Hyperglycaemic States were misdiagnosed as DKA.

Impact of Ramadan on ICU admission patterns and outcomes

I. Ben Saida[1], H. Kallel[2], S. Chaouch[2], R. Toumi[1], W. Zarrougui[1], M. Boussarsar[1]
[1]Medical intensive care unit, farhat hached university hospital, Université de Sousse, Faculté de Médecine de Sousse, LR N° LR12SP09.Heart Failure, Sousse, Tunisia; [2]Medical intensive care unit, Farhat hached university hospital, Sousse, Tunisia
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001356

INTRODUCTION. Fasting Ramadan is a religious obligation for muslims and one of the five pillars of Islam. Even though those unable to fast are exempt, many individuals refuse and chose to fast. This may lead to life threatening conditions and an increase in ICU demand.
OBJECTIVES. To investigate the impact of lifestyle changes during Ramadan on ICU admission patterns and outcomes.
METHODS. It was a retrospective cohort study carried out in a 9-bed medical ICU of Farhat Hached teaching hospital. Patients who were admitted to the ICU during the month of Ramadan, the preceding month (Chaaban), and the following month (Shawal) over a period of 10 years (2018–2009) were included. Underlying condition, severity of illness, diagnosis at admission, management and outcomes were recorded. Patients were divided into three groups according to the time of presentation in relation to the month of Ramadan. Demographic, clinical features and outcomes were compared between groups.
RESULTS. During the review period, 748 patients were included (G1= 257 ; G2=230 and G3=261). Patients' characteristics were : median age 57[35-71]years ; male, 438(58.6 %) ; median SAPSII, 30[20-42] ; median Charlson index, 3[0-5]. The main reason for admission were respiratory disorders, 408(54.4 %).
Patients with chronic kidney disease (CKD) as underling condition and hypovolemic Shock as clinical presentation were more frequently admitted during Ramadan and/or Shawal vs Chaaban respectively (8(3.5%), 19(7.3%), 6(2.3%) ; p=0.016) and (14(6.1%), 13(5%), 4(1.6%) ; p=0.031). Furthermore, patients during Ramadan and/or Shawal were more likely to have inverted urinary sodium to potassium ratio vs Chaaban respectively (94(48.7%), 77(36.8%), 58(28.3%) ; p=0.000). There was no significant difference in length of stay nor in mortality.
CONCLUSION. While there were no differences in any studied outcomes in patients admitted to ICU before, during Ramadan or after, there was a significant increase in patients presenting with history of CKD, hypovolemic shock and inverted urinary sodium to potassium ratio.

Swedish intensive care. Low number of beds, short length of stay. A description of resources and outcomes

L. Engerström[1], C. Agvald-Öhman[2]
[1]Department of anasthesia and intensive care, Vrinnevisjukhuset, Gamla Övägen, Norrköping, Sweden, Norrköping, Sweden; [2]Department of anaesthesia and intensive care, Karolinska University Hospital Huddinge, Stockholm, Sweden
Correspondence: L. Engerström
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001372

INTRODUCTION. The patients cared for in intensive care and the available resources differs between regions. Swedish intensive care is like in the other Scandinavian countries characterized by short length of stay and the number of intensive care beds is low.
OBJECTIVES. The objectives of the study is to describe the characteristics of Swedish intensive care patient characteristics and resources and describe the outcome measured as raw and risk-adjusted mortality.
METHODS. Data publicly available from the Swedish intensive care registry (SIR, www.icuregswe.org) for 2018 is presented. SIR covered 81/84 (96 %) of the Swedish general-, pediatric-, burns-, neuro- and cardiothoracic intensive care units, 100 % of the general intensive care units. Mortality data is imported to SIR from the Swedish National Population Register.
RESULTS. There were 527 ICU-beds in Sweden in 2018 with enough staff to be used for intensive care. That is 5.2 intensive care beds per 100 000 inhabitants. There were in mean 0.7 nurses and 0.7 assistant nurses per bed. The mean SAPS3 score was 56.2 while the intensive care mortality was 8.9 % and the 30-day mortality 19.2 %. The 30-day mortality rate has previously been shown to be higher than the in-hospital mortality rate. The standardized mortality rate (SMR) using SAPS3 general formulae and 30-day mortality as outcome was 0.63. A Swedish recalibration of the SAPS3 is therefore used for comparisons in Sweden.

CONCLUSION. The Swedish intensive care is characterized by low number of beds and high SAPS3 scores, but neither raw- or risk-adjusted mortality rates are high.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001384

INTRODUCTION. Patients admitted to intensive care unit (ICU) often have at least one or more organ failures that require special care with high mortality risk.
OBJECTIVES. The aim of the present study was to determine ICU mortality rate and associated risk factors in a Tunisian medical ICU.
METHODS. A prospective observational cohort study over an eighteen-month period from September 15th, 2015 to March 15th, 2017 in a medical intensive care unit of FarhatHachedUniversity Hospital (Sousse-Tunisia). Were included all patients hospitalized for more than 48 hours. Data collected were patients' demographics, clinical characteristics, therapeutics and outcomes. Multivariate analyses were performed to identify risk factors associated with ICU mortality.
RESULTS. 258 were included, they were 60.1±17.7yrs mean aged, predominantly male, 161(62.4%); with at least two comorbidities, 145(56.2%); immunocompromised, 26(10.1%); Charlson Score Index>3, 45(17.4%). SAPSII>30 on admission, 119(46.1%); 186(72.1%) needed mechanical ventilation. Median[IQR] mechanical ventilation duration, 7[4-12.5]days with median[IQR] length of stay, 8[4-17]days. Mortality rate was 37.2%. In multivariate analysis, risk factors associated to ICU mortality were the occurrence of healthcare-associated infections (RR,7.1,95%CI,[2.6-19.6]; p<0.0001), and non-invasive ventilation failure (RR,13.0, 95%CI,[4.5-38.0]; p<0.0001).
CONCLUSION. The present study conducted in a medical ICU identified healthcare-associated infections and non-invasive ventilation failure as independent risk factors associated with ICU mortality.

Predictors of 6-month mortality in elderly ICU survivors

H. Zorgati[1], I. Ben Saida[2], N. Fraj[2], MA. Boujelbèn[1], W. Zarrougui[2], K. Meddeb[2], M. Boussarsar[2]
[1]Medical intensive care unit, Farhat hached university hospital, Sousse, Tunisia; [2]Medical intensive care unit, farhat hached university hospital, Université de Sousse, Faculté de Médecine de Sousse, LR N° LR12SP09.Heart Failure, Sousse, Tunisia
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001386

INTRODUCTION. Worldwide there is an increase in the life expectancy and thus an increasing of ICU demand for elderly patients. However, little is known about their long-term outcomes after ICU discharge.
OBJECTIVES. To evaluate outcomes and risk factors associated with 6-month mortality after ICU discharge in elderly patients.
METHODS. It is a mixed method study conducted in a 9-bed medical ICU from January 2016 to January 2017 including all old ICU survivors (≥65years). Information regarding demographic and clinical characteristics were obtained from medical records. At 6 months post-ICU discharge, follow-up was performed by phone-calling patients or their families. Univariate and multivariate analyses were carried out to identify predictors of 6-month mortality after ICU discharge.
RESULTS. Among 178 old patients admitted during the study period, 94 patients were discharged alive. Baseline characteristics of elderly ICU survivors were: median age, 74[69-77]years ; median Charlson score, 4[4-5] ; Knauss C or D, 71(75,5%) ; Mac Cabe≥2, 42(44,7%) ; median SAPSII, 32[27-40] ; invasive mechanical ventilation (IMV) on admission 27(28,7%) and vasopressors use, 65(36,5%). The median length of stay was 8[5-15,5]days. Among the elderly ICU survivors, 27 could not be contacted by phone and 21 died within the 6-month period after discharge. Figure 1 displays the Kaplan-Meier survival curve in elderly ICU survivors at 6 months. Univariate analysis identified factors associated to 6-month mortality after ICU discharge respectively: Knauss C or D (95,2% vs 67.4%, p=0.013) ; history of arrhythmia (38,1% vs 10,9%, p=0,023) and prolonged ICU stay(≥15 days) (42.9% vs 17.4%, p=0.026). Multivariate regression model identified the following factors as independently associated to 6-month mortality: Knauss C or D (OR, 9.01 ; 95%CI, [1.03-78.53] ; p=0.026), history of arrhythmia (OR, 6.12 ; 95%CI, [1.42-26.42] ; p=0.015) and prolonged ICU stay (OR, 4.3 ; 95% CI, [1.15-16.21] ; p=0.03).
CONCLUSION. Knauss C or D, history of arrhythmia and prolonged ICU stay were identified as risk factors associated with 6-month mortality of elderly ICU survivors.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001395

INTRODUCTION. Several studies show that in the event of bed shortage, admissions and discharges are triaged, and shortens length of stay (1-5).
OBJECTIVES. Relational analysis of the bed occupancy level in the ICU with respect to admissions and discharges and their possible effect on the length of stay of patients.
METHODS. An observational, prospective study was performed on patients admitted from October 1, 2015 to April 30, 2018 in the medical-surgical ICU of the Hospital Complex of Navarra, with 24 beds. Variables such as age, APACHE II on admission and type of admission (elective surgical patient, urgent surgical patient, emergency medical patient, polytrauma, hospitalized in medical service, hospitalized in surgical service and others) are also included. Markov chains transition matrices are used to analyze the probabilities of changing the bed occupancy, globally and according to an occupation level. On the one hand, the percentage of each change in the occupation level is calculated with respect to the possible total changes that take place, that is, considering 17 beds occupied, moving to 19 beds in the following day represents 0,74% of the total of all possible changes for all beds and occupations. And on the other hand, the percentage of each change considering only the movements that occur in a given occupation level, of all changes that occur with 17 occupied beds, moving to 19 beds in the next day has a probability of 11,3%. Multivariate analysis of the relationship between the length of the stay and bed occupation at the time of patients' discharge was carried out, adjusting for the rest of variables studied. Statistical significance $p < 0,05$.
RESULTS. We analyzed 2217 patients. Average age of 62,9 years (SD 14,8), APACHE II of 14,2 points (SD 8,1), length of stay of 7,7 days (SD 12,7, median 3,0) and occupation at the time of discharge of 19,4 beds (CI 19,3-19,6, median 20), with 17,2% of > 22 beds occupied and 8,2% of> 23 beds. In the analysis of the probabilities of transitions in bed occupancy, it is observed that, given an initial occupation, it is most likely to stay the next day at that same level. In addition, given an occupation level, there is more probability of admitting a new patient than of discharging up to 21 beds, where the trend is reversed being statistically significant. The multivariate analysis in terms of length of stay was significant only for occupations > 23 beds (-2,4 days, CI -4,5- -0,2). APACHE II (0,2 days, CI 0,1-0,3), urgent surgical patient (3,2 days, CI 1,1-5,3), polytrauma (6,4 days, CI 3,9-9,0) and the admitted medical patient (3,6 days, CI 1,5-5,8) were also significant.
CONCLUSION. Above 85% occupancy, bed management is observed, which involves triage of admissions and discharges. The influence of the occupation level on the patient's length of stay is only significant at maximum occupation.

Are we documenting enough? Improving documentation for 'out of theatre' emergency endotracheal intubation in large UK District General Hospital

S. Islam, M. Singh, Y. Li
Anaesthetics, Royal Wolverhampton NHS Trust, Wolverhampton, UK, United Kingdom
Correspondence: S. Islam

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001399

INTRODUCTION. Endotracheal intubation for airway control is performed in emergency situations and should be documented post procedure. The United Kingdom Intensive Care Society (UKICS) recommends using an invasive procedure checklist and post intubation document. Within Royal Wolverhampton NHS Trust exists an emergency intubation checklist, however documentation of events is variable between clinicians. We have created a standardised method of documentation using a 'blue sticker' which follows a similar structure to the UKICS post intubation document. It provides a clear, concise and cost effective method of recording important information regarding intubation which can be easily identified in the case notes with a lower risk of misplacement.
OBJECTIVES. Improve use of the emergency intubation checklist and documentation of rapid sequence inductions in a clear and concise manner.
METHODS. Retrospective review of 28 case files for emergency intubations from May to July 2018. We assessed nine important categories; Rapid sequence induction (RSI), use of intubation checklist, laryngoscopy grade, endotracheal tube (ETT) parameters (size, length and confirmation), and administered drugs (name, dose and additional). The data was input into a spreadsheet and analysed, producing graphs for interpretation. The project was re-evaluated in February 2019 to measure improvements following the introduction of the sticker. 22 case files were reviewed and anaylsed using the same methodology.
RESULTS. Comparisons between the two data sets showed similar indications for intubation. The leading cause was following cardiac

arrest (32%) in both sets of data. Documentation of the subcategories all improved individually, with the largest improvements in additional drugs used (41%), drug dose (34%), and tube confirmation (33%). The sticker was used in 23% of the case note after the first round of implementation. The use of the checklist had also improved by 24%. Prior to introduction of the sticker, 11% had no documentation of events, and 0% covered all 9 categories. After implementation, 23% had all 9 categories documented. The lowest number of categories documented was 2 (5%).There was also an improvement in the mean number of categories from 4.35 to 6. The mode and median improved from 5 and 6, to 6, and 5 to 6 respectively.
CONCLUSION. Before the project, documentation varied between clinicians, but was poor overall. After introduction of the 'blue sticker', there has been a great improvement. When the sticker is used documentation has been clear and easily identified in the case notes containing all essential information. Improvement in training clinicians to use the resources available will improve this further.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001400

INTRODUCTION. Health care associated infections in the intensive care setting (ICU-HAIs) presenta worldwide medical challenge, increasing the need to implement national and international surveillance strategies.
OBJECTIVES. The objective of the present study was to determine incidence and risk factors of ICU-HAIs in a Tunisian medical ICU.
METHODS. A prospective observational cohort study, going from September 15th, 2015 to March 15th, 2017, in a medical intensive care unit of Farhat Hached UniversityHospital (Sousse-Tunisia). Data collected were patients' demographics, clinical characteristics, therapeutics, HAIs incidence rate. HAI definitions and incidence rates were carried out using the Centers for Disease Control and Prevention National Health-Care Safety Network (CDC/NHSN) recommendations. Univariate and multivariate statistical analyses were carried out to determine ICU-HAIs risk factors.
RESULTS. During the study period, 258 patients were included. They were 60.1±17.7yrs mean aged, predominantly male, 161(62.4%); with at least two comorbidities, 145(56.2%); immunocompromised, 26(10.1%); Charlson Score Index >3, 45(17.4%). Antibiotherapy prior to admission, 154(59.7%). SAPSII>30 on admission, 119(46.1%); 186(72.1%) needed mechanical ventilation. Median[IQR]ventilation duration, 7[4-12.5]days; median[IQR] length of stay, 8[4-17]days equating to 3.357 patient-days. Eighty four patients (32.6%) developed 112 HAIs, 33.4 infections/1000days of hospitalization. Ventilator Associated Pneumonia, 24.3VAP/1000ventilator-days; central-venous-catheter-associated infection, 27.5CVC-AI/1000CVC-days. Risk factors associated with acquiring ICU-HAI were length of stay≥7days (RR 9.42, 95%CI[2.33-38.08]; p=0.002), prolonged duration of sedation (RR,1.15, 95%CI,[1.02-1.31]; p=0.021), and non-invasive ventilation failure (RR,2.70,95%CI,[1.009-7.27]; p=0.048).
CONCLUSION. The present study showed higher ventilator associated pneumonia and central-venous-catheter-associated infection rates compared to International Nosocomial Infection Control Consortium report for 2010-2015. Length of stay>7days, prolonged sedation and non invasive ventilation failure were independent risk factors associated with acquiring ICU-HAIs.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001404

INTRODUCTION. Healthcare-associated infections (HAI) are a major cause of morbidity and mortality in patients admitted in intensive care.
OBJECTIVES. The aim of the present study was to determine mortality rate and associated risk factors in patients with HAIs in the intensive care unit (ICU).
METHODS. A prospective cohort study was conducted in a medical intensive care unit (ICU) at Farhat Hached University Hospital (Sousse-Tunisia), from September 15th, 2015 to March 15th, 2017. Were included all patients hospitalized for more than 48 hours. Surveillance was carried out till discharge or death. Data collected were patients' demographics, clinical characteristics, therapeutics. HAI definitions and incidence rates were carried out using the Centers for Disease Control and Prevention National Health-care Safety Network (CDC/NHSN) recommendations. Logistic regression was performed to identify independent risk factors of mortality in patients with HAIs.
RESULTS. 258 patients were included over the study period. They were 60.1±17.7yrs mean aged, predominantly male, 161(62.4%); with at least two comorbidities, 145(56.2%); immunocompromised, 26(10.1%); Charlson Score Index >3, 45(17.4%). Antibiotherapy prior to admission, 154(59.7%).SAPSII>30 on admission, 119(46.1%); 186(72.1%) needed mechanical ventilation. Median ventilation duration, 7[4-12.5] days with median length of stay,8[4 –17] days equating to3.357 patient-days. Eighty four patients (32.6%) developed 112 HAIs, 33.4 infections/1000 days of hospitalization. Ventilator Associated Pneumonia, 24.3 VAP/1000ventilator-days; central-venous-catheter-associated infection, 27.5 CVC-AI/1000CVC-days. Mortality rate in HAIs patients was at 63.1%. Ventilator associated pneumonia was identified by multivariate analysis as anindependent risk factor for HAI-associated mortality (RR, 17.1, 95%CI, [5.1-57.2]; p<0.001).
CONCLUSION. The present study showed Ventilator associated Pneumonia to be associated with HAIs mortality the in intensive care.

001411

Trends in the use of intensive care by very elderly patients in a Tunisian hospital

H. Zorgati[1], I. Ben Saida[2], D. Ben Braiek[1], S. Kortli[1], N. Fraj[2], W. Zarrougui[2], MA. Boujelbèn[1], M. Boussarsar[2]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001411

INTRODUCTION. Due to advancements in medical technology and management of illnesses in the past decade, an increasing proportion of critically ill patients are elderly. Given the limited healthcare resources available, admissions to intensive care in very elderly patients are often restricted. The benefits of an ICU hospitalization for those patients remain unclear.
OBJECTIVES. To describe trends of mortality of very old patients admitted in ICU during the last 9 years.
METHODS. A retrospective observational study was performed in a medical ICU at a tertiary hospital of Farhat Hached from January

2009 to December 2017 and included all patients aged 80 years or more. Comorbid illness, severity at admission, diagnosis, length of stay and outcomes were recorded from medical patients 'charts.
RESULTS. During the study period 2352 patients were admitted to ICU. 232(9, 98%) were older than 80 years. Patients demographic and clinical characteristic's were : median age, 83[81-85] ; male, 143(61.6%) ; median SAPS II, 40[33-51] ; median Charlson comorbidity score 5[2-6] ; Knauss C or D, 146(62,9%) ; MacCabe≥2, 193(83,2%) ; invasive mechanical ventilation (IMV), 168(72,4%) ; median duration of IMV, 3[2-8]days ; vasopressors use 154(66,4%) ; median length of ICU stay was 6[3-10]days. The mean reason for admission was respiratory disorder for 139(59, 9%). Overall mortality rate was 59.9%. Figure1 shows trends in mortality rates of ICU admissions and of very elderly ICU patients between 2009 and 2017.
CONCLUSION. The use of ICU by very elderly patients was similar throughout the 9-year study period. In-hospital mortality was consistently high in those patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001419

INTRODUCTION. Traditionally, health research has been conducted in "academic" or university-affiliated hospitals, whereas most patients receive care in "community" hospitals. However, the line between "academic" and "community" hospitals is blurring in terms of research involvement, as community hospitals increasingly prioritize research engagement in addition to clinical excellence. In this study nested within an international probiotics trial (PROSPECT: Probiotics: Prevention of Severe Pneumonia and Endotracheal Colonization Trial), we describe the contribution of Canadian community hospitals.
METHODS. In PROSPECT, we randomized critically ill patients with expected mechanical ventilation of ≥72 hours to receive either 1x10e10 colony forming units (CFU) of *L. rhamnosus* GG or an identical placebo, twice daily, to evaluate the effect of probiotics on infectious outcomes, diarrhea and other clinical endpoints. Trial participation was open to all interested centers. In this study, we compared trial metrics, patient demographics and outcomes between academic and community hospitals using t-tests and Chi-square, based on the first 2/3 of enrolled patients in PROSPECT.
Trial Registration: www.clinicaltrials.gov : NCT02462590
RESULTS. Of the 44 participating centers, 41 (93.2%) were Canadian and 7 (15.9%) were community ICUs. All academic hospitals were located in urban centres, whereas amongst the 7 community hospitals, only 1 was located in an urban center, 2 were in suburban areas, and the remaining 4 were located in smaller communities near urban centers. Of the 1766 trial patients that were analyzed, 189 (10.7%) were enrolled in community ICUs. Regarding trial metrics, patients in community ICUs were less likely than in academic ICUs to be coenrolled in other randomized trials or observational studies (9.0% vs 23.0%, p<0.001) whereas protocol adherence defined as patients receiving at least one dose of study product were similar between community and academic ICUs (88.1% vs 90.9%). Several patient characteristics were similar between community and academic ICUs, including proportion of female participants (34.9% vs 41.0%, p= 0.117) and illness severity (APACHE II score 21.1 vs 22.2, p=0.075). However, some patient characteristics were different between community and academic ICUs, including mean age (62.6 vs 59.9 years, p=0.036), and medical admission status (93.7% vs 76.5%, p<0.001). Regarding patient outcomes, ICU and hospital mortality rates were higher in community ICUs than in academic ICUs (29.1% vs 21.2%, p= 0.015) and (37.2% vs 27.3%, p= 0.006), respectively, whereas the proportions of patients with *C. difficile* colitis during ICU stay and post ICU stay were similar between community and academic ICUs (1.1% vs 1.8%, p=0.764) and (1.1% vs 0.9%, p = 0.686), respectively.
CONCLUSION. Community hospital engagement in ICU research can enrich study populations with more geographically diverse participants, thereby improving the generalizability of results, while simultaneously hastening trial completion.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001425

INTRODUCTION. Increasing complexity in the ICU environment represents a safety challenge. Medical errors are frequent, and their consequences can be fatal. One of the main sources of error is interprofessional communication within ICU team. Clinical debriefing, a process of formal reflection about our clinical practice, can improve processes, professional performance and safety culture. However, it is difficult to implement due to lack of knowledge and tools. TALK ® is a multiprofessional structured clinical debriefing tool designed to guide reflection in clinical teams to improve safety.
OBJECTIVES. To implement TALK® in the ICU setting and analyze its effect in culture safety.
METHODS. We designed a prospective and longitudinal study. TALK® tool was implemented in 2 different ICU in the same University Hospital. The implementation comprised 1h training sessions, focused discussions and distribution of materials (flashcards, posters).

Debriefing was considered a non-mandatory multidisciplinary phenomenon. Debriefing events were systematically registered following an interview with the team at the end of every shift. We also explored leadership and participation in debriefing episodes, improvement decisions agreed upon during debriefing and barriers encountered. Data were collected in 15-day periods for baseline, immediate (q week) and 3 months follow-up. Additional follow-up measurements are planned at 6, 12 and 24 months.
RESULTS. Data on 119 baseline and 114 immediate follow-up shifts have been collected. There have been 36 debriefings in 30 shifts among the two periods. Debriefing were performed in 13,5% of the shifts during pre-implementation period(n=16/119), and in 12,3% of the shifts in the post-implementation period (n=14/114) (not significant difference). However, consideration to do debriefing increased from 36,8% to 94% between the pre- and post-implementation period. Not having any issues to discuss was the main reason not to do debriefing in both periods. Debriefing was led mainly by nurses (72,2%), followed by physicians (13,8%), residents 8% and nurse assistants (5%). Three months follow up data results will also be available for presentation at the conference.
CONCLUSION. Implementation of TALK® tool was feasible and it was associated to an increase in the consideration to do debriefing during shifts, but not to an increase in performing debriefing in the immediate post-implementation period.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001297

INTRODUCTION. Bioimpedance vector analysis (BIVA) is a noninvasive, and rapid screening tool for estimation of fluid status in different populations, but there are scant data in critically ill patients.
OBJECTIVES. To evaluate the relationship of fluid balance assessed by percentage of fluid accumulation (%FA), a conventional tool, and by BIVA-derived variables, and to determine which parameter derived by BIVA is the best for predicting 28-day mortality.
METHODS. We conducted a prospective, clinician-blinded, observational study in patients admitted to medical ICUs with an expected length of ICU stay of at least 72 hours. We performed BIVA measurements and cumulative fluid balance calculation and recorded physiological variables on day 0, 3, and 7 after ICU admission. BIVA results included percentage of fat free mass hydration (%FFMH), and phase angle (PhA). The correlation between BIVA-derived values, %FA, and 28-day mortality were analyzed. The parameters that associated with 28-day mortality were identified, and the significant parameters then were analyzed using the area under the ROC (aROC) curve for searching the cutoff value to predict the mortality.
RESULTS. Sixty-nine patients were enrolled, with a mean age of 61 ± 21 year, and a mean Acute Physiology and Chronic Health Evaluation II (APACHE II) score of 23 ± 8. The median %FA were 7.04%, 9.9%, and 11.48% on day 0, 3, and 7 after ICU admission. Based on BIVA-derived values, the median %FFMH were 79.8 %, 79.6%, and 79.2%, and the median PhA were 4.9, 4.9, and 5.1, on day 0, 3, and 7 after ICU admission, respectively. According to 28-d mortality, no differences of %FA and BIVA-derived variables, which measured on D0, and D3 after admission between non-survivors and survivors. The median %FA on D7 was higher in non-survivors than in survivor [14.8% (10.9%, 24.1%) vs 6.9% (1.1%, 15.2%), $p = 0.003$]. The median PhA on D7 of non-survivors was 3.6 (3.2, 4.1), while that of survivors was 5.5 (4.6, 6.4) ($p < 0.001$). Whereas, the median %FFMH on D7 of non-survivors was not statistically different with that of survivors [79.2% (75.9%, 85%) vs 78.5% (74.4%, 82.3%), $p = 0.4$]. Phase angle of less than 4.5 on the 7th day after admission could predict 28-d mortality with the OR of 2.1, (95% CI 1.2–3.4, $P < 0.001$).
CONCLUSION. BIVA-derived variables, percentage of fat free mass hydration (%FFMH) and phase angle (PhA) had good correlation with percentage of fluid accumulation (%FA) on day 3 and day 7. Only PhA on the seventh day after admission were associated with the 28-day mortality. PhA of less than 4.5 might be used as cut-off value for guidance of fluid management in critically ill patients.

INTRODUCTION. The optimal dosing strategy of aminoglycosides (AG) remains debated in intensive care units (ICUs).
OBJECTIVES. We investigated the international practices of AG regarding dosing and therapeutic drug monitoring in ICU patients.
METHODS. A prospective, multicentre, observational, cohort study was conducted in 59 intensive care units (ICUs) across 5 countries. All patients admitted to the ICU and receiving AG therapy for septic shock were included in the present study.
RESULTS. We enrolled 931 patients (mean ± standard deviation (SD), age 63 ± 15 years, female 364 (39%), median SAPS II 51

((interquartile (IQR):38-65)) receiving AG as part of empirical (761, 84%) or directed (147, 16%) antimicrobial therapy for sepsis or septic shock. The AG used was amikacin in 625 (67%), gentamicin in 312 (34%) and tobramycin in 15 (2%) patients. Aminoglycosides were mainly used for pulmonary (405, 44%), abdominal (233 (25%), urinary (126 (14%) infections and bacteremia (158, 17.0%). Aminoglycoside resistance was reported in 58 (18%) of documented infections. The median duration of therapy was 2 ((IQR 1-3) days, the median number of AG doses was 2 ((IQR 1-2), the mean dose was 25 ± 6, 6 ± 2, 6 ± 1.6 mg/kg of total body weight for amikacin, gentamicin and tobramycin respectively, and the median dosing interval was 26 (IQR 23.5- 43.5) h. Proportion of changes in median serum creatinine levels during AG therapy were -7% (IQR-24%; 12%). Therapeutic drug monitoring (TDM) of peak and trough concentrations was performed in 445 (48%) and 501 (57%) patients after the first dose. After the first AG dose, only 250 (56%) patients achieved the PK/PD target of Cmax/MIC >8 and 336 (67%) had concentrations above Cmin recommended thresholds. The ICU mortality rate was 27.3% with multivariable analysis showing AG resistant isolate (OR 8.31, 95% CI: 1.31-78.30, p=0.0355), SOFA score (OR 1.54, 95% CI: 1.24-2.03, p=0.0004) and directed antimicrobial therapy (OR 0.08, 95% CI: 0.01-0.70, p= 0.0254) as independent predictors of ICU mortality. We could show no correlation between AG dosing or PK/PD target attainment and clinical outcomes (Table 1).

CONCLUSION. Short courses of high AG doses are mainly used in ICU patients with septic shock although wide variability in AG practices is reported. Efforts to optimize the first AG dose and to perform TDM are still needed.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000840

INTRODUCTION. Antibiotic dosing in the critically ill patient is predominantly "one-size-fits-all" despite often grossly deranged pharmacokinetics and pharmacodynamics. Other than intermittent monitoring of aminoglycosides and glycopeptides (mainly for toxicity), there is miminal routine therapeutic drug monitoring (TDM), and none is offered in real time. This leads to dual issues of both under-treatment - post-mortem studies reveal persistent septic foci in >70% cases (1) – or toxicity (2,3). Since only the free (unbound) fraction of an antibiotic is active against bacteria in infected tissue, a tissue-based technique such as microdialysis (MD) may provide real-time monitoring of tissue concentrations (4).

OBJECTIVES. This study aims to determine the feasibility of *in vivo*microdialysis, monitoring real-time changes of different dosing regimens of meropenem at six different sites simultaneously, with comparison against direct blood level measurement.

METHODS. Healthy male Wistar rats (300-350g) underwent general anaesthesia and surgery for vascular access and MicroEye®(Probe Scientific, Bedford, UK) insertion into 6 sites: muscle, subcutaneous, liver, peritoneal cavity, trachea and jugular vein. The microdialysate flow rate was set at 1 µL/min. Six rats received a meropenem bolus of 30 mg/kg i.v., administered over 30 min; another 6 rats received a continuous meropenem infusion of 2.5 mg/kg/h.Tissue microdialysates and blood were sampled at 10 and 15 minute intervals, respectively for 90 minutes' duration. Meropenem concentrations in all samples were measured using High Performance Liquid Chromatography (HPLC, Agilent 1260II) ANOVA with post-hoc Dunn's tests were used to seek statistical significance.

RESULTS. The meropenem bolus generated a similar pattern of microdialysate drug concentration changes over time in all tissues, with no statistically significant difference in area under the curve (AUC). Peak concentrations (Cmax 5.43-15.72 µg/mL were reached in all tissues by 50-60 min (this includes a 20 minute lag-time for dead-space tubing) followed by a gradual decrease to zero at 100 min [Figure 1]. With continuous infusion, steady state was reached in all tissues by 50-60 min (0.33-1.16µg/mL), with liver AUC being significantly lower than venous (22.54 vs 69.22 µg/mL; p=0.008) [Figure 2].

CONCLUSION. In conclusion, MicroEye® shows promise as a novel point-of-care tool for monitoring tissue antibiotic concentrations.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000459

INTRODUCTION. From humans to rodents, cardiac contractility, vascular tones, fluid homeostasis and kidney function are all physiological hallmarks impacted by the engagement of the Apelin-receptor (APJ). Both Apelin-13 (APLN-13) and Elabela (ELA) endogenous APJ agonists exhibit bioactive properties and positive effects to support myocardial function both in endotoxemia and peritonitis models of sepsis in rats [1,2]. Because the apelinergic system stimulation has gained credibility as a potential alternative therapeutic pathway a first pilot study was undergone to evaluate the hemodynamic effects of APLN-13 or ELA perfusion in a clinically relevant large animal model of sepsis.
OBJECTIVES. Assess the acute hemodynamic impacts of APLN-13 or ELA infusions in healthy or septic sheep.
METHODS. Polymicrobial sepsis was induced by autologous feces injection into the abdominal cavity. Hemodynamics monitoring was assessed by arterial thermodilution (right: Swan-Ganz, left: PiCCO) and Left Ventricle (LV) catheterization to record LV End-Systolic Pressure and dP/dtmax. When shock criteria were reached (decrease of 40% of the baseline (bsl) Mean Arterial Pressure (MAP) and Cardiac Output (CO), SCVO2 <70%, lactatemia> 2 mmol/L) sheep received a Lactate Ringer bolus (30ml/kg in 1hr) before random assignment to a continuous infusion of 5 incremental doses of APLN-13 or ELA perfused in 20 min (from 0.007 to 3.6 µM/kg/hr) or equivalent volume of Normal Saline (NS).
RESULTS. APJ expression (qPCR) was confirmed in ovine heart & kidney. APLN-13 infusion was inotropic compared to NS, while ELA decreased cardiac function in healthy sheep (% from bsl at 1.8µM/kg/hr; CO, NS: 6±4%, APLN-13: 26±9% p<0.05 vs NS, ELA: -20±1% p< 0.05 vs NS; dP/dtmax, NS: 7±8%, APLN-13: 52±15% p<0.05 vs NS, ELA: -34±2% p<0.05 vs NS).
Sustained Gram negative bacteremia was documented and shock criteria were met 240±55min after feces injection, along with acute kidney dysfunction (urine output: bsl 108±18 ml/hr vs shock 9±3 ml/hr, p<0.05; creatinine, bsl: 2.7±0.1 mmol/L vs shock: 3.6±0.3 mmol/L, p< 0.05). Without significant impact on MAP, APLN-13 was the only one inotrope in septic sheep (% to shock time-point at 0.7µM/kg/hr; CO, NS: 11±3%, APLN-13: 48±13% p<0.05 vs NS, ELA: -25±11%, ; dP/dtmax, NS: 5±15%, APLN-13: 78±12% p<0.05, ELA: -2±9 %).
CONCLUSION. A differential hemodynamic signature of APLN-13 and ELA was observed in healthy and septic sheep opening new physiological questions on the apelinergic system regulatory role in the cardiovascular function. The APLN-13/APJ axis is emerging as a new candidate pathway to manage hemodynamics in septic shock and could be an alternative to catecholamines.

Cardiac fibroblastic LRP1-dependent endocytosis of liver angiotensinogen promotes septic cardiac dysfunction via NLRP3 inflammasome pathway

J. Rong[1], Z. Zhang[2], Y. Xu[1], J. Wang[1]

INTRODUCTION. Sepsis combined with cardiac dysfunction leads to a significant increase in mortality. The renin-angiotensin system (RAS system) plays an important role in the development of sepsis induced myocardial dysfunction (SIMD), while angiotensinogen (AGT) is the only known substrate of the RAS system, and its effect on SIMD has not been illuminated.
OBJECTIVES. To investigate whether inhibition of AGT ameliorates SIMD and explore its potential mechanism.
METHODS. Male C57BL/6 mice were intraperitoneally injected by either lipopolysaccharide (LPS) or PBS, and then taken down after 6 hours. Cardiac function was evaluated by echocardiography and the survival rate was monitored every hour for a 72-hour period. Plasma AGT level was measured by ELISA while hepatic and cardiac AGT expression were determined by real-time quantitative PCR (RT-qPCR) and western blot. Expression of proinflammatory cytokine was assessed by RT-qPCR. Combination of AGT and its receptor, low density lipoprotein receptor related protein1 (LRP1), was confirmed by surface plasmon resonance (SPR).
RESULTS. LPS injection significantly activated AGT expression both in liver and heart, and also elevated plasma AGT level after 6 hours. We further generated hepatocyte-specific AGT-deficient (hepAGT-/-) mice and cardiomyocyte-specific AGT-deficient (carAGT-/-) mice. Interestingly, we found that hepatic AGT knock-out led to a distinct reduction of AGT expression in liver but in heart it showed a remarkably decreased AGT protein level with a compensatory augment of mRNA level. However in carAGT-/- mice, cardiac AGT expression was restrained in mRNA level but did not change in protein level, while hepatic AGT remained unchanged compared with their wild-type counterparts. These facts implied that cardiac AGT was mainly derived from circulation rather than local synthesis. We then demonstrated that hepatic conditional AGT deletion in mice triggered resistance to septic cardiac dysfunction and lethality accompanied with less cardiac proinflammatory cytokine production, like tumor necrosis factor alpha (TNF-α), Interleukin 1 beta (IL-1β), and Interleukin 6 (IL-6). Contrarily, cardiac conditional AGT deletion in mice had a similar phenotype with wild-types. Furthermore, we identified liver derived AGT entered cardiac fibroblast via LRP1 mediated endocytosis, which in turn activated NLRP3 inflammasome and improved TNF-α, IL-1β as well as IL-6 production.
CONCLUSION. Hepatocyte-specific deficiency of AGT ameliorates SIMD via preventing cardiac fibroblastic LRP1-dependent endocytosis

and then decreasing NLRP3 inflammasome assembly, which alleviates proinflammatory factors releasing. These findings provide potential therapeutic targets in liver to treat SIMD.

Does sepsis affect tissue concentrations of antibiotic? A pre-clinical study with in-vivo monitoring of meropenem using microdialysis

K. Tam[1], I. Longo[2], D. Brealey[3], M. O'connell[4], M. Singer[5]

INTRODUCTION. Antibiotic handling is significantly altered in sepsis and other critical illnesses due to changes in metabolism and excretion, protein binding and volumes of distribution [1,2]. This handling will vary markedly between septic patients yet antibiotics are generally given as a 'one-size-fits-all' dosing regimen with fixed adjustments only made for severe renal dysfunction. Monitoring of tissue antibiotic concentrations should enable better titration of dose to avoid under- or over-treatment [3].
OBJECTIVES. To compare tissue and blood concentrations of meropenem in sham rats and during the early stage of sepsis (faecal peritonitis) using a type of microdialysis probe, MicroEye®,and compare these levels with that measured in blood and healthy rats.
METHODS. Male Wistar rats (300-350g) underwent brief general anaesthesia to enable instrumentation for vascular access. They were randomised to a sham control group or a septic group that received an intraperitoneal injection of faecal slurry to induce peritonitis. Fluid resuscitation was commenced from 2 hours. At 6 hours, the animals were re-anaesthetised and MicroEye® (Probe Scientific Ltd, Bedford, UK) microdialysis catheters were inserted into muscle, subcutaneous tissue, liver, peritoneal cavity, trachea and jugular vein. Meropenem 30mg/kg was administered over 30 min with tissue and blood microdialysates sampled respectively at 10 and 15 min intervals for a total of 90 min. Meropenem concentrations were measured using High Performance Liquid Chromatography (HPLC, Agilent 1260II). Blood samples were also taken for a direct measurement of meropenem levels. ANOVA with post-hoc Dunn's tests were used to seek statistical significance.
RESULTS. Following a single bolus of meropenem, there was a similar pattern of microdialysate drug concentration changes over time in all tissues in both sham and septic groups [Figures 1,2]. Peak concentrations were reached by 50-60 minutes in both study groups (this includes a 20 minute lag-time for deadspace tubing. There was no statistically significant difference in the area under the curves (AUC) for meropenem concentration in most tissues, except for trachea (p<0.05) and peritoneum (p=0.11) that were higher in the septic group [Figure 3].
CONCLUSION. In early sepsis, tissue concentrations were generally similar to sham rats, except within the trachea. Further work is needed to increase sample size and to perform repeat studies at later timepoints.

INTRODUCTION. Pendelluft, defined as movement of gas within the lung from regions characterized by a short time-constant to regions with long time-constant, has been described in animal models of assisted mechanical ventilation and associated with lung tissue over-stretching [1]. Due to the different contents of O_2 and CO_2 as compared to fresh gas, pendelluft might also reduce ventilation efficiency. We hypothesized that during weaning, increased patient's inspiratory effort due to withdrawal of ventilator support might trigger pendelluft phenomenon, exacerbating patient's fatigue.
METHODS. We enrolled 18 difficult weaning patients undergoing pressure support ventilation (PSV). Electrical impedance tomography (EIT) signal was recorded while PSV was progressively reduced from clinical level (baseline) to 2 cmH_2O (or the lowest tolerable level); four ventral-to-dorsal lung regions of interest were identified for pendelluft measurement. A regional gas movement (>5ml) occurring in a direction opposite to the global EIT signal was considered diagnostic for pendelluft.
RESULTS. Pendelluft was detected by EIT in 8/18 patients; in those patients PSV reduction increased pendelluft (p=0.036), in the others it did not (see Figure). In pendelluft patients, PSV reduction was associated with decreased tidal volumes (from 415 [377-502] to 355 [272-402] mL, p=0.012) and increased respiratory rates (from 23 [15-27] to 29 [20-36] breaths/min, p=0.017), while minute ventilation remained stable (from 9 [6.4-11.3] to 9 [7-11.9] L/min, p=NS). In the no-pendelluft group, the change in tidal volumes was not significant, as were the change in respiratory rate and minute ventilation (all p=NS). $EtCO_2$ increased in the pendelluft group (from 38 [32-43] to 40 [33-49] mmHg, p=0.027), but not in the no-pendelluft group.
CONCLUSION. Occult pendelluft can be measured by EIT, and is frequently present in difficult to wean patients. When present, pendelluft increases with the reduction of ventilator support and is associated with a significant change of the ventilatory pattern. Pendelluft-associated ventilatory inefficiency might play a role in weaning failure.

INTRODUCTION. Ultra-protective ventilation with tidal volume (VT) reduction below 6 ml/kg predicted body weight (PBW) in severe ARDS may reduce alveolar strain, driving pressure and hence ventilator-induced lung injury, with main drawback of worsening respiratory acidosis. We hypothesized that VT could be reduced down to 4 ml/kg PBW, with clinically significant decrease in driving pressure, without the need for extracorporeal CO2 removal, while maintaining pH in the range targeted in recent randomized controlled trials on ARDS.
METHODS. We conducted a non-experimental before-and-after multicenter study on 35 ARDS patients with PaO2/FiO2 ≤ 150 mm Hg,

within 24 hours of ARDS diagnosis. After inclusion (H0), VT was reduced to 4 ml/kg PBW and further adjusted to maintain pH ≥ 7.20, respiratory rate was increased up to 40/min and PEEP was set using the PEEP-FiO2 table of the high PEEP arm of the ALVEOLI trial. This strategy was applied until positivity of a PEEP weaning trial. The primary judgment criterion was the driving pressure on day 2 of the study, as compared to study inclusion. Data are presented as median [1st quartile-3rd quartile].

RESULTS. One patient's next of kin withdrew consent leaving 34 analyzable patients. Patients' age was 67 [53-73] year, SAPS II amounted to 50 [35-58], 29 patients (85%) had pneumonia as ARDS risk factor, SOFA at inclusion was 13 [11-14], and PaO2/FiO2 at inclusion was 101 [78-132] mm Hg under a PEEP of 10 [8-12] cmH2O. From inclusion to day 2, driving pressure decreased significantly from 12 [9-15] to 8 [6-11] cmH2O, while VT decreased from 6.0 [5.9-6.1] to 4.1 [4.0-4.7] ml/kg PBW. On day 2 of the study, VT was below 4.2 ml/kg in 22 patients (65% [IC95% 48%-79%]), and below 5.25 ml.kg-1 in 30 patients (88 % CI95% [73%-95%]). Time with VT below 4.2 ml/kg and 5.25 ml/kg averaged 2 [0.5-2.0] days and 2 [1-4] days, respectively. Respiratory rate increased significantly from 28 [23-30] /min to 40 [35-40]/min and 37 [30-40]/min on day 2 and 3 of the study, respectively. PEEP was significantly increased from hour 4 to day 3 after inclusion as compared to baseline, while intrinsic PEEP was not significantly modified during the first four days of the study. PaO2/FiO2 and PaCO2 increased significantly from baseline values as early as hour 4 up to day 3 after inclusion, while pH was significantly lower than baseline only at hour 4 and hour 10. Sedation drugs were not significantly modified.

Regarding safety, 2 patients (6%) presented with acute cor pulmonale after inclusion. Right ventricle/left ventricle ratio increased non-significantly from 0.50 [0.50-0.72] at H0 to 0.66 [0.60-0.76] on day 2. Eleven patients (32%) presented with severe mixed acidosis with pH < 7.15. Multivariate analysis identified renal SOFA at inclusion (OR: 1.91 [CI95% : 1.08-3.71] per 1 unit increase) and pH at inclusion (OR: 0.91 [CI95% : 0.80-0.99] per 0.01 unit increase) as variables independently associated with occurrence of any episode of severe mixed acidosis during the study. Fourteen patients (41%) died before day 90 with median delay between inclusion and death amounting to 16 [9-22] days.

CONCLUSION. Ultraprotective ventilation may be applied in approximately 2/3 of moderately severe to severe ARDS patients, with a 4 cmH2O median reduction of driving pressure, at the price of severe mixed acidosis in approximately 1/3 of the patients.

Dysfunction of cerebral autoregulation in adult patients treated with veno-venous Extracorporeal Membrane Oxygenation (v-v ECMO) for severe Acute Respiratory Distress Syndrome (ARDS). An observational prospective study

INTRODUCTION. Patients with severe ARDS are likely to develop cerebral hemodynamic impairment due to respiratory failure leading to hypoxemia and hypercapnia. ECMO therapy, by restoring normal level of PaO2 and PaCO2, is a life-saving treatment when hypoxemia is refractory to conventional treatment. However, ECMO support itself may cause neurological complications, affecting both long- and short-term outcome.

OBJECTIVES. Aim of the study was to evaluate cerebral autoregulation (CA) impairment in ARDS patients undergoing v-v ECMO and to assess whether normalization of arterial blood gases induced by the treatment can restore this dysfunction.

METHODS. Adult patients with severe ARDS requiring v-v ECMO were consecutively enrolled in our university hospital. Prior neurological disease and any condition hampering cerebral blood flow measurement were excluded from study. CA was assessed using Mxa, a Transcranial Doppler-derived index of dynamic CA, expressing the correlation between mean flow velocity in middle cerebral artery and mean arterial pressure; a Mxa values >0.20 shows impaired CA. Transcranial Doppler was performed before ECMO institution (PRE), at day 0, 1, 2, 4 and 7 of ECMO therapy and after ECMO removal (POST). Hemodynamic and respiratory parameters were recorded concurrently. Data are presented as median (IQR).

RESULTS. We enrolled 31 patients: age 48 (41-57) yrs; male 65%; pneumonia was the cause of ARDS in 94% of patients; ICU length of stay 27 (16-38) days; v-v ECMO duration 13 (8-17) days; APACHE II 26 (23-34); SAPS II 66 (60-72); 28-days mortality 35%. During ICU stay, clinical neurologic complications confirmed at neuroimaging were found in 5 (16%) patients, 3 ischemic and 2 hemorrhagic. Mxa was 0.25 (-0.12-0.50) PRE ECMO, 0.13 (0.04-0.20), -0.05 (-0.08-0.09), -0.03 (-0.19-0.05), 0.04 (-0.04-0.21) and -0.01 (-0.05-0.08) at day 0, 1, 2, 4 and 7 of ECMO therapy, respectively, and 0.04 (0.00-0.18) POST-ECMO, showing a trend toward restoration of CA from PRE-ECMO to day 7 (p=0.063). Furthermore, restored CA was maintained also after ECMO removal. Concomitant values of PaCO2 in mmHg were 54 (44-79) PRE ECMO, 47 (35-54), 46 (42-56), 44 (39-52), 44 (41-52), 44 (39-52) at day 0, 1, 2, 4 and 7 of ECMO therapy, respectively, and 44 (41-49) POST-ECMO; concomitant values of pH were 7.33 (7.16-7.46) PRE-ECMO, 7.42 (7.34-7.46), 7.42 (7.35-7.46), 7.43 (7.39-7.48), 7.42 (7.37-7.47), 7.40 (7.36-7.46) at day 0, 1, 2, 4 and 7 of ECMO therapy, respectively, and 7.43 (7.33-7.46) POST-ECMO. Significant correlations were found between Mxa and values of PaCO2 (p=0.002), pH (p< 0.001) and hemoglobin (p=0.001). A pH value of 7.35 could discriminate between impaired and preserved CA with a sensitivity of 0.88 and a specificity of 0.59.

CONCLUSION. In ARDS patients with refractory hypoxia, v-v ECMO therapy through normalization of arterial blood gas levels, may restore CA. Mxa values during ECMO support are significantly correlated with PaCO2, pH and hemoglobin.

INTRODUCTION. Surface electromyography allows to detect non-invasively and at the bedside the inspiratory activation of diaphragmatic and intercostal muscles.Our hypothesis was that the timing of neural activation of these muscles during a spontaneous breathing trial could be different in patients successfully extubated and in patients failing weaning.

OBJECTIVES. To evaluate the timing of diaphragmatic and intercostal neural activation during weaning from mechanical ventilation in critically ill patients.

METHODS. In 24 patients, who underwent at least 72 hours of mechanical ventilation, surface electromyography, s-EMG (Dräger, Lubeck, Germany), was applied for 5-8 minutes during a spontaneous breathing trial (SBT).The delta time between the beginning of diaphragmatic neural activation and the peak of intercostal muscles neural activation was calculated on a breath by breath basis (fig.1). Further, for each patient, we recorded the percentage of breaths in which the neural activation of the intercostal muscles occurred after the peak of the diaphragmatic neural activation (i.e. in the diaphragmatic expiratory phase).

RESULTS. Fourteen patients were successfully extubated whereas 10 patients were reintubated within 48 hours.

In failed vs successful weaning the delta time between the peak of diaphragmatic and the intercostal muscles neural activation was respectively 0,63 ± 0,20 and 1 ± 0,39 sec (p < 0.05). (FIG. 2)
The % of intercostal muscles activation occurring in the diaphragmatic expiratory phase was respectively 63,8% ± 21,34% vs 14,26%± 8,22% (p< 0.05) in failed vs successful weaning. (FIG. 2)
CONCLUSION. In the present study the delta time between the diaphragm and the intercostal muscles activation and the neural activation of the intercostal muscles during the diaphragmatic expiratory phase were higher in patients failing weaning than in patients successfully weaned from mechanical ventilation.
We speculate that s-EMG may be a promising tool to predict weaning failure in a non-invasive way.

INTRODUCTION. Recently, the role of ventilation-associated mechanical ventilation power (MVP) has been emphasized in lung injury. It is argued that MVP correlates with ventilation-induced lung injury (VILI) and prognosis. However, the relationship between MVP and prognosis needs to be further investigated. Electronic recording systems (ERS) can easily calculate mechanical ventilation power by using mechanical ventilator parameters.
OBJECTIVES. The aim of this retrospective study was to evaluate the relationship of the first 24 hours MVP with the survival and length of ICU stay.
METHODS. ERS data were retrospectively reviewed for patients receiving invasive mechanical ventilation for ≥ 24 hours and ICU stay ≥48 hours between 2015-2018. Patients ≥ 18 years were included. During the first 24 hours, MVP was calculated every 30 minutes and averaged.Formula: MVP(J/minutes)= 0.098 x tidal volume x respiratory rate x (Ppeak – ½ ΔP)ΔP is driving pressure. Based on a previous study, the patients were classified into two groups (Group 1: MP < 17 J/min, Group 2: MP ≥17 J/min) (ref 1).
Oxygenation, gas exchange values, and APACHE II and SOFA scores in the first 24 hours and survival were recorded. The primary outcome was ICU mortality.
RESULTS. A total of 1219 patients were included in the study. A significantly higher mortality rate was detected in Group 2 (p<0.001 Table 1). Demographic data and relation of MVP and driving pressure with mortality are shown in Table 2 and 3.
CONCLUSION. Our results suggest that higher baseline MVP values are related with poorer outcome.

INTRODUCTION. Proenkephalin A 119-159 (penKid) is a filtration marker and has been proposed as a sensitive biomarker of glomerular function. In this ancillary study of the PRONOburn cohort we evaluated the association of admission plasma penKid with kidney events in severely ill burn patients.
METHODS. PRONOburn is a French prospective, observational study designed to investigate factors associated with outcome of burn

patients. All consecutive severely burn patients (inclusion criteria: age>18 years, total body surface area burn >15% and non-opposition to participate) admitted to 2 participating burn intensive care units (ICU) in France were included. The primary endpoint of this ancillary study was to evaluate the predictive value of penKid for 90 day mortality. Secondary endpoints were to evaluate the predictive value of penKid for in-ICU AKI, as well as for a combined endpoint (90 mortality and/or in-ICU AKI). AKI was defined using the KDIGO definition. Subclinical AKI was defined as patient without AKI in the first seven days but a penKid concentration>80pmol/L on admission.

RESULTS. From April 2014 to April 2016, 109 consecutive patients were enrolled. Mean age was 48 (IQ 33-64) years, mean Sequential related organ failure assessment was 4 (IQ1-4), 67% (N=73) were male. Total burn surface area was 35 (IQR 25-53). Overall 90 day mortality was 27.5 % (N=30), 35.7% (N=39) had AKI during ICU stay and 44% (N=48) had the combined endpoint. Penkid was significantly higher in non-survivors compare to survivors (113.2pmol/L [IQR 57.5-182.1] vs 54.8pmol/L [IQR 36.0-76.7]; p<0.0001) and in patient with in-ICU AKI compare to patient without (91.4pmol/L [IQR 56.5-153.4] vs 53.1pmol/L [IQR 34.4-67.9]; p<0.0001). Penkid provided added value on top of creatinine and SOFA score to predict 90 day mortality (combined c index=0.766 vs. 0.716; p=0.004 and 0.812 vs. 0.762; p<0.001, respectively). PenKid c index to predict in-ICU AKI was 0.755. Penkid added value on top of creatinine and SOFA score to predict the combined endpoint (c index=0.839 vs. 0.799; p=0.006 and 0.878 vs. 0.806; p<0.001, respectively). Day 3 penKid measurements added value on top of admission measurement to detect both mortality and the combined end point. Finally, there was a progressive increase risk of mortality from patients without AKI, sub-AKI and AKI (Survival rate 91% [95% CI 83.8-98.9], 66.7% [95% CI 48.1-92.4] and 40.4% [95% CI 26.1-62.4]; respectively, p<0.0001).

CONCLUSION. Admission penKid concentration was associated with risk of mortality in burn patients. It added value on top of creatinine and SOFA to predict 90 day mortality. Sub-AKI detected with penKid was associated with risk of death.

INTRODUCTION. Plasma proenkephalin A 119-159 (penKid) is a filtration marker and has been proposed as a sensitive biomarker of glomerular function. As such it was found predictive for septic kidney events including acute kidney injury (AKI) in sepsis. In this ancillary study of the FROG-ICU and AdrenOSS-1 cohorts we evaluated the association between subclinical acute kidney injury (sub-AKI; defined by supra-normal penKid) and outcome.

METHODS. FROG-ICU was a European prospective, observational study of 2087 critically ill patients designed to investigate long-term mortality in patients with invasive mechanical ventilation and/or vasopressors or inotropes for more than 24 hours. AdrenOSS-1 was a European prospective, observational study with 583 sepsis and septic shock patients. sub-AKI was defined by an admission penKid concentration above the normal range (i.e. > 80 pmol/L) in patients without acute kidney injury (AKI). AKI was defined by the KDIGO (Kidney Disease: Improving Global Outcomes) criteria.

RESULTS. 2015 from the FROG cohort and all 583 patients from the AdrenOSS cohort were eligible for data analysis. 28-day mortality was 22% in both cohorts. 8.6% and 9.4% of patients from the FROG and AdrenOSS cohorts had sub-AKI (11.5% and 17.5% of non-AKI; respectively). Median SOFA score was similar in non-AKI and sub-AKI patients in the FROG cohort, and slightly higher for sub-AKI in AdrenOSS-1 (6 vs 5 points, p=0.011). Compared to non-AKI patients, patients with sub-AKI were more likely to receive hemodynamic support (p<0.001). We found a significant stepwise increase of 28-day mortality risk from non-AKI (9.1%) to sub-AKI (20.5%) to AKI patients (34.9%) in the FROG cohort, and the AdrenOSS cohort (8.7%, 21.1% and 28.7%, respectively). In all patients, admission penKid concentration was associated with 28-day mortality: c index = 0.664 (p<0.001) for penKid and 0.618 (p<0.001) for creatinine in the FROG cohort and 0.661 (p<0.001) for penKid and 0.589 (p=0.006) for creatinine in the AdrenOSS cohort.

CONCLUSION. Sub-AKI detected using admission penKid was associated with high cardiovascular failure and short-term mortality in critically ill patients. PenKid better predicted 28-day mortality risk than serum creatinine.

INTRODUCTION. Acute kidney injury (AKI) is independently associated with prolonged hospital stay and impaired outcome. Creatinine is most used to assess kidney function. However, following a decrease in glomerular filtration rate, plasma creatinine concentration increase is insensitive and late. This hampers the diagnosis of AKI and research related to therapies. The novel plasma biomarker proenkephalin (PENK), a stable byproduct of the endogenous opioid enkephalin, is currently studied for its reflection of kidney function and thereby detection of AKI. Kinetics of PENK during a period of AKI compared to creatinine are unknown.

OBJECTIVES. To determine whether or not the plasma biomarker PENK is able to diagnose AKI earlier than plasma creatinine.

METHODS. In this prospective study, all patients admitted to our Intensive Care Unit (ICU) with an ICU duration >1 day and not already fulfilling AKI criteria on admission were included. Plasma creatinine concentrations were determined using daily routine sampling. Residual material was collected and frozen to determine PENK retrospectively using Sphingotec immunoassay [1]. AKI was diagnosed using the KDIGO criteria [2] with the most sensitive (AKI-stage 1) measure of a creatinine concentration rise of 0.3 mg/dL (26.5 µmol/L) within 2 days. One sample t-test was used to assess the difference in time of the increase before and decrease after the occurrence of AKI. Receiver operating characteristics (ROC) curves were created to assess the diagnostic performance of PENK.

RESULTS. We included 189 critically ill patients on the ICU, median [IQR] age was 65 [55-72] years, 119 patients (63%) were male. 56 patients (24%) developed AKI during ICU admission. PENK concentrations increased (mean±SEM) 0.4±0.08 day earlier than creatinine ($p<$ 0.0001), figure 1-A. When creatinine decreased, PENK concentrations also decreased 0.7±0.22 day earlier. The area under the ROC curve of the PENK concentration the day before the diagnosis of AKI was 0.82 (95%CI 0.75-0.89), with an optimal cut-off value of 66 pmol/L resulting in sensitivity and specificity of 83% and 75%, respectively, see

figure 1-B. The positive and negative likelihood ratio was 3.3 and 0.30, respectively.
CONCLUSION. PENK is freely filtrated through the glomerulus without active secretion or resorption and may therefore be capable to detect AKI more swiftly compared to plasma creatinine. Furthermore, PENK plasma concentrations the day before diagnosis of AKI as a diagnostic test is classified as good in an unselected population of critically ill patients.

INTRODUCTION. Venous congestion is considered to play a role in the development of Acute Kidney Injury (AKI). Currently no strict definition for venous congestion exists and all proxies have limitations.
OBJECTIVES. To assess whether signs of venous congestion, defined as interstitial pulmonary syndrome and as a non-collapsing inferior vena cava (IVC), both observed by bedside ultrasonography, were associated with the development of AKI in a population of critically ill patients in the Intensive Care Unit (ICU).
METHODS. In this sub-study of the Simple Intensive Care Studies-II (NCT03577405)(1), bedside ultrasonography was performed by trained researchers within 24 hours of ICU admission. The number of B-lines (0-5) was assessed according the Bedside Lung Ultrasound in Emergency protocol(2). Pulmonary interstitial syndrome was defined as three or more B-lines in two or more bilateral fields. IVC collapsibility was assessed using the IVC-Collapsibility Index and a value of less than 20% as cut off score for IVC-congestion (accounting for mechanical ventilation where appropriate)(3). Congestion was assessed as a categorical variable (0: no signs of congestion, 1: one of two signs of congestion, and 2: both signs of congestion) and AKI as a binary variable following KDIGO criteria. Via multivariate logistic regression analysis, corrected for age, we determined an association between signs of venous congestion and AKI.
RESULTS. From May 15th 2018 to April 8th 2019 a total of 426 patients were included. We excluded 152 patients (36%) with pre-existing renal failure or lack of ultrasonography images. Of the remaining 274 patients, 128 patients (46%) developed AKI within 72 hours of admission. In total 97 patients (35%) had no collapsing IVC, 31 patients (11%) had pulmonary interstitial syndrome and 11 patients (3%) had both (figure 1). Congestion was associated with AKI in univariate analysis, and this association remained after correction for age (OR 1.54, 95%CI 1.01-2.38, p=0.045).
CONCLUSION. Interstitial syndrome and/or a non collapsing IVC as signs of venous congestion were associated with AKI in a finding cohort. Bedside ultrasonography measurements of venous congestion early during admission could predict the development of AKI in critically ill patients. Further studies have to elucidate the validity and efficacy of these findings.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001705

INTRODUCTION. Acute kidney injury (AKI) is common in critically ill patients and is strongly associated with high mortality. Renal replacement therapy (RRT) is an important supportive therapy for patients with AKI. In particular, continuous renal replacement therapy (CRRT) is used for hemodynamically unstable critically ill patients with loss of kidney function. Previous studies have shown that the overall mortality of patients with AKI requiring CRRT is high—over

50%—indicating that further improvement is necessary for this unacceptable poor outcome.
There have been numerous reports on a recent decrease in mortality among critically ill patients. It is of interest whether the characteristics and outcomes of patients with AKI-RRT have changed over time.
OBJECTIVES. To examine recent trends in patient characteristics and mortality in patients with AKI receiving RRT, including CRRT and intermittent RRT (IRRT), in intensive care units (ICUs)
METHODS. From the Diagnosis Procedure Combination database in Japan during 6 months (July–December) from 2007 to 2016, patients with AKI who received RRT in ICUs were identified and examined for trends in patient characteristics and overall mortality by RRT modality and main diagnosis category subgroup. Logistic regression analysis was performed to adjust for patient characteristics.
RESULTS. Overall, 51,758 patients starting RRT were identified (3.9% of all patients admitted to ICUs; CRRT: 39,471 (76.3%) patients; IRRT: 12,287 (23.7%) patients) in 287 hospitals. The crude in-hospital mortality declined from 44.9% to 36.1% (P for trend <0.001). Compared with 2007, the adjusted odds ratio (aOR) for in-hospital mortality was 0.66 [95% confidence interval (CI): 0.60–0.72] in 2016, and the decreasing trend was observed in both patients starting CRRT (aOR 0.68, 95% CI 0.61–0.75) and IRRT (aOR 0.58, 95% CI 0.45–0.74) and in all subgroups: sepsis aOR, 0.68 (95% CI 0.57–0.81); cardiovascular surgery, 0.58 (0.45–0.76); coronary artery disease, 0.85 (0.60–1.20); non-coronary heart disease, 0.78 (0.65–0.94); central nervous system disorders, 0.42 (0.28–0.62); trauma, 0.39 (0.22–0.72); and others, 0.64 (0.50–0.83).
CONCLUSION. This nationwide study confirmed a consistent decline in mortality among patients with AKI on RRT in ICUs, although several patient characteristics were changing over time.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001005

INTRODUCTION. Unplanned admissions to intensive care units (ICU) are associated with high mortality rates [1]. In the UK, the Royal College of Physicians recommend that patients on general wards with a National Early Warning Score (NEWS) of ≥7 should be reviewed by the critical care team [2]. However, the NEWS only considers vital sign measurements. We recently showed that a simple risk score (LDTEWS:NEWS), which combines NEWS with routine laboratory results, was better able to identify patients who may require critical care [3]. Recently, machine learning algorithms have shown potential to outperform standard statistical approaches when predicting patient outcomes using data from electronic health records [4].
OBJECTIVES. To develop and externally validate a risk score to predict unplanned admissions to intensive care using machine learning.
METHODS. This was a retrospective cohort study of emergency medical admissions to two large acute hospitals groups (Portsmouth Hospitals, PH and Oxford University Hospitals, OUH). We excluded admissions where the patient was: discharged alive on the day of admission or had no vital signs observations in the 24 hours prior to the initial ICU admission or hospital discharge. Seven vital signs, seven common laboratory tests and the patient's gender were extracted from hospital records as described previously [3]. Using these data, a novel risk score (XgICU) was developed from five years' of admissions to one hospital (PH) using gradient-boosted decision trees (xgboost [5]). Optimal hyper-parameters of xgboost were identified through a random search with five-fold cross-validation on the development cohort. XgICU was externally validated on one year of admissions from OUH. The discrimination of XgICU, NEWS and LDTEWS:NEWS for observations within 24 hours (median 9 ; interquartile range 4-6) of unplanned ICU admission was assessed using the c-statistic.
RESULTS. The external validation cohort (OUH) comprised 16,309 admissions (median age = 73 years), of which 159 (1.0%) patients had an unplanned admission to the ICU. The novel risk score (XgICU) showed substantially better discrimination (0.920, 95% confidence interval 0.913–0.927) than both LDTEWS:NEWS (0.894, 0.885–0.904) and NEWS (0.876, 0.865–0.887). At the recommended escalation threshold of ≥7, NEWS identified 53% of observations in the 24-hour window preceding an unplanned ICU admission to be above the threshold. At an equivalent false positive rate (5%), LDTEWS:NEWS was marginally more sensitive (55%), whilst the sensitivity of XgICU was 64%.
CONCLUSION. Using the same vital sign and laboratory data as LDTEWS:NEWS, gradient-boosted decision trees were substantially better at identifying observations above the escalation threshold in the 24 hours prior to unplanned transfers to the ICU. If carefully applied, machine learning algorithms could provide powerful tools to aid clinical decision making for critically ill patients.

Gender Disparity in Critical Care Publications: A novel female first author index

S. Chary[1], K. Amrein[2], S. Mehta[3], K. Christopher[1]
[1]Division of renal medicine, Brigham and Women"s Hospital, Boston, United States of America; [2]Division of endocrinology and diabetology, Medical University of Graz, Graz, Austria; [3]Department of medicine, University of Toronto, Toronto, ON, Canada
Correspondence: K. Christopher
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001163

INTRODUCTION. Bibliometric analyses in science show gender disparity exits in publications and citations which are crucial for academic and professional advancement.
OBJECTIVES. To summarize the state of gender equality in original critical care research.
METHODS. We conducted a bibliometric analysis of original research publications in critical care medicine from 2008-2018 in 11 journals: NEJM, JAMA, Lancet, BMJ, ICM, Critical Care, CCM, CHEST, AJRCCM, Annals of Intensive Care, and Journal of Critical Care. We included only clinical trials, observational studies, systematic reviews, meta-analyses and experimental studies. We utilized PubReMiner to produce full names and country from PubMed. Gender for the first and last authors was assigned manually and by Gender API a web-based gender determination platform. Publication citations were determined via the Web of Science. We defined the novel Female First Author index (FFA index) for an individual last author. FFA Index = (#Female first authors in publications by an individual last author/ #Total publications by the individual last author).
RESULTS. 7370 manuscripts that met criteria had first and last author gender determined: 2237 manuscripts with female first authors were identified (30.4%), 1140 manuscripts had female last authors (15.5%). There were 5153 different individual first authors with 34.1% individual female first authors. 19.6% of the 3890 individual last authors were female. The mean impact factor for manuscripts with female first authors was 5.98 and male first authors was 6.27 (ANOVA p= 0.055). This relationship did not change with restriction to higher impact factors (ie >5, 10, or 20). Average citations per year for female first authors was lower compared to those for male first authors at 3.79 vs. 4.63 respectively, (ANOVA p< 0.001). Female last authorship was associated with increased odds of female first authorship. After adjustment for impact factor, journal and year, female last authorship was associated with a nearly 2-fold increase in female first authorship [OR=1.87 (95%CI 1.64, 2.13); P<0.001]. Geographically, only Finland, the Netherlands and Greece approach gender parity in first authorship. In our data, the proportion of female first authorship has not increased over the last 10 years. The mean Female First Author index (FFA index) for all 3890 individual last authors was 30.5%. In male last authors (N=3125), the mean (SD) FFA index was 27.6 (41.2)%. In female last authors (N=763), the mean (SD) FFA index was 42.5 (47.6)%. The gender differences in FFA index were significant ($\chi 2$ = 46.6; P < 0.001). For male last authors with 5 or more senior author manuscripts (N=251), the mean (SD) and median FFA index were 28.7% (26.8%) and 20.0%. For female last authors with 5 or more senior author manuscripts (N=20), the mean (SD) and median FFA index were 47.5% (23.9%) and 46.4%. The gender differences in FFA index in those with 5 or more senior author manuscripts were significant ($\chi 2$ = 12.9; P < 0.001).
CONCLUSION. Female representation at prominent authorship positions in critical care publications is still far from achieving gender parity. By creating an authorship index score, we have now established a frame of reference for the advancement of female first authorship. Bridging this authorship gap can advance women in academics towards true gender equality.

Time-Sensitive Deep Learning for ICU Outcome Prediction Without Variable Selection or Cleaning

J. Deasy[1], P. Liò[1], A. Ercole[2]
[1]Department of computer science, University of Cambridge, Cambridge, United Kingdom; [2]Department of medicine, University of Cambridge, Cambridge, United Kingdom

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001277

INTRODUCTION. Accurate prognostication is important for shared decision making as well as for benchmarking. Deep Learning (DL) with many predictors can outperform traditional models (e.g. APACHE II). ICU data is a particular challenge as it consists of multiple investigations, physiological measurements and treatments at different sampling times, any of which may also be subject to error. Furthermore, as ICU admissions are dynamic with prognostic accuracy which changes over time, and current techniques cannot make predictions at arbitrary times, a temporally-sensitive model would help guide optimal decision-making for trials of intensive care.
OBJECTIVES. We present a novel DL survival algorithm using the entire multivariable patient time-series, regardless of variable type or frequency and without the need for variable selection or cleaning. Furthermore, we seek to be able to track predicted survival probability over time for optimal prediction.
METHODS. Using data from the MIMIC-III dataset, we represent all 57,823 possible event types from the first 48 hours of each patient's ICU stay using a flexible latent space embedding previously described. In this way, an adaptable recurrent DL model with 1,998,828 parameters is also able to learn erroneous data values to be discarded. By collapsing the time-series to arbitrary resolution, we train the model to predict mortality after each hour of the patient's stay.
RESULTS. A total of 18,067 patients with 21,110 ICU stays and 208,572,237 events were used for training. The median [IQR] patient age was 65.8 [52.8; 77.8] and there were 2,764 (13.1%) in-hospital deaths. Hourly predictions for patient survival to hospital discharge were made for the first 48 hours of their stay in the ICU. On a 10-fold cross-validation, our model obtains a mean AUROC of 0.90 (95% CI 0.88-0.92) for prediction at 48 hours, exceeding several recent deep learning models. Furthermore, the model is able to track predictions over time and showed that prediction strength improves throughout the first 48 hours after admission - rapidly for the first 12 (to AUROC>0.8) before levelling out at 48 hours.
CONCLUSION. Our model is time-sensitive and able to achieve state of the art survival predictions while overcoming the need for data selection or pre-processing. This is a significant advantage when considering the high data density of the ICU. Predictive performance increases over the first 48 hours of the ICU stay, providing a rationale for time-limited trials in the ICU and suggesting that the timing of decision making can be optimised/individualised.

INTRODUCTION. Acute kidney injury (AKI) is a frequently observed complication encountered in the intensive care and greatly affects the elimination of commonly prescribed drugs such as antibiotics and anti-convulsants. As defining AKI in clinical practice is challenging, pharmacokinetic models often rely on creatinine values as their input. We hypothesize that predicting creatinine values ahead of

time would improve these models and optimize dosing strategies in critically ill patients. Additionally, we foresee that clinicians could use these predictions to guide management. Machine learning provides a novel approach to analyze large quantities of data and improve predictive accuracy. To this point, no machine learning models have focused on the prediction of creatinine values.

OBJECTIVES. We set out to predict creatinine as a continuous variable ahead of time to improve pharmacokinetic modeling and guide clinical therapy.

METHODS. A retrospective cohort study of 26.251 critically ill adult patients admitted between 2004 and 2017 was conducted in the Amsterdam UMC, The Netherlands. Patients with a stay shorter than 48 hours and medium care patients were excluded from the analyses. A total of 45 features were collected and included patient demographics, device data, laboratory values, and clinical observations. Non-sequential methods (Lasso, Random Forest) and sequential methods (LSTM) were tested. The granularity of data was one hour, more frequent data was condensed by calculating the mean per hour, missing data was imputed using several imputation approaches for the deep learning models (LSTM-naïve, LSTM-Mask, LSTM-Naïve-MFeat, LSTM-Mask-MFeat). Using a train-validation-test split (60-20-20%), a continuous value of creatinine was predicted ahead of time for a 24-hour interval, using 24 hour of previous data as input into the model. The last known creatinine value served as a baseline.

RESULTS. A total of 8330 patients fulfilled the inclusion and exclusion criteria (median age 65.9 [IQR 54.1-74.8], 36% female). Of these, 5482 patients developed AKI during their ICU stay, with median creatinine values ranging from 92.0 to 242.0 for non-AKI and KDIGO AKI stage 3 patients respectively. 51.2% of the stage 3 patients received renal replacement therapy. Last creatinine as a baseline resulted in an R2 of 0.80 (SE±0.002). Random forest performed best (R2 0.86, SE±0.001), followed by the LSTM-Mask (R2 0.84, SE±0.002). In the random forest model, last creatinine and creatinine trends, renal replacement therapy, and pH came out as most important predictors.

CONCLUSION. In this study we showed machine learning models improve the prediction of continuous creatinine values. Further enhancement of the models is likely to improve performance. Predictions for different time intervals would make the models more suitable for integration in the daily workflow.

Network topology: a novel method for understanding hospital strain and the role of the ICU

K. Kohler, A. Ercole
University division of anaesthesia, University of Cambridge, Cambridge, United Kingdom
Correspondence: K. Kohler
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001637

INTRODUCTION. Hospitals can be described as complex adaptive systems, where discrete interventions are often unable to remedy problems. Network science methods provide tools to analyse the architecture of such complex systems. We apply these tools to emergency surgical admissions to give a better understanding of the structure behaviour of our service and will allow us to develop predictive methods for service needs, eg ICU bed capacity.

METHODS. We selected all unplanned surgical admissions over a two and a half year period and used the electronic care records to extract the locations of the patients during their admission. From this we constructed a network representation of the care system and added a measure of daily emergency department load to investigate the influence of hospital strain on the system. Here we focused on patients who had a stay in ICU or HDU areas.

RESULTS. The graph shows the network representation of the emergency surgical ICU patients with the nodes representing a ward or area. The edges connecting them represent the transfers of patients between the two wards (width proportional to the frequency of transfers). The nodes are coloured by their 'betweenness centrality', a measure of the importance of a node to the function of the system. In this graph ICU is densely connected to most areas of the hospital and is therefore highly sensitive to disruptions or problems elsewhere.

We constructed networks for the busiest and calmest days in the emergency department. The analysis shows that flow through the system is reduced in busy times (lower flow hierarchy) and patients are sent to a larger range of areas from ED (higher ED degrees). Additionally, we have a higher percentage of transfers between different ICU areas during busier times, possibly reflecting increased non-medical transfers.

CONCLUSION. The network representation yields the expected results of extensive interconnectedness and the effects of system strain on flow of patients. The increased load in ED may be due to a bottleneck into the hospital or due to higher demand. The next steps will be further analysis of the influence of strain, patient subgroup analysis and the development of predictive tools.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000071

INTRODUCTION. In most emergency situations or severe illness, critical care patients are unable to give consent for enrollment in a clinical trial. In such circumstances, the decision of whether or not to participate in a clinical trial is made by a legal representative (1).

OBJECTIVES. To address the willingness of patients admitted to the intensive care unit (ICU) to be enrolled in a scientific study as a volunteer and to assess the agreement between ICU patient's and their legal representative's opinion concerning enrollment in a scientific study.
METHODS. This survey was conducted in two hospitals (one private and one public) in São Paulo, Brazil. Adult patients (≥18 years) with preserved cognitive function accompanied by a surrogate admitted to the ICU were eligible for this study. A survey containing 28 questions for patients and 8 questions for surrogates was conducted by the investigator preferably within the first 48 hours of ICU admission. The survey of patients comprised three sections: demographic characteristics, opinion about participation in clinical research andknowledge of the importance of research. The survey of legal representatives contained two sections: demographic characteristics and assessment of the legal representatives' opinion on authorizing patients' to be enrolled in research.
RESULTS. Between January 2017 and May 2018, 208 pairs of ICU patients and their respective legal representatives answered the survey. The median (IQR) age of patients was 60 (43-75) years, 49% were female and 56.7% had a higher educational level. The median (IQR) age oflegal representatives was 49 (37-59) years, 66% were female and 68.8% were next of kin (spouse/son/daughter). Of the 208 ICU patients who answered the survey, 73.6% (153/208) would like to be enrolled in study as a volunteer. Of those patients, 65.1% (97/149) would continue participating in a research even if their legal representative did not support their enrollment. The agreement between patients' and surrogates' opinion concerning participation was poor [Kappa=0.11 (IC95% -0.02 to 0.25)]. If a deferred consent were obtained, 69.1% (103/149) of patients would continue participating in the study until its conclusion, and 23.5% (35/149) would allow researchers to use only the already collected data, but would withdraw the study in this occasion.
CONCLUSION. The surrogate's opinion reflects poorly on critically ill patient's opinion concerning enrollment in clinical research. To boost patient's recruitment in clinical trials, efforts to improve patients and relative's knowledge of the importance and value of medical research need be made.

INTRODUCTION.*Do-not-resuscitate* (DNR) orders apply to the decision to withhold *cardiopulmonary resuscitation* (CPR) and may already occur on ICU admission or when the patient´s condition worsens, alone or with other *limitation of life-sustaining therapy* (LT).
OBJECTIVES. To investigate the change in use of DNR orders in European ICUs over 16 years
METHODS. All centres that participated in the Ethicus-1 study were invited to participate in a follow-up study (Ethicus-2). Consecutively admitted patients who died or had LT during a 6 month period from September 1, 2015 to September 30, 2016 were prospectively studied. End-of-life Practices (EOLP) and region definitions from the Ethicus-1 study were used and comparisons made [1].
RESULTS. Twenty-two ICUs participated in both studies, enrolling patients (Ethicus-2; Ethicus-1): total (1785;2807); Northern Europe (NE) (424; 587); Central Europe (CE) (893; 906); and in Southern Europe (SE) (468; 1314). The use (% Ethicus-2; % Ethicus-1) of DNR orders for the different regions was: NE (93; 80), CE (83; 72), SE (78; 55). When a decision to either WH CPR or WD CPR was made, a DNR order was written in (% Ethicus-2; % Ethicus-1): NE (84; 82), CE (93; 84), SE (37; 32).
CONCLUSION. The use and the documentation of DNR orders increased in all European regions ICUs that participated in ETHICUS-1 after 16 years. WH CPR were the first and the most common LT. Written DNR orders and documentation of decisions to WH CPR in the medical record are still not frequent in SE.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000474

INTRODUCTION. A patient's admission in the Intensive Care Unit (ICU) can lead to intense stress symptoms in the patient's family, resulting in anxiety, depression and emotional distress.
OBJECTIVES. To investigate on the coping mechanisms of the ICU patient's family, depending on socio-demographic characteristics and the relative-patient closeness.
METHODS. Family members (first degree relatives, close relatives and intimate friends) of patients hospitalized in a University ICU constituted our research material. A questionnaire for sociodemographic data and the Family Crisis Oriented Personal Evaluation Scales (F-COPES) were completed by family members after their beloved one's ICU admission. F-COPES consists of 5 subscales: 'Acquiring social support', 'reframing', 'seeking spiritual support', 'mobilizing family to acquire and seek help' and 'passive appraisal'.
RESULTS. Two hundred and twenty-three family members, 81 (36.3%) men and 142(63.7%) women, mean-aged 41.4±11.9 years, corresponded to 147 ICU patients were studied. Family members were children (40.8%), siblings (19.3%), spouses (16.1%), parents (4.9%), other family members (17%) and friends (1.8%). Regarding the strategies used to deal with family crisis, it became evident that the quest for social help (31.27±4.72), the mobilization of the family to get and receive help (14.26±3.17) and the passive attitude (14.04± 2.81) were those most commonly used. Gender differences were observed almost in every F-COPES subscale; women achieved higher scores and differences were more prominent in social support subscale (p=.001). First degree relatives exhibited lower scores in 'spiritual support' and 'accept help' subscales (p=.021 and p=.014 respectively). Offspring exhibited lower scores in 'spiritual support' subscale compared with siblings (p=.015) and friends (p=.006) and lower scores in 'accept help' subscale compared with 'friends' (p=.008). Elementary school graduates exhibited higher scores in 'reframing' subscale compared with university and postgraduate students (p=.005 and p=.021 respectively).
CONCLUSION. Male spouse and offspring are most disadvantaged among ICU patients' family members in terms of effective coping

strategies, while 'reframing' is used less frequently among family members with higher level education.

INTRODUCTION. Communication strategies have an important impact on end-of-life decision (EOLD) processes in intensive care units (ICUs) (1), but current communication and decision-making practices in German ICUs are unknown.

OBJECTIVES. This study presents data from the subset of German ICUs which participated in the worldwide Ethicus-2 study on end-of-life care practices in ICUs.

METHODS. Observational study of consecutive ICU patients who died or had end-of-life decisions (EOLD) to limit therapies during a 6-months period.

RESULTS. A total of 1092 patients were included, 13% of patients were mentally competent at the time of EOLD. Advance directives were present in 270 (27%) patients. Discussion of EOLD occurred with 92% of mentally competent patients and shared decision making (SDM) was reported in 90%.

In general, physicians asked for or received information about patient wishes in 816 (78%) cases, most commonly from the family (94%) and sometimes from the patient (18%). However, the question whether patient wishes were followed if they were known was answered positively in 98% of 641 patients, constituting only 59% of the total. Patients with EOLD more often had advance directives (29% vs. 11%, Chi2=12.69, p= 0.00037) and information about patient treatment desires were more frequent (83% vs. 34%), Chi^2=118.73, p≤0.0001) than in patients without EOLD.

The question whether physicians discussed EOLD with the family was not answered in 11% of patients. For the remaining patients, physicians reported using SDM in 76%; the family was told the decision in 19% and the family was asked to decide in 5% of patients. Physicians' reasons for not discussing EOLD with the family included unresponsiveness to therapy (38%) or unavailability of family (19%). Agreement with the final EOLD occurred in 99% between physicians and nurses in 98% of cases between health care providers and family.

CONCLUSION. In the majority of patients, physicians seek knowledge about patients' treatment wishes, mostly from the family or the patients themselves if those are mentally competent. Advance directives are legally binding in Germany, therefore the fact that every fourth patient with EOL care has an advance directive is noteworthy. Our data suggest that when advance directives are present, they are considered in the process of EOL decision-making. When patient wishes are known, they are usually followed. On the other hand, our data suggest that patient wishes remain elusive in about half of the included ICU patients. Physicians commonly discuss EOL decisions with the family. The most frequent communication model is shared decision-making with the family.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000815

INTRODUCTION. Communication about end-of-life decisions (EOLD) may have changed over time.

OBJECTIVES. This study evaluated differences in EOLD in European intensive care units (ICUs) 16 years after the Ethicus-1 study (1,2)

METHODS. Consecutively admitted ICU patients who died or had life-sustaining treatment limitations during a self-selected 6-month period from September 1, 2015 to September 30, 2016 were prospectively studied. Previous EOLD definitions from the Ethicus-1 study were used (1) and comparisons made between studies.

RESULTS. Twenty-two ICUs participated in both studies. with 1785 patients in Ethicus-2 (424 in North Europe (NE), 893 in Central Europe (CE), and 468 in South Europe (SE) versus 2806 patients in Ethicus-1 (587 in NE, 906 in CE and 1,314 in SE). Comparing Ethicus-1 with Ethicus-2, more patients had capacity to make decisions in Ethicus-2 (4% vs. 16%) and more physicians asked for or received information about patient's treatment desires (20% vs. 47%). This information was elicited more often from patients (11% vs 14%) and less often from the family (93% vs 40%). More physicians had information about patient wishes in Northern and Central Europe (54% and 53,) than in Southern Europe (28%). The most frequent reasons for not discussing EOLD with family were patient's unresponsiveness to therapy (39% vs 17%) or unavailability of family (36% vs. 9%).

CONCLUSION. Today, ICU physicians in Europe seem to be better informed about patients' wishes and patients appear to engage more

with ICU physicians than 16 years ago. Still, the North-South divide persists. In Northern and Central Europe, every second ICU physician who was responsible for EOLD had asked for or had received information about patients' wishes in contrast to less than a third of ICU physicians in Southern Europe. Cultural differences like patriarchalism or religiosity may play a role.

Autonomic responses to passive leg raising in healthy volunteers

S. Sondergaard
Regional Hospital Silkeborg, Silkeborg, Denmark
Correspondence: S. Sondergaard
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000040

INTRODUCTION. Passive leg raising (PLR) has been promoted as an confirmation of volume responsiveness perioperatively and in patients in the intensive care when ΔCO or ΔSV >10-15%. A guideline has been published (1). Still, much needs to be defined: patient characteristics, feasibility of assessment in ICU populations, impact of concurrent morbidity and medication, the role of the homeostatic mechanisms of the body and the physiologic frame necessary to understand and interpret the PLR.
OBJECTIVES. The aim was to describe the changes in spectral energy of the sympathetic (SNS) and parasympathetic (PNS) divisions of the autonomic nervous system in healthy subjects performing a passive leg raising maneuvre.
METHODS. Eleven healthy subjects passed through 5-10 minute phases of semi-recumbent, passive leg raising and back to semi-recumbent positions while ECG was recorded at 1000 Hz and haemodynamic variables (HR, MAP, SV and CO) were collected by the Finometer. ECGs were characterized in their spectral aspects by Kubios Pro. PNS, SNS indices, spectral (LF, HF, LF/HF) and Finometer variables were analysed with respect to relative and absolute changes through transitions from initial to leg-raised positions and back to initial position, following the suggestions of Monnet & Teboul (1).
RESULTS. All subjects increased SV>10% (but not CO) and were by definition volume responsive. Some increased HR and MAP, some decreased. Over all, COs were unchanged by topographical change. In semirecumbent positions (relative hypovolemia) SNS index increased. In PLR (relative hypervolemia) PNS index increased.
CONCLUSION. In supposedly normovolemic subjects the gravitational dislocation of central blood volume elicited a response from the divisions of ANS to maintain homeostasis. From a histocentric point, incorporating the Guyton venous return (2) and the Krogh two-compartment venous compartment (3) models, their organisms had no need of increased SV or CO. Homeostatic reflexes worked to adapt the ratio of stressed/unstressed volumes by mobilising from (↗SNS/↘PNS in semirecumbent) or demobilising (↘SNS/↗PNS in PLR) to the splanchnic circulation. This interpretation warrants closer scrutiny of the autonomic nervous system in the context of PLR in the intensive care or perioperative setting.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000139

INTRODUCTION. Tailored fluid therapy has received increasing attention in the management of patients with acute circulatory failure in both the intensive care unit (ICU) and operating room (OR). The only physiological reason to give a fluid challenge (FC) to a patient with acute circulatory failure is to increase the stroke volume (SV) ultimately leading to an increase in oxygen transport. However, this is only achieved in approximately 50% of ICU and OR patients. The values of the ventilator-induced dynamic changes in pulse pressure and stroke volume [pulse pressure variation (PPV) and stroke volume variation (SVV), respectively] are often unreliable in a significant number of ICU and OR patients. To overcome these limitations, bedside functional hemodynamic assessment has gained in popularity. The functional hemodynamic test (FHT) called passive leg raise (PLR), has been successfully used since 2009 to assess fluid responsiveness in ICU patients. Since the reliability and the limits of PPV, SVV and PLR in predicting fluid responsiveness has been already extensively investigated in different clinical settings, we conducted a systematic review of the literature and performed a metanalysis aimed at assessing the overall quality, external validation, consistency and risk of bias of the other FHTs available in both the ICU and OR.
METHODS. We considered a FHT as a clinical maneuver affecting heart-lung interactions and causing a different hemodynamic response in fluid responders and non-responders. MEDLINE, EMBASE and Cochrane Databases were screened for relevant articles using a FHT, with the exception of the PLR. The QUADAS-2 scale was used to assess the risk of bias of the included studies. In-between study heterogeneity was assessed through the I2 indicator. Bias assessment graphs were plotted and Egger's regression analysis was used to evaluate the publication bias. The metanalysis determined the pooled area under the receiving operating characteristic (ROC) curve, the sensitivity, specificity and threshold for two FHTs: the EEOT (end-expiratory occlusion test) and the mini-fluid challenge (FC).
RESULTS. The electronic search identified 7,674 titles. After text selection, 21 studies met the inclusion criteria, 7 performed in the OR and 14 in the ICU between 2005 and 2018. The search included 805 patients and 870 FCs with a median (IQR) of 39 (25-50) patients and

36 (29 - 50) FCs per study. The median fluid responsiveness was 54% (45-59). The pooled area under the ROC curve for the end-expiratory occlusion test (EEOT) was 0.96 (95% CI 0.92-1.00). The pooled sensitivity and specificity was 0.86 (95%CI 0.74-0.94) and 0.91 (95%CI 0.85-0.95) respectively, with a best threshold of 5% (4.0–8.0). The pooled area under the ROC curve for the mini-FC was 0.91 (95% CI 0.85-0.97). The pooled sensitivity and specificity were 0.82 (95%CI 0.76-0.88) and 0.83 (95%CI 0.77-0.89), respectively, with a best threshold of 5.4% (3.0–7.0).

CONCLUSION. The EEOT and the mini-FC reliably predict fluid responsiveness in the ICU and OR. Other FHTs have been tested insofar in heterogeneous clinical settings, and, despite promising results, warrant further investigations.

A systematic review of practice patterns for treatment of atrial fibrillation in critically ill patients

L. O'Bryan, OC. Redfern, J. Bedford, P. Watkinson
Critical care research group, University of Oxford, Oxford, United Kingdom
Correspondence: L. O'Bryan
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000603

INTRODUCTION. New-onset atrial fibrillation (NOAF) occurs commonly in critical care and can lead to longer hospital stay, an increased risk of thromboembolic stroke and higher in-hospital mortality.(1) Treatment guidelines for atrial fibrillation (AF) in the general population are less safe and effective when applied to the critically ill patient.(2,3) At present, there are no consensus recommendations for the management of NOAF which are specific to critically ill patients.(4) Previous systematic reviews have identified a paucity of high-quality evidence to inform clinical practice and published studies suggest that current approaches to treatment vary considerably.(1,4)

OBJECTIVES. To systematically review published studies that report current practices for management of NOAF in critically ill patients

METHODS. We searched EMBASE, MEDLINE and Web of Knowledge for observational studies reporting data related to treatments used for NOAF in critically ill adult patients. The outcome of interest was the treatment(s) given to patients with NOAF. Treatments could be drugs to control cardiac rate or rhythm (including magnesium), DC cardioversion or anticoagulants. Data relating to study design, setting, population, interventions, outcomes and risk of bias were extracted. Risk of bias assessment was performed using an adapted Newcastle-Ottawa Scale.

RESULTS. We initially obtained 1,406 search results, of which we included 9 studies with a combined total of 8,689 patients. Of drugs used for rate/rhythm control, amiodarone use was reported most often (in 8 studies) followed by beta-blockers (7 studies), calcium channel blockers (5 studies), digoxin (5 studies) and magnesium (4 studies). Rate of DC cardioversion use was reported in 8 studies. Anticoagulant use was reported in 4 studies. As a proportion of all patients across studies, amiodarone was used in 48.9%, beta-blockers in 36.1%, magnesium in 29.8%, calcium channel blockers in 18.8%, digoxin in 17.8% and DC cardioversion in 16.2%. Anticoagulants were used in an average of 44.0% of patients. When comparing practices between countries, studies from Europe demonstrated higher rates of amiodarone use when compared to studies from the USA. The mean proportion of patients treated with amiodarone in European studies was 69.3%, compared with 47.7% in American studies. In contrast, American studies reported use of either a calcium channel blocker or beta-blocker in 49.7% of patients, compared with 24.2% in European studies.

CONCLUSION. There is a clear difference in practice patterns between the USA and Europe in antiarrhythmic use for NOAF management. Even within countries it appears that practices vary significantly. Furthermore the use of anticoagulation varies considerably. Future research should focus on comparing the efficacy of the most commonly used anti-arrhythmic agents including amiodarone, beta-blockers, calcium channel blockers and magnesium. Large cohort studies should test the rates of ischaemic stroke and bleeding associated with anticoagulation in a generally critically unwell population with NOAF.

Higher skin blood flow is associated with better hemodynamic tolerance to fluid removal in patients with acute respiratory distress syndrome

W. Mongkolpun[1], B. Péter[1], JL. Vincent[2], J. Creteur[1]
[1]Department of intensive care, ULB Erasme, Anderlecht, Belgium; [2]Department of intensive care, ULB Erasme, Brussels, Belgium
Correspondence: W. Mongkolpun
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000729

INTRODUCTION. A negative fluid balance (NFB) can improve oxygenation in patients with acute respiratory distress syndrome (ARDS) but an excessive NFB can result in hemodynamic instability and tissue hypoperfusion. Skin blood flow (SBF) measurements can provide an indication of tissue perfusion.

OBJECTIVES. We hypothesized that SBF measurements could predict hemodynamic tolerance (HT) during induction of a NFB in patients with ARDS.

METHODS. We prospectively included hemodynamically stable (mean arterial pressure (MAP) $\geq$ 65 mmHg with no increase in norepinephrine (NE) dose in the last 6 hours) patients with ARDS (Berlin criteria) in whom a strategy of fluid removal was applied to reach a NFB of more than 1 L in 24 hours. SBF was measured (Periflux 5000, Perimed; index finger; Perfusion unit: PU) for 3 min at basal temperature before the NFB strategy (T0) and 24 hours later (T24). Hemodynamic variables, the PaO2/FiO2 ratio, central venous oxygen saturation (ScvO2) and blood lactate concentrations were also recorded at H0 and H24. HT after NFB (H24) was defined as MAP $\geq$ 65 mmHg with no increase in NE dose. In patients with a NFB $\geq$ 1 L at H24, a receiver operating characteristic (ROC) curve was constructed to assess the best predictive values for HT. Data are reported as medians with 25th and 75th percentiles.

RESULTS. We studied 35 mechanically ventilated patients with ARDS (pneumonia (29), abdominal infection (5), pancreatitis (1)). Clinical

characteristics are shown in Table1; 11/35 patients received continuous hemofiltration. At T0, there were no differences in SOFA score, hemodynamic variables, NE dose, PaO2/FiO2, ScvO2, time from diagnosis or furosemide dose between patients with and without HT (Table 1). At T24, the degree of NFB did not differ significantly between the group with and without HT (1.7 (1.2-2.0) vs 1.3 (1.1-1.9) L,p=0.1). Patients who tolerated a NFB had lower lactate levels (1.1 (0.7-1.2) vs 1.4 (1.0-1.7) mmol/L, p=0.03) and higher SBF (151 (81-194) vs 70 (45-135) PU, p=0.01) than those who did not. MAP, cardiac index (CI) and ScvO2 were similar in patients with and without HT. SBF decreased in patients with and without HT (p<0.01) but was higher at H24 in patients who tolerated the NFB than in those who did not (100 (35-173) vs 35 (22-78) PU, p=0.01). The area under the ROC curve to predict HT after a NFB was higher for baseline SBF (0.92[0.83-0.99]) than for lactate level (0.72 [0.58-0.87]) and ScvO2 (0.69 [0.53-0.85]) (both p=0.03), with a cut-off ≥ 125 PU (sensitivity 90, specificity 93%).

CONCLUSION. Baseline SBF can predict good hemodynamic tolerance to a NFB in patients with ARDS.

Table 1 (abstract 000729). See text for description

	All patients (N=35)	NFB with HT (N=18)	NFB without HT (N=17)	p
SOFA at T0	10 (7-11)	9 (6-11)	11 (8-12)	0.2
MAP at T0 (mmHg)	71 (69-72)	72 (71-73)	69 (68-72)	0.5
Heart rate at T0 (bpm)	100 (86-114)	98 (85-108)	94 (66-116)	0.2
Cardiac index at T0 (L/min/m^2) (N=27)	2.7 (2.1-3.0)	2.7 (2.4-3.1)	2.5 (2.0-3.0)	0.7
Norepinephrine dose at T0 (mcg/kg/min) (N=27)	0.2 (0.03-0.3)	0.2 (0.04-0.30)	0.1 (0.03-0.3)	0.5
PaO2/FiO2 at T0	134 (86-193)	136 (115-200)	143 (87-198)	0.4
Time from diagnosis to initial NFB (hours)	74 (49-96)	72 (48-96)	74 (64-94)	0.6
Furosemide dose during NFB (mg/24 hours)	80 (70-120)	80 (80-120)	80 (60-120)	0.9
Negative fluid balance at T24 (L)	1.3 (1.1-2.0)	1.7 (1.2-2.0)	1.3 (1.1-1.9)	0.1

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001254

INTRODUCTION. During the resuscitation process of septic shock, use of dynamic parameters over static parameters to assess fluid responsiveness has been proposed. Surprisingly, scarce evidence is available showing a beneficial clinical outcome effect of dynamic parameters over static parameters to guide fluid resuscitation.

OBJECTIVES. To evaluate the impact on mortality of a fluid resuscitation protocol based on the use of dynamic parameters compared to static parameters to assess fluid responsiveness in the resuscitation process of severe sepsis and septic shock patients.

METHODS. Prospective, randomized, multicenter study. Adult patients with severe sepsis or septic shock, with evidence of tissue hypoperfusion, and under mechanical ventilation. At ICU admission, patients were randomized to one of the two fluid resuscitation protocols: *Control Group*, where fluid resuscitation was guided by Central Venous Pressure (CVP), according to the recommendations of *Surviving Sepsis Campaign 2012*; and *Intervention Group*, where fluid resuscitation was guided by Pulse Pressure Variation (PPV), Systolic Volume Variation (SVV), or Passive Leg Raising (PLR) maneuver. The fluid resuscitation protocol was followed during the first 72h of ICU stay. Main study outcome was 28-day mortality. Baseline patient characteristics, hemodynamic data, metabolic data, fluid balance, organ failure evolution, and ICU/hospital stay were also recorded.

RESULTS. The study was interrupted after two years because of low patient inclusion rate. A total of 60 patients were included in 12 centers. 66.6% of the patients were randomized to control group (n=40), and 33.3% to intervention group (n=20). There were no differences in baseline patients characteristics between the two groups. Median age was 62 ± 15 years, 65% male, 82% in septic shock, with initial SOFA score 12 ± 4 points. Lactate at inclusion was 4.7 ± 3.6 mmol/L. Global mortality was 30%, 47% in the control group and 21% in the intervention group (p = 0.1). There were no differences in lactate evolution at 6 and 24 hours of admission. Fluid balance during the study period (72h) was significantly increased in the control group (5812 ± 4818 mL vs 3035 ± 3031 mL, p 0.02).

CONCLUSION. A fluid resuscitation protocol based on dynamic parameters to assess fluid responsiveness is associated to a decreased fluid balance in the first 72h of the resuscitation process of septic shock. The inclusion of these dynamic variables may help to limit excessive fluid administration, potentially improving the outcome in this population of patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000349

INTRODUCTION. Frailty significantly impacts ICU patient's outcomes, recovery and healthcare utilization. However, knowledge about changes in frailty after ICU admission and associated factors is limited.

OBJECTIVES. To assess frailty before ICU admission and determine differences between frail and non-frail patients; to study changes in frailty in the year after ICU admission and its associated variables.

METHODS. Adult patients admitted for ≥12 hours to a university hospital ICU between July 2016 and December 2017 were included (MONITOR-IC study, clinicaltrials.gov NCT03246334). Moribund patients were excluded. Frailty was assessed using the Clinical Frailty Scale (CFS) (range 1 'Very fit' to 9 'Terminally ill') before ICU admission (T0), at hospital discharge (T1), and three (T2) and 12 months (T3) after ICU admission. Baseline differences between 'non frail' (scale 1-4) and 'frail' patients (scale 5-9) were compared. We calculated CFS mean differences between time points. We used multiple linear regression to determine factors associated with frailty change scores over one year (T0-T3).

RESULTS. A total of 1300 patients was included: mean age 61 (±14.9 years), 65% male and 66% planned ICU admissions. Median baseline CFS score was 3 [IQR:2-4]. Frail patients (12%) were significantly more often female, lower educated, divorced or widowed, living in a healthcare facility, had more often a chronic condition and an unplanned ICU admission.

At T1 the number of frail patients increased from 12 to 43%. At T2 and T3 this decreased to 15% and 9%. After one year, 30% had a lower CFS score compared to T0 (less frail), 31% a higher score (more frail) and in 39% the score did not change. Factors significantly associated with lower scores after 12 months, were planned admission (B=-0.306), mechanical ventilation (B=-0.320) and higher baseline CFS score (B=-0.711). Factors significantly associated with higher scores were age (B=0.013), living in a healthcare facility before admission (B=1.199), hospital LOS (B=0.023), and being discharged to a nursing home (B=0.861). APACHE IV score, chronic diagnosis, admission type and ICU LOS were not associated with changes in frailty.

CONCLUSION. Frailty levels changed in the first year after ICU admission. After one year, one third of the patients were more frail and one third less frail. Several factors, including age, living in healthcare

facilities, hospital LOS and discharged to a nursing home were associated with being more frail after one year.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001013

INTRODUCTION. Early identification of the deteriorating patient is a priority for healthcare professionals. Previous studies have examined the prognostic accuracy of early warning and critical care scoring systems, however comparative data is rare(1,2).
OBJECTIVES. Compare the prognostic accuracy of the Intensive Care National Audit & Research Centre (ICNARC) physiology score, the NHS National Early Warning Score (NEWS) and the Sequential Organ Failure Assessment (SOFA) score for predicting acute (7-day) mortality in the deteriorating ward patient.
METHODS. Data for this abstract were taken from the (SPOT)light study; a multicentre prospective observational cohort study of the deteriorating ward patient referred for assessment by critical care. From the physiology measurements at ward assessment, the ICNARC physiology, NEWS and SOFA scores were calculated with missing values given zero weights as previously recommended(3–5). Survival status was obtained from the NHS Information Service with acute mortality defined as death within 7 days of the first ward assessment by critical care. Statistical analysis was undertaken using R. Unadjusted logistic regression was used to test for the association between each score as a continuous variable and acute mortality, with odds ratios calculated. Performance of scoring systems was assessed by discrimination using receiver operating characteristic (ROC) curve analysis. ROC curves were plotted and the area under the curve (AUC) calculated using the PRROC package(6).
RESULTS. 48 hospitals reported 15,158 visits for ward assessment over 369 study months (mean age 67 years, 51.9% male). 2708 (18%) patients died during the 7-days following ward assessment, 1539 (57%) of these deaths occurred within the first 48 hours. There was a clear correlation between physiological severity and acute mortality using either ward based (NEWS) or critical care scoring systems (SOFA, ICNARC). For predicting acute mortality, the AUC-ROC values (95% CI) were similar between the scoring systems with NEWS 0.67 (0.66-0.68), SOFA 0.65 (0.64-0.67) and ICNARC 0.68 (0.67-0.69).
CONCLUSION. The results demonstrate that NEWS, ICNARC and SOFA have equivalent accuracy for predicting acute mortality in the deteriorating ward patient. This result is of important practical value as using simpler scores such as NEWS or SOFA could facilitate greater efficiency when assessing patients in the ward setting.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001660

INTRODUCTION. Improved survival following sepsis has been widely reported and asserted, even for those with severe sepsis treated in an intensive care unit (ICU). These favourable mortality trends are often interpreted as the success of healthcare investment and sepsis research. Reliable interpretation of long-term trends requires an appropriate metric with comprehensive data to prevent misinterpretation.
OBJECTIVES. To review temporal trends in sepsis-related incidence and mortality based on a retrospective analysis of a eighteen-year jurisdictional dataset.
METHODS. Sepsis-related hospital admissions were electronically identified using international consensus criteria mapped to ICD-10AM codes. Risk-adjustment was derived from available demographic and diagnostic codes. Mixed-effects regression models were employed to identify significant temporal trends.
RESULTS. Over eighteen years the population in Victoria (6.2 million) grew by 34.5%. 447,417 sepsis-related records were identified including 80,455 (18.0%) treated in ICU. 44,561 (10.0%) in-hospital deaths were reported. Annual population-derived mortality rate remained unchanged for both total (60.0±3.4 per 10^5, p=0.72) and ICU (19.8±1.6 per 10^5; p=0.73) cohorts. Hospital mortality rates declined significantly (p<0.001) but were static when adjusted for population size (p=0.074) and total sepsis burden (p=0.14). Total population (VIF=37.6), adult population (VIF=51.0), and hospitla sepsis burden (VIF=24.2) were all collinear with 'year of separation'.
CONCLUSION. Sepsis-related incidence is rising but sepsis-related mortality has not declined over the past eighteen years in the State of Victoria. Reports of apparent decline in sepsis mortality rates may be due to rising admissions and incomplete risk-adjustment.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001690

INTRODUCTION. Mismanagement of deterioration is the most common area of systemic failure in avoidable patient death across the NHS.[1] To address this issue, national guidelines recommend routine analysis of patient safety data to identify areas of service failure and to highlight opportunities for corrective action.[2] We previously described a novel 'failure to rescue' (FR) scoring system that can be applied to unplanned ICU admissions (UPAs) from ward areas, to identify any aspects of care that may have contributed to patient deterioration.[3]
Using data collected over a 4-year period, here we validate this score and explore the association between the FR score, illness severity and patient outcome.
METHODS. All adult UPAs in a single university foundation trust between January 2014 and December 2018 were reviewed. As previously described, the FR score consists of 18 questions that objectively appraise four categories of care failure in the pre-ICU admission period.

1. Failure to record: Were frequency of vital signs increased? Were vital signs complete?
2. Failure to recognise: Was deterioration recognised?
3. Failure to escalate: Was the patient escalated, was there evidence of an escalation block?
4. Failure to manage: Where appropriate diagnostic tests performed? Was there timely review?

Scores range 0 to 18.5; higher scores indicate greater failures in care. Additional data collected included: patient demographics, APACHE II score, ICU admission, ICU and hospital mortality.
RESULTS. 3112 patients were included; median age 63(IQR 51-73), 59% male, median admission APACHE II scores 19(14-23) with a 66% survival rate to hospital discharge. Median total UPA score was 2(1-4) which was higher in patients who did not survive (p<0.001). Patients who suffered cardiac arrest prior to ICU admission also had higher UPA scores (p<0.001). The majority of patients scored between 0-3; and the most commonly occurring category of care failure was Failure to manage in 20% of cases.
In a multivariate logistic regression model controlling for age, sex and APACHE II score total UPA score retained significance for prediction of hospital mortality (OR 1.040, 95% CI 1.007-1.040, p=0.017, overall p value <0.001). The area under the receiver operating curve for this model was 0.735 (0.718-0.753), p<0.001.
CONCLUSION. In this large observational cohort, we have demonstrated the ability of the FR scoring system to identify categories of care failure. We have demonstrated an association between higher scores (greater failures in care) and worse patient outcomes. This system provides critical information about patient deterioration, allowing focused quality improvement projects that may be tracked via FR scores over time.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001259

INTRODUCTION. Ultrasound guidance of peripheral venous catheter (PVC) insertion may increase the success rate of the procedure.
OBJECTIVES. We performed randomized pre-hospital clinical study to compare two different techniques of ultrasound guided PVC insertion and conventional cannulation technique regarding the success of the first attempt of PVC insertion, the overall success, the number of attempts required for successful PVC placement, the time required to introduce PVC and the incidence of pre-hospital complications.
METHODS. Pre-hospital prospective controlled randomized clinical trial allocated patients treated by emergency medical service to either undergo PVC insertion fully controlled by ultrasound (ultrasound guidance of the tip of the PVC until it penetrates the lumen; Group A); or to undergo PVC insertion partially controlled by ultrasound (target vein identification only; Group B); or to receive PVC by conventional approach without any ultrasound guidance (Group C). The study outcomes were monitored until takeover of the patient to the hospital.
RESULTS. A total of 300 adult patients were enrolled. The success of the first attempt (group A: 88%, group B: 94%, group C: 76%, p< 0.001) and overall success rate (A: 99%, B: 99%, C: 90%, p<0.001) were significantly higher in the groups A and B than in the group C without significant differences between the groups A and B. The number of attempts was significantly lower (A: 1.18±0.54, B: 1.05± 0.22, C: 1.22±0.57, p<0.001) and the time required for the procedure shorter (A: 75.3±60.6, B: 43.5±26.0, C: 82.3±100.9 s, p<0.001) in the group B than in the groups A and C.
CONCLUSION. Pre-hospital ultrasound guidance of PVC placement was associated with higher success rate than conventional method, irrespective of the technique of ultrasound guidance. However, PVC insertion partially controlled by ultrasound was superior to full ultrasound guidance in terms of the time and number of cannulation attempts required.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000433

INTRODUCTION. Fluid therapy is a cornerstone of modern medical practice, particularly in acute settings such as intra-operative or intensive care. The acidosis attributed to Normal Saline has a clear dose-dependent effect with larger volumes associated with this phenomenon. However, the exact quantitative impact of this solution when used in a restrictive paradigm is not adequately assessed in the current literature. Thus, this study attempted to assess the effects of vs. Normal Saline when used in restrictive quantities as determined by a predefined the hemodynamic algorithm.
OBJECTIVES. To determine the equivalence or otherwise of Normal saline in comparison to balanced salt solution for intra- operative fluid replacement in elective, adult open abdominal surgery on serum chloride level using a restrictive fluid therapy algorithm.
METHODS. 120 adult patients were randomized to receive either Normal saline or Plasmalyte as the predominant fluid during surgery using a computer-generated the random number. Patients received a bolus of 150ml of study fluid at induction and 2ml/kg/hr + urine output+ blood loss every hour. Systolic Pressure variation and Pulse Pressure variation was assessed every time the systolic blood pressure < 90 mm Hg or < 20% from baseline whichever was higher using the predefined algorithm. Arterial blood gas samples were repeated every two hours until the end of surgery. Additional samples were also obtained pre-induction and 24 hours after the end of surgery for the biochemistry variables. Previous studies had reported a difference of approximately 6 mEq L-1 in the chloride levels when saline was used in comparison to Plasmalyte at the volumes infused in the study. Assuming an α of 0.05 and a power of 80%, 120 patients were required to demonstrate that the limits of a two-sided 95% confidence interval would exclude a difference in the Chloride concentration of <3 mEq L-1 between the two groups at the conclusion of surgery.
RESULTS. 120 patients were enrolled in the study. Fig 1is the CONSORT diagram.
The chloride anion level decreased by a mean of 0.54 ± 3.29 in the Plasmalyte group and increased by mean of -0.43 ± 4.90 in the normal saline group, the difference between the two insignificant (p value=0.22). Subgroup analysis of 50 patients with duration of surgery exceeding 4 hours demonstrated chloride increase until 2 hours in both groups and thereafter a drop was noted by the 4th hour. (FIGURE 2)
Higher total urine output was recorded in Plasmalyte group (p= 0.006, significant) with a mean difference of 69.368 ml, 95% CI (19.0 to 119.7). (FIG 3)
CONCLUSION. CONCLUSIONS: Restrictive fluid regimen shows equivalence in the choice of crystalloid fluid (Plasmalyte versus Normal saline) used for intraoperative fluid therapy.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000704

INTRODUCTION. Postoperative infections are a major challenge for perioperative medicine. It is a major contributor to morbidity and mortality worldwide. Sensitivity and specificity of traditional biomarkers for predicting and diagnosing infection are often reduced in this setting. Lack of precision combined with the importance of early diagnosis and treatment emphasize the need for more sensitive markers of infection. Adrenomedullin (analyzed indirectly with mid-regional proadrenomedullin, MR-proADM) is a novel peptide that has predominantly vasoactive and immunological properties and seems to be an important prognostic marker for sepsis. However, whether one could use MR-proADM for the prediction and early diagnosis of postoperative infections remains unclear.
OBJECTIVES. To investigate the association between elevated levels of MR-proADM perioperatively and infectious complications in the 30 days following surgery.
METHODS. This was a preplanned substudy of the Myocardial Injury in Noncardiac Surgery in Sweden (NCT03436238). We enrolled 504 patients undergoing major elective abdominal surgery in a multicenter prospective cohort study. MR-proADM levels were measured preoperatively, immediately postoperatively, and on days 1, 2 and 3 after surgery. Postoperative infections were registered at 30 days after surgery by a blinded assessor. The relationship between MR-proADM levels and the presence of infection was investigated. ROC-curves were constructed in order to obtain a cutoff value maximized for sensitivity.
RESULTS. MR-proADM was significantly higher at all postoperative data points across all patients compared to preoperatively. There were significant differences in MR-proADM levels between patients who developed an infectious complication and those who did not. This difference were noted immediately after surgery and at days 2 and 3. A cutoff was obtained from ROC-analysis which revealed that 1.043 nmol/L could significantly discriminate blood infection from no infection groups with a sensitivity of 89 % and specificity of 41 %.
CONCLUSION. MR-proADM levels immediately after surgery, at day 2 and day 3 predict infectious complications in the 30 day postoperative time period.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001264

INTRODUCTION. Perioperative atrial fibrillation (POAF) is associated with significant short and long-term complications.
OBJECTIVES. To establish the incidenceof POAF after noncardiac surgery and investigate the association between the preoperative NT-pro-BNP level and POAF.
METHODS. The Vascular events In non-cardiac Surgery patlents cOhort evaluatioN (VISION; NCT00512109) Study was an international prospective cohort study of a representative sample of adults ≥45 years of age who underwent non-cardiac surgery. One of the predefinedobjectives was to determine the 30-day incidenceof clinically important POAF (defined as POAFresulting in angina, congestive heart failure, symptomatic hypotension, or requiring treatment). We estimated the relationship between preoperative NT-pro-BNP levels and clinically significantPOAF using multivariable logistic regression models with restricted cubic splines.
RESULTS. In 37,664 patients with no prior history of AF, the incidence of POAF was 1.0% (95% CI, 0.9-1.1; 369 events). It was 3.2% (95% CI, 2.3-4.4) in patients undergoing major thoracic surgery, 1.3% (95% CI, 1.2-1.5) in major nonthoracic surgery, and 0.2% (95% CI, 0.1-0.3) in low-risk surgery. NT-pro-BNP measurement was obtained in 9789 individuals before surgery. An increase in the preoperative NT-pro-BNP level from 39 ng/ml (first quartile) to 228 ng/ml (third quartile) was associated with an unadjusted OR for developing POAF of 3.92 (95% CI, 2.32-6.65), and anadjusted OR of 2.55 (95% CI, 1.49-4.36).

CONCLUSION. Clinically important POAF was observed in every one hundredth patient having noncardiac surgery. Preoperative NT-pro-BNP levels were strongly associated with an increased risk of POAF.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001686

INTRODUCTION. Shivering is an unpleasant condition which usually occur as a complication after both general and regional anaesthesia in patient underwent either elective or emergency surgery.
The elderly constitute an important risk group due to the physiological alterations that occur in the aging process and contribute to a diminished thermoregulation capacity.
OBJECTIVES. Present prospective, randomized, and controlled study was performed to determine the benefits of warmed liquids infusion compared with infusion of liquids kept at room temperature in maintaining normal core temperature and prevent shivering after general anesthesia in elderly.
METHODS. After obtaining institutional approval and written informed consent from all patients, 62 patients with American Society of Anesthesiologists physical status of I-III, aged 65 years and above, who were scheduled for elective surgery under general anesthesia, were included in this prospective, randomized study. Exclusion criteria included history of head injury, thyroid disease, severe cardiovascular and respiratory disease, a core temperature of ≥ 37.5°C.
Our patients were randomly allocated to receive crystalloid at room temperature (31 patients, Group A, without infusion warmer) or warmed at 37°C (31 patients, Group B, with infusion warmer) .
Shivering was graded using the Bedside Shivering Assessment Scale.
The occurrence of shivering during surgery and in the recovery room was recorded.
The data obtained were analyzed with SPSS software with a significance level of p.
RESULTS. At the end of surgery, core temperature was 36.8 +/- 0.1 degrees C in the group receiving warmed fluids and 35.7 +/- 0.3 degrees C in the control group (P < 0.05).
During recovery, four patient shivered in the group receiving warmed fluids and seventeen in the control group (P < 0.05).
The severity of post-anesthesia shivering was also significantly less in the infusion warmer group (P < 0.05).
CONCLUSION. The use of infusion warmer may help in reducing the incidence of hypothermia and shivering after general anesthesia in elderly patients.
Prevention of hypothermia and shivering should be done with multimodal approach, either by pharmacological or non-pharmacological strategies.
Warm IV saline solution given before, during, and after surgery, is the cheapest and easiest way to maintain core temperature, preventing hypothermia and shivering.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001743

INTRODUCTION. A standard subcutaneous low-molecular weight heparin (LMWH) thromboprophylaxis yields subtherapeutic level of plasma anti-FXa activity (anti-FXa) in intensive care unit (ICU) patients. Moreover, the ability of the anti-FXa to predict clinical adverse events is limited.
OBJECTIVES. To assess coagulation status in mixed ICU patients randomized to receive enoxaparin thromboprophylaxis either as a standard subcutaneous bolus (SCB) or continuous intravenous infusion (CII) for three consecutive days.
METHODS. A randomized, single-blind study at two tertiary university hospitals was conducted. Thirty-eight mixed ICU patients were studied by conventional coagulation parameters. Additionally, 18 patients were analyzed for thrombin generation by calibrated automated thrombogram (TG-CAT). Blood samples were taken prior the study start (i.e. baseline), at 51 (i.e. the final peak level of the SCB group) and at 72 (i.e. the final through level of the SCB group) hours from the study start.
RESULTS. At baseline, no difference in coagulation status was observed. The inhibition of prothrombin fragments F1+2 (F1+2) was significantly superior at 51 and 72 hours in the CII group compared to the SCB group. Correspondingly, a significant increase in antithrombin (AT 3) level was observed within the CII group whereas the level in the SCB group remained unchanged (Table 1). At 51 hours lag time (7.5 vs. 4.3 min, p <0.05) and time to peak (14.3 vs. 7.7 min, p <0.05) of the TG-CAT analysis were significantly prolonged in the SCB group. At 72 hours peak thrombin was significantly lower in the CII group vs. the SCB group: 364 nM vs. 271 nM, p <.05. The final through level of plasma anti-FXa was higher in the CII group: 0.05 IU/ml vs. 0.12 IU/ml, p=0.067.
CONCLUSION. Continuous intravenous infusion of enoxaparin thromboprophylaxis resulted in more prominent inhibition of prothrombin fragments and better preservation of the natural anticoagulant antithrombin level in comparison to standard subcutaneous care.

Dealing with the aftermath of critical illness – the ENSURE (ENabling and SUpporting REcovery) intensive care follow up clinic

A. Lockwood, T. Jackson, R. Appelboam
Intensive care, Royal Devon and Exeter Hospital (Wonford), Exeter, United Kingdom
Correspondence: R. Appelboam
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000057

INTRODUCTION. Patients who survive intensive care are left with long term psychological, physical and cognitive impairments which may persist

for up to 15 years following discharge. Collectively, these impairments are known as post intensive care syndrome (PICS), which affects up to 70% of survivors (1). These impairments are not limited to patients alone, with carers also carrying a high burden of psychological and social co-morbidity (2).
OBJECTIVES. To assess the effectiveness of a 5 week multidisciplinary programme (clinic) for intensive care survivors and their carers on optimising physical and psychological recovery.
METHODS. Survivors of intensive care were invited to clinic with their carers, within 3 months of hospital discharge. Patients could also self-refer, or be referred by their family doctor.
On one morning a week, for 5 weeks, a selection of professionals from the multidisciplinary team (Consultant, Physiotherapist, Nurse, Psychologist, Dietician, Occupational Therapist, Pharmacist) attended and delivered a combination of group sessions and 1:1 sessions.
Using hospital data and self-administered questionnaires, information on patient characteristics, health status, and caregiver strain were collected. Patient outcome data were collected using the EQ-5D Health Questionnaire and self-efficacy scores at week 1, week 5, 3 months and 12 months. Carer outcomes were collected using a carer strain index. Professional interventions were recorded, and qualitative outcomes collected using standardised feedback forms.
RESULTS. A total of 28 patients have attended in 4 cohorts so far, with 22 family members. 25% self referred or were referred by their doctor. All patients completed their programme. 5 patients (18%) were trauma patients, 13 (46%) were medical, and 10 (36%) were surgical.
CONCLUSION. Patients and carers presented to our clinic with evidence of altered health status and carer strain. This multidisciplinary follow up clinic is an effective intervention in providing support and therapy for patients and their carers after intensive care, and results in improvements in self-efficacy and health status. The clinic is received positively by all who attend.

How does healthcare quality influence care left undone in neonatal and paediatric intensive care units?

A. Bagnasco[1], S. Rossi[2], N. Dasso[1], G. Catania[1], M. Zanini[1], G. Aleo[1], L. Sasso[1]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000215

INTRODUCTION. Providing high-quality care is a priority worldwide (WHO, 2018). One way of evaluating quality is the investigation of nursing care models. A topic under investigation in the last decade, due to its impact on the quality of health care, is the care left undone phenomenon (Ball et al., 2014). Understanding how healthcare quality is related to care left undone could contribute to quality improvement (Recio-Saucedo et al., 2018).
OBJECTIVES. Investigate which nursing staff and work environment variables could influence the prevalence of care left undone in Neonatal and Paediatric Intensive Care Units (NICUs and PICUs).
METHODS. We extracted data from the RN4CAST@IT-Ped project, a larger cross-sectional, observational, multicentre Italian study. The project involved 13 Italian hospitals, associated to Italian Association of Paediatric Hospitals, and the NICU and PICU nurses and paediatric nurses was enrolled using convenience sampling. We asked which activities, from a list of 13, were necessary but left undone because of lack of time during the last shift worked. Data were analysed through descriptive and inferential statistics methods (logistic regression), with IBM SPSS 22.0 software.
RESULTS. We analyzed the answers of 451 nurses. Poor health care, depersonalization and emotional exhaustion, and intention to leave the job are some variables that could influence the omission of some nursing activities, like surveillance, pain management, information and education, and mobilization (OR min=OR 1,024, p=0,026; OR max=OR 2,469, p=0,001). A good work environment is a protective factor related to the omission of nursing activities, like the development of nursing care plans (OR=0,512, p=0,001).
CONCLUSION. Our results are consistent with international literature showing that nurses miss some activities, especially in the presence of some environmental and personal conditions. Understanding the relations that underlay the nursing care left undone could be a starting point to develop improvement measures to both better patient-centred care and quality of health care.

INTRODUCTION. Sense of coherence (SOC) relates to the ability to endure stressful life events, and is divided into comprehensibility (SOC C), manageability (SOC MA) and meaningfulness (SOC ME). Low SOC reflects low coping ability and is strongly associated with post-traumatic stress symptoms (PTSS). It is not known whether nurse led follow-up consultations can improve SOC in discharged intensive care unit (ICU) patients with moderate to high PTSS.

OBJECTIVES. An a priori defined post hoc analysis of a randomized controlled trial (RCT) on nurse led follow-up consultations in discharged ICU patients with moderate to high levels of PTSS was performed, where both the effect on total SOC (as a composite endpoint), and on each of the three SOC dimensions (SOC C, SOC MA and SOC ME) was evaluated.
METHODS. ICU patients ≥18 years admitted to one of five ICUs at Oslo University Hospital (OUH) for ≥24 hours were included. Patients were screened on PTSS (PTSS-10) immediately after ICU discharge, and those with PTSS-10 score ≥25 (clinically relevant symptoms) were randomized to an intervention (IG) or control (CG) group. IG patients received up to three individually adjusted nurse led follow-up consultations immediately after ICU discharge, and one and two months later. Consultations were based on trauma focused cognitive behavioural therapy combined with narrative method to process traumatic memories and achieve coherence of what happened during the ICU stay. The SOC Scale with 13 items on a 1-7 scale measured the total score (range 13-91), but also the score for each of the three dimensions SOC C, SOC MA and SOC ME. This was done immediately after ICU discharge (baseline), and after 3, 6 and 12 months. Possible differences between IG and CG were analysed using linear mixed models for repeated measures.
RESULTS. In total, 523 patients were screened and 224 (43%) had PTSS-10 score ≥25 (53% male, median age 52 years) and were randomized into IG (n=111) and CG (n=112). No statistically significant differences were found between IG and CG in total SOC (p= 0.47), SOC C (p=0.58), SOC MA (p=0.17) or SOC ME (p=0.78) over time from baseline to 12 months. During the same time period total SOC increased in both groups, with a non-significant trend towards a different time trajectory in IG and CG (Table).
CONCLUSION. Nurse led follow-up consultations in discharged ICU patients with moderate to high risk of PTSS, did not reveal any significant effect on the composite endpoint SOC or on any of the three SOC dimensions.

REFERENCE(S)

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000586

INTRODUCTION. Pain has been shown to be a serious and challenging problem for intensive care unit (ICU) patients. Research is, however, scarce on pain related issues in ICU patients immediately after ICU discharge to the ward, with a significant lower nurse – patient ratio compared to the ICU.
OBJECTIVES. The aim of this study was to investigate pain intensity and pain interference in ICU patients immediately after ICU discharge, and the association between pain and sense of coherence (SOC, reflecting coping), post-traumatic stress symptoms (PTSS), memories from the ICU stay and demographic and clinical variables. SOC, PTSS, and memories from the ICU stay were hypothesized to be associated with pain after ICU discharge.
METHODS. In this a priori defined sub-study of a randomized controlled trial on PTSS in ICU patients, 523 consenting patients aged ≥ 18 years admitted for ≥ 24 hours in one of five ICUs at Oslo University Hospital filled out Brief Pain Inventory (BPI) immediately after ICU discharge. BPI is measuring pain intensity using a numeric rating scale (NRS) from 0 (no pain) to 10 (pain as bad as you can imagine), pain interference with daily life (NRS 0-10) and pain location using a body map. The patients also answered questionnaires measuring PTSS (PTSS-10-I), SOC (SOC-13) and memories from the ICU stay (ICU memory tool). Data analyses were performed using descriptive statistics and multiple linear regression analysis.
RESULTS. Among the 523 included patients, 469 (90%) experienced pain, and 280 (54%) reported moderate to severe (NRS 4-10) worst pain intensity. Mean pain intensity and mean pain interference were 5.9 (SD 2.7) and 4.5 (SD 2.7), respectively. The majority of patients reported pain in the abdomen (43%), lower back (28%), and shoulder/forearm (22%). Variables significantly associated with worst pain intensity were; shorter ICU stay (beta -0.06, 95% CI [-0.09, 0.03]), low SOC (beta -0.03, 95% CI [-0.05, -0.00]), scary ICU memories (beta 0.44, CI [-0.25, 0.66]) and having undergone surgery (beta 1.15, 95% CI [0.17, 2.14]).Variables significantly associated with higher pain interference were scary ICU memories (beta 0.17, 95% CI [-0.02, 0.36), higher PTSS (beta 0.09, 95% CI [0.07, 0.11), prior anxiolytic use before hospital admittance (beta 0.53, 95% CI [0.01, 1.05]), trauma admission (beta 1.24, 95% CI [0.55, 1.92]) and regional analgesic use in the ICU (beta 0.53, 95% CI [0.06, 1.00]).
CONCLUSION. In total, 90% of the patients reported pain immediately after ICU discharge, and more than half of the patients reported moderate to severe pain. In addition, the association between low SOC and pain intensity highlights the importance of coping in patients after an ICU stay. The association between pain interference and prior anxiolytic use, scary memories and PTSS brings attention to the significance of psychological issues when relieving pain in ICU patients after ICU discharge.

Physical and Psychological Outcomes of patients discharged from a rehab active Critical Care Unit in the United Kingdom

F. Howroyd, J. Oldhams, A. Waqaar, D. McWilliams
Critical care rehab team, Queen Elizabeth Hospital Birmingham, Birmingham, United Kingdom
Correspondence: D. McWilliams
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000892

INTRODUCTION. Survivors of critical illness often experience ongoing physical, psychological and cognitive morbidity, collectively known as 'post intensive care syndrome' [1]. These effects can last for months to years after hospital discharge [2]. A recent trial of early and structured rehabilitation within our Intensive Care Unit (ICU) demonstrated a greater intensity of physical rehabilitation than that provided as standard care in previous trials [3]. Currently the psychological status of patients leaving our 'rehab active' ICU is unknown.
OBJECTIVES. 1. To identify levels of anxiety, depression, psychological distress and mobility reported at ICU discharge.
2. To explore the impact of mobility levels upon psychological outcomes.

METHODS. All patients under the care of a specialist critical care rehabilitation team and surviving to ICU discharge between December 2018 and February 2019 were included in the analysis. Patients were asked to complete the Hospital Anxiety and Depression Scale (HADS) and the Intensive Care Psychological Assessment Tool (IPAT) questionnaires within 48 hours of transfer from ICU to the ward. Manchester Mobility Scores (MMS) were also recorded by the patients' physiotherapist.
RESULTS. A total of 33 patients were included in the analysis, with 73% (n = 24) able to mobilise at the point of ICU discharge (defined as an MMS score of 6 or above). 42% (n = 14) of patients demonstrated symptoms of anxiety (HADS score > 7), 58% (n = 19) showed symptoms of depression (HADS score > 7) and 70% (n = 23) showed risk of psychological distress (IPAT score of 7 or above).
A sub analysis of outcomes (see table 1) demonstrated patients with MMS of ≤ 5 were more likely to be anxious (78% vs 29%, p<0.05) and had a longer ward length of stay (38.6 vs 17.5 days, p<0.05). No significant difference was seen for depression or IPAT.
CONCLUSION. A high prevalence of psychological morbidity was observed amongst ICU survivors on discharge to the ward. Increased mobility levels at the point of ICU discharge were associated with a reduction in the incidence of anxiety and shorter ward length of stay. However, symptoms of psychological distress were high within both groups. Our results identify the need for more structured follow up and psychological support of intensive care survivors on discharge to the ward.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000865

INTRODUCTION. In the past, quality and improvement in healthcare have focused on what proffesionals think should be valued and have been less interested in what serve userd felt was important. In the Intensive Care Unit, the patient's perspective, as well as their relatives', is central to quality improvement.
OBJECTIVES. To evaluate patients and relatives' satisfaction in an Intensive Care Unit (ICU).
METHODS. Information was collected from June to September 2018 through a survey adapted to patients and family members. The questionnaire included a 7-score Likert scale conformed by different items aimed at assessing the quality of the service provided to patients in the ICU.
Based on the work of Mora Lourido (2015), we took the dimensions created to measure the technical and structural human quality in the ICU, and we conducted an analysis of means using the student's T, to check the differences in patients and relatives' satisfaction.
RESULTS. The measurement scale was consisted of 7 dimensions, whose average values are shown in the attached table.
CONCLUSION. There are statistically significant differences in patients and relatives' satisfaction in all dimensions except those related to satisfaction with caretakers. In general, patients are more satisfied tan realtives with the ICU, with the exception of food, which is worse valued by patients. The quality of the ICU has received the highest score by both groups, being the dimension that has more weight in the satisfaction of patients and relatives. On the contrary, satisfaction with food is the item that has received the worst assessment.

Can the traditional morbidity and mortality (M&M) process be used to enhance staff wellbeing on the intensive care unit (ICU)?

A. Cavalier[1]; J. Macallan[1]; M. Alice[1]; T. Samuels[1]; F. Lamb[1]
[1]Critical care, East Surrey Hospital, Redhill, United Kingdom
Correspondence: J. Macallan
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000920

INTRODUCTION. Intensive care staff wellbeing is important and often overlooked. Emotional distress may result from involvement in traumatic events and witnessing death on the ICU. ICU staff should be offered opportunities to discuss these sensitive and emotional issues. The current morbidity and mortality (M&M) presentation model used in our ICU is only attended by ICU doctors. It is focused on educational and clinical aspects of patient deaths. The national General

Provision of Intensive Care Services guidelines version 2 (GPICSv2) 2018 now includes guidance for staff support (1).
OBJECTIVES. To assess whether the current M&M model allows staff wellbeing and emotional welfare to be explored and if this is required on a regular basis.
METHODS. ICU doctors of all grades were surveyed; on their attendance at M&M presentations; whether staff wellbeing was discussed; whether they would like this to be reviewed regularly; and whether they felt it would be beneficial for other ICU staff (nurses and therapists) to attend and contribute.
RESULTS. Sixteen doctors were surveyed (5 consultants, 6 middle grades and 5 SHOs). 14 of those had attended an ICU M&M presentation in the last 12 months. Of those that had attended, 5 out of 14 felt that the current M&M model allowed staff wellbeing and emotional issues to be discussed. 13 (81%) doctors surveyed would like to have a regular opportunity to discuss such issues. 15 (94%) doctors surveyed felt it would be beneficial for nurses and other MDT members to attend and contribute at the M&M presentation.
CONCLUSION. Staff wellbeing impacts upon quality of care (2). Doctors working on our ICU feel that it would be beneficial to incorporate a debriefing section at M&M meetings to discuss emotional welfare and staff wellbeing. Introducing this discussion and inviting all members of the multi-disciplinary team (MDT) may reduce the impact of the 'Second Victim Phenomenon' (3) caused by distressing events. M&M meetings could be improved to provide this opportunity by incorporating regular discussion about emotional distress caused by cases. Although it has been recommended in the consultation document of GPICSv2 (1), we cannot find any large studies in the literature to assess the impact of this. To enable safe facilitation of debrief sessions it is likely to be beneficial for staff members to undertake formal training. Further work is needed to assess the benefit of inviting members of the MDT to M&M. We plan to expand this survey out to all MDT members on our own ICU as well as conducting a larger survey across other intensive care units to assess this. We propose a change in the presentation format to include discussion on staff wellbeing and invite all MDT members to participate in discussion to provide a supportive environment.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000922

INTRODUCTION. The evolvement of airway pressures within the MV may reflect the modification of the viscoelastic properties of the respiratory system and hence predict poor outcome.
OBJECTIVES. To identify a relationship between airway pressures and mortality in MV patients.
METHODS. A retrospective charts' review of MV patients admitted to a medical ICU of Farhat Hached hospital from November 2015 to February 2018. Were collected patients' characteristics at admission and respective airway pressures (Peak, plateau, driving and intrinsic PEEP) at admission and at day 4. Trends of airway pressures (Paw) (Paw at day 4 - Paw at admission). High pressure ratio (HPR) is defined as the number of days spent with high pressures : Peak≥40 and/or plateau ≥30; and/or driving pressure ≥15 and/or; intrinsic PEEP ≥6; divided bylength of stay) and outcomes were recorded from chosen eligible charts. Univariate and multivariate regression analyses were performed to identify factors independently associated with mortality. ROC curves were used to check for the discriminative properties of the significant factors.
RESULTS. 304 mechanically ventilated patients were collected within the study period. 199(65%) were non-COPD patients. They were 50± 18 years aged; ARDS, 17(8.5%); pneumonia, 14(7%); Pulmonary edema, 10(5%); SAPS II, 35.1±15.7; pH, 7.31±0.14; PCO2, 42.4±19.9 mmHg; PaO2/FiO2, 210.6±109.2 mmHg; MV duration, 8.9±9.4 days; tracheostomy, 18(9%); length of stay, 10±10 days. Mortality, 114(57%). Median [IOR] trends of Paw : delta Peak, delta plateau, delta driving, delta intrinsic PEEP were respectively; 0[-5,5], 1[-2,3], 0[-2,3], 0[-2,0]. Median HPR, 0.15[0,1]. Univariate analysis and multivariate logistic regression analysis showed an association between Paw trends and mortality : 1) For non-COPD patients; delta Peak, (OR, 1.10; 95%CI, [1.03-1.19]; p=0.007), HPR, (OR, 38.3; 95%CI, [6.4-228.3]; p=0.000), 2) For COPD patients; delta plateau, (OR, 1.11; 95%CI, [1.01-1.22]; p=0.03), HPR (OR, 14.3; 95%CI, [3.6-56.6]; p=0.000). For non-COPD patients, respective ROC AUCs for delta Peak and HPR (0.73, 0.69) confirmed interesting discriminative properties to predict mortality. For COPD patients, respective ROC AUCs for delta plateau and HPR (0.70, 0.75) confirmed interesting discriminative properties to predict mortality.
CONCLUSION. The present study demonstrated that airway pressures' trends in MV patients could predict mortality.

000944

An airway pressures score for the prediction of poor outcomes in mechanically ventilated patients

MA. Boujelbèn[1], N. Fraj[2], W. Zarrougui[2], E. Ennouri[1], D. Ben Braiek[1], H. Zorgati[1], A. Azouzi[1], I. Ben Saida[2], K. Meddeb[2], M. Boussarsar[2]
[1]Medical intensive care unit, Farhat hached university hospital, Sousse, Tunisia; [2]Medical intensive care unit, farhat hached university hospital, Université de Sousse, Faculté de Médecine de Sousse, LR N° LR12SP09.Heart Failure, Sousse, Tunisia

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000944

INTRODUCTION. Poor outcomes in mechanically ventilated (MV) patients may be related to strenuous viscoelastic properties of the lungs and difficult respiratory mechanics which could be illustrated by elevated airway pressures (Paw).
OBJECTIVES. To identify the properties of a validated airway pressures score for the prediction of poor outcomes in mechanically ventilated patient.
METHODS. A retrospective chart reviews (from November 2015 to February 2018) of MV patients was conducted in the MICU of Farhat Hached teaching of Sousse, Tunisia. A Mortality prediction score (Paw-MPS) was developed and validated around three items (plateau at day 4 ≥18cmH2O, + 1 point; delta peak ≥2, + 1 point; HPR ≥ 0.34, + 2 points) where delta peak=trends of Ppeak (Ppeak at day 4 of ICU stay - Ppeak upon admission and HPR=number of days spent with high pressures : Peak ≥40 and/or plateau ≥30; and/or driving pressure ≥14; and/or auto-PEEP ≥6cmH2O; divided by length of stay). Poor outcomes were defined as : a ventilator-free days at day 28 (VFDs) = 0 and a composite outcome : death or length of stay ≥ 14 days. ROC curves were used to assess discriminativ e properties of Paw-MPS to predict outcomes.
RESULTS. A total of 304 MV patients were included. Their main characteristics were : mean age, 56±18years; male sex ratio, 64.8%(n= 197); mean SAPS II, 34.9±14.3; pH, 7,3±0,1; pCO2, 50±23mmHg; P/F ratio, 204±101 mmHg; AE/COPD, 105(34.5%); ARDS, 25(8.2%); restrictive lung disease, 20(6.6%); pneumonia, 14(4.6%); pulmonary edema, 11(3.6%); median mechanical ventilation duration, 3[6-14] days; tracheostomy, 44(14.5%); median length of stay, 13[6-21] days; median VFDs, 0[0-2] days; mortality, 173(56.9%). Mean plateau at day 4, 20.9±6.6 cmH2O; median delta peak, 0[-5;5] cmH2O; HPR, 0.15[0-0.6]; mean Paw-MPS, 2.2±1.2. For the prediction of composite outcome,

the Paw-MPS demonstrated respectively for the whole population, COPD patients and non-COPD patients the following ROC-AUCs : (AUC=0.75; 95%CI, [0.685- 0.809]; p≤10); (AUC=0.7; 95%CI, [0.620- 0.859]; p=0.002) and (AUC=0.74; 95%CI, [0.666- 0.819]; p≤10). For the prediction of zero VFDs, the Paw-MPS demonstrated interesting ROC-AUC only for COPD patients : (AUC=0.71; 95%CI, [0.602- 0.816]; p≤10).

CONCLUSION. This simple prognostic score based on airway pressures seems to demonstrate interesting discriminative properties to predict poor outcomes of patients requiring invasive mechanical ventilation.

Predicting hospital mortality in very elderly patients (VEP):preliminary analysis

E. Bertellini[1], G. Melegari[1], A. Marudi[1], M. Pavesi[1], F. Gazzotti[1], A. Barbieri[2]
[1]Anestesia e rianimazione, Ospedale Civile di Baggiovara, Baggiovara, Italy; [2]School of anaesthesia and intensive care, University of Modena and Reggio Emilia, Reggio Emilia, Italy
Correspondence: G. Melegari
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001117

INTRODUCTION. Nowadays the rate of patients with age ≥ 80 years old (VEP) admitted in intensive care unit (ICU) is increasing. Prognostic scores are necessary to determine the best therapeutic strategy, and when to withdrawal therapies. Recently, it was suggested to use Frailty index in elderly to better predict hospital mortality [1].

OBJECTIVES. It was investigated the predicting hospital mortality comparing ROC curve of SAPSII, first SOFA and Frailty index in VEP admitted in ICU.

METHODS. There were collected data from all unselected VEP patients for 3 consecutive months in ICU for different reasons: scheduled surgery, sepsis, cardiac arrest, haemorrhage or neurological coma. There were recorded all general data of patients and also measured SAPS II, first SOFA, Frailty index and hospital mortality (28 days mortality). Ethical Committee Modena procedure 184/16.

RESULTS. During the study period were admitted 34 patients with mean age of 84.06±0.52, 54.29% medical admissions, 31.43% unscheduled surgery, and 14.29% scheduled surgery. The hospital mortality was the 57.58%, the mean value for the length of stay in ICU was 12.47 days (CI 7.78-17.16). The mean value of SAPSII was 50.18± 4.07, first SOFA 7.0±0.71, Frailty Index 3.87±0.24. SAPSII showed an AUC curve of 0.96 (CI 0.88-0.99), first SOFA AUC 0.90 (CI 0.79-0.99), Frailty index 0.58 (CI 0.39-0.78). SAPSII and first SOFA did not show any difference, but both predicted better than Frailty index with p<0.001.

CONCLUSION. Frailty index can assess the resilience of elderly patients, but it does not predict hospital mortality as SAPSII or first SOFA because they measure the impact of multiple organ failure at ICU admission. The sample size of the study is limited, anyway SAPSII and first SOFA show a good predicting performance in VEP with ROC curve ≥0.9. Frailty index does not improve SOFA score predicting performance even if combined with first SOFA [2]. Physicians need easy and powerful prognostic scores, in ICU settings: SAPS and first SOFA represent an useful tools also in elderly.

Reducing mortality of Severe Sepsis and Septic Shock: Results of a 12 years teaching of protocolized management a a University Hospital of a developing country

A. Gajardo, D. Pérez, A. Hernández, F. Cayupi, N. Medel, C. Luengo
Critical care unit, department of medicine, University of Chile Clinical Hospital, Santiago, Chile

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001231

INTRODUCTION. Sepsis and septic shock are worldwide health emergencies. Implementation of early, adequate and effective diagnostic and therapeutic measures within a protocolized strategy could ameliorate patients outcomes. We present the experience of a university hospital where a physiological, evidence-based protocolized sepsis management has been progressively implemented and taught to post-graduate physicians and residents over the last 12 years. Constant post-graduate training and a local well spread protocol could create in the institution the ability to diagnose and start resuscitation at the emergency room, operating rooms and wards, before patients arrive at the ICU, improving their outcomes.

OBJECTIVES. To compare the mortality of septic patients before and after a teaching program, including a physiological, evidence-based protocol for sepsis management was installed at a university hospital in Chile.

METHODS. Retrospective cohort study based on patients medical records. We included patients with severe sepsis or septic shock admitted to ICU in 2 time periods: 2005-2006 (pre-intervention, n= 109) and 2017-2018 (post-intervention, n= 91). We characterized septic patients and assessed outcomes in both periods. To evaluate the interventions' effect on mortality, we used logistic regression models adjusting by sex, age, organic dysfunctions, and lactate levels.

RESULTS. Patients in both periods were similar in terms of: age (61.3 ± 17.1 versus (*vs*) 61.4 ± 16.4 years old (yo), p-value= 0.95), sex (45% *vs* 57% men, p-value= 0.09), and number of dysfunctions (3 [IQR 2-3] *vs* 3 [IQR 2-4], p-value= 0.07). The percentage of septic patients admitted directly from the emergency room increased significantly in the post-intervention period compared to the pre-intervention

period (41% *vs* 16%, p-value<0.001), and admissions from intermediate care units decreased significantly (67% *vs* 40%, p-value< 0.01). Mortality was higher in the pre-intervention than in the post-intervention period (42.2 *vs* 23.1%, p-value= 0.005). The effect of the intervention was independent of sex, age, organic dysfunctions and lactate levels (OR= 0.36, p-value= 0.007).
CONCLUSION. A teaching strategy and implementation of a physiological and evidence-based protocol for sepsis management reduced the mortality of septic patients in our hospital.

Complications and outcome of patients with severe influenza infection admitted to intensive care unit

O. Kampouropoulou, A. Sakagianni, K. Mandis, S. Michelidou, K. Valakis
Intensive care unit, SISMANOGLIO GENERAL HOSPITAL, ATHENS, Greece
Correspondence: A. Sakagianni
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001393

INTRODUCTION. Seasonal influenza epidemic constitutes a global health problem with serious complications leading to high morbidity and mortality, particularly among elderly patients and patients with chronic underlying conditions According to WHO, the most effective way to prevent the disease is annual vaccination.
OBJECTIVES. To evaluate the complications and outcome of patients with confirmed influenza infection requiring admission to the intensive care unit during 2018-2019 flu season in a tertiary hospital in Greece. We also investigated factors associated with poor prognosis.
METHODS. This is a retrospective observational study that included all patients admitted to the ICU of a tertiary hospital for complicated influenza infection, between October 1st 2018 and April 10th 2019. Demographic variables, clinical features, comorbidities, complications and ICU outcome were reviewed.
RESULTS. A total of 15 patients were included with a median age of 68 (range 49-87) years. Nine of them (60%) were male. Eleven patients (73%) were infected with influenza A and four patients (27%) with influenza B. 46,6% of the patients (n=7) were vaccinated against influenza. Median length of ICU stay was 17 days (range 4-37) and the ICU mortality rate was 33% (n=5). The median APACHE II score on admission was 25 (range 21-38). The most common underlying diseases of the patients were chronic obstructive pulmonary disease (53%), diabetes mellitus (47%) and coronary artery disease (20%). 60% were smokers and 33% were immunosuppressed (Rheumatoid Arthritis, Chronic Lymphocytic Leukemia, Multiple Sclerosis, Sarcoidosis). The majority of patients presented bacterial superinfections-40% (n=6) ventilator associated tracheobronchitis or pneumonia and 13% (n=2) secondary bacteremia. More frequent complications were acute kidney injury (AKI) in 8 patients (53%) requiring CRRT in one third of the cases, acute heart failure (n=5, 33%), and rhabdomyolysis (n=5, 33%). Less frequent complications were myopathy/neuropathy (20%), ARDS (13%), encephalitis (7%), pulmonary embolism/DVT (7%), and invasive aspergillosis (7%). Compared with survivors, non-survivors were older (median age 71 vs 63,5), had longer ICU stay (median 26 days vs 13,5d), higher APACHE II score (median 30 vs 26), suffered more infectious complications (80% vs 30%), more cardiac complications (80% vs 20%), and presented AKI in 100% of the cases (vs 30% of survivors). Among survivors 40% (n=4) were vaccinated, and 60% (n=3) among non-survivors.
CONCLUSION. Findings from our single center study suggest that patients requiring intensive care management during the recent influenza outbreak, in contrast with previous years, suffered less ARDS and more extra-pulmonary complications. Although our study population is limited, and we cannot extrapolate conclusions, it seems that vaccination did not protect against multiple organ failure and fatal outcomes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001536

INTRODUCTION. The survivors of diseases, with the presence of impairment of cognitive, psychological and functional, but the reversible potential rooms 5 years after intensive therapy (ICU) therapy has not yet been Characterized and understood. (1) Cognitive dysfunction in this population is characterized by new deficits (exacerbation of preexisting mild deficits) in global cognition, memory, attention / concentration, and executive functions.
OBJECTIVES. To assess cognitive and functional status in patients followed by occupational therapy in neurocritical patients.
METHODS. A retrospective analysis of the patients hospitalized in a neurological intensive care unit, followed by occupational therapy from March to June 2018, was carried out. The cognitive status was assessed through CAM-ICU (Confusion Assessment Method) and MEEM (Mini Mental State Examination), and functional status by means of the muscular strength degree MRC (Medical Research Council) and MIF (Functional Independence Measure), applied on admission and discharge from the ICU.
RESULTS. During the period, 50 patients were followed up, of which 32 were female, with a mean age of 68.4 years and an ICU stay of 5.05 days. The activation of the occupational therapy team occurred in the first 2 days of hospitalization in 80% of the cases. Among the patients evaluated, there was an improvement in cognitive ability in 94.1% of ICU discharge, in relation to admission. The motor capacity showed improvement of 80.4% during the evaluation period.

CONCLUSION. Early occupational therapy may favor occupational performance and promote quality of life, exploring the interests, needs, and functional and cognitive abilities of individuals, minimizing the impact of long-term stay in the hospital environment.

A prospective assessment of the demographics and neuroprognostication practices of a high volume out-of-hospital cardiac arrest centre

M. Naughton, T. Bagnall, M. Ahmed
Cardiothoracic Intensive Care, St George's Hospital Atkinson Morley Wing, London, United Kingdom
Correspondence: M. Naughton
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000976

INTRODUCTION. Out-of-hospital cardiac arrest (OHCA) remains a significant cause of mortality[1]. In response to the wide-ranging specialist input required to optimise the care of these patients dedicated centres have been set up with evidence they may improve survival[2]. However, survival rates remain low with considerable ongoing morbidity with respect to neurological recovery.
OBJECTIVES. 1. To examine the demographics of arrests presenting to a 'Heart Attack Centre'.
2. To corroborate work investigating prognostic factors for survival to hospital discharge.
3. To examine our neuroprognostication practices.
METHODS. All patients following OHCA between October 2018 and March 2018 were included as part of an ongoing prospective registry. Patients were excluded if arrest was secondary to trauma or was iatrogenic. Patient and arrest demographics were collected alongside clinical and investigation findings including age, downtime, initial rhythm, pupil reactivity, corneal reflex, M score and CT and EEG reports.
RESULTS. 39 patients were identified. Two patients were excluded as they had traumatic or iatrogenic arrests. 18 of the 37 remaining patients survived to hospital discharge. The table and graphs below demonstrate increased survival to hospital discharge with shockable rhythms and shorter downtimes.
CT heads were performed 27 of 37 cases, with EEGs performed in only 5 of 37 cases. The right sided graph in the figure demonstrates the limited role for CT in prognosis. Furthermore, clinical examination findings which are crucial for neuroprognostication including M score and pupilliary response were only documented 39%-77% of occasions.
CONCLUSION. Our findings corroborate previous work that shockable rhythms and short downtimes are good prognostic factors. The higher than previously reported survival rate may lend further support to the role of specialist centres. Despite this, a combination of inadequate documentation and a reliance on limited array of tools for neuroprognostication such CT head alone clearly does not provide reliable accuracy for neuroprognostication. We are therefore implementing a new standardised approach, which incorporates a wider use of multi-modal tools such as quantitative pupillometry and investigations such as neuron specific enolase.

INTRODUCTION. Cardiac arrest mortality varies from less than 7% to up to 26% according to a number of variables, including time from event to resuscitation and underline cause (1). Post cardiac

arrest syndrome treatment plays a pivotal role in the patient's outcome.

OBJECTIVES. To evaluate the importance of clinical and biochemical data at the time of admission in ICU and their variations over time in patients admitted for out of hospital cardiac arrest (OHCA).

METHODS. Single centre prospective observational study of patients admitted for OHCA. Enrollment period was from January 2018 to January 2019. Primary endpoint was to assess the organ dysfunction in patient with OHCA considering serum lactate (SL), troponin I and neuron-specific enolase (NSE) analysed at the admission in our intensive care unit (t0), after 24 h (t1), 48 h (t2) and 72 h (t3). T test statistic and ANOVA for repeated measurement were performed.

RESULTS. Preliminary results of 33 patients were enrolled, the average age was 62 y.o. (± 19.3), male patients where 25 (75.75%). The presentation rhythm was ventricular fibrillation in 19 patients (57.5%), pulseless electrical activity in 7 (21.2%) and asystolia in 4 (12.1%), in 3 patients (9.1%) the initial rhythm was unknown.

Ischemic underlying cause was suspected in 22 patients (66.6%) who underwent coronary angiography. A culprit lesion was found and treated in 13 patients (39,4%)(11 mono and 2 multivessel disease). The putative other causes of CA were: primary ventricular tachyarrhythmias (24.2%), hypoxia (18.2%), chronic heart failure decompensation (6.06 %), intoxication and haemorrhagic shock (12.1%). Six patients have been supported with Veno-Arterial ECMO of whom two were successfully weaned.

15 patients died in the ICU, with a mortality rate of 45.45% among all patients admitted for OHCA. 9 patients died within the first 72 hours for the severity of the anoxic brain damage.

Patients survived had lower SL values at t0 (3.88 ± 1.8 mmol/L) that significantly decreased over time (p 0.002), compared to non-survivor (p 0.65) who had higher values (8.85 ± 5.39 mmol/L) without significant variations (p>0.05). NSE values between survivor (26.9 ± 8.7mcg/L) and non-survivor (128.3 ± 57.7 mcg/L) varies significantly at t0 (p0.001). NSE increased significantly in non-survivors over time (p 0.01) whereas it did not change in those who survived (p 0.5). TNI values and mean temperature obtained during the first 24 hours mild hypothermia (35.2 ° ± 0.4 vs 35° ± 0.41) did not vary significantly amongst groups (p < 0.05).

CONCLUSION. Mortality rate in patients experiencing OHCA remains high. SL and NSE values at the admission and SL variation over the observation time showed the best discriminator power between survivor and non-survivor compared with the other studied variables.

INTRODUCTION. Medical Emergency Teams (MET) are constituted by healthcare providers, trained in Advanced Cardiovascular Life Support (ACLS) and Resuscitation. In our institution, these teams are composed by one ICU nurse and a physician with experience in intensive care and/or medical emergency.

The activation criteria includes cardiac arrest or patients deteriorating condition, to any person within the hospital area, either inpatients or others (visitors, staff.). These teams were implemented to respond to critical situations avoiding cardiorespiratory arrest (CRA) or to improve outcomes after CRA.

OBJECTIVES. We present a retrospective analysis conducted at Hospital São Bernardo – Centro Hospitalar de Setúbal, Portugal, of the MET's intervention in ACLS from 2013 to 2018. Immediate mortality and intra-hospital mortality post-ACLS were evaluated.

The aim of this work was to compare our results with actual best practice and with our previous analysis to identify our pitffals in ording to improve.

METHODS. Data was obtained from the ICU department database, created in 2011 with the purpose of periodic audits. All activations due to or that evolved to cardiac arrest during the team approach, from January 2013 to December 2018, were included.

RESULTS. During the study period, there were a total of 262 cardiac arrests, 11,7% of all activations, with an average of 43,7 cases per year.

Time response was around 2 minutes and 36 seconds. The majority of activations were to Level 0 and level 2 wards, summing up to 85,5% of all cases. The most frequent first documented cardiac arrest rhythm was asystole in 53%, followed by pulseless electric activity (PEA) in 31% and pulseless ventricular tachycardia or fibrillation in 16%. An average of 7 cycles of ACLS were performed with a success rate over 40% (between 31 and 50%, through the years). Survival to hospital discharge of all CRA was 16,5% with a survival rate after return of spontaneous circulation (ROSC) of 37,4%

CONCLUSION. Our results are in accordance to the best practice in rate of discharge post CRA (between 16-18%) (1,2). Nonetheless the incidence of asystole is still higher than expected (30-40%), which may reflect delayed recognition (3). Despite this, our study, revealed a tendency of improvement along the years.

INTRODUCTION. Extracorporal life Support (ECLS) is a rescue strategy with increasing popularity and experienced a sharp increase in performance over the years. Nevertheless, survival in this clinical scenario is still pretty low.

OBJECTIVES. In a retsrospective analysis we tried to evaluate the population who might benefit most from ECLS. We speculate that ECLS in CPR may be able to increase hospital survial.
METHODS. Retrospective analysis of an institutional data set from 2006-2016
RESULTS. 207 patients in cardiogenic shock were scheduled for venous-arterial-ECMO as a ECLS system. Mean age was 63,6 years, 13,3 SD. Overall mortality was 67,6% (140/207). 94 received ECLS during reanimation. Mortality in this group was 69,1%. 113 patients in severe cariogenic shock were provided with an ECLS system and in this group 33,6% survived.
CONCLUSION. Mortality in patients with ECLS is still high and in a recently published systemic review 1-year survival was 36,7% (1). These results are in line with our data. Amazing is the fact that survival after cardio-pulmonary resuscitation (CPR) was similar as in non-CPR. In this regard ECLS seems to be beneficial since hospital mortality after in hospital CPR has been reported as high as 85% (2). Mortality after ECLS treatment is still high and the subgroup of patients which will benefit from this invasive procedure mostly are patients during CPR. However, these results have to be confirmed by examining a greater cohort.

INTRODUCTION. Reducing time of cardiac arrest is the goal to obtain better prognosis in every setting from the street to the cardiac catheterization laboratory.
Epinephrine is the standard medication for acls but its effect on both recovery of spontaneous circulation and amelioration of neurological prognosis remains controversial (1). As a consequence there's need to develop pharmacological strategies to reduce time to ROSC and to cerebral reperfusion especially when ECLS is not available.
METHODS. We report a case of a 60 years old male patient with refractory cardiac arrest secondary to myocardial infarction unresponsive to common therapies in whom intracoronary injection followed by endovenous infusion of calcium sensitizer levosimendan was able to gain and mantain ROSC
RESULTS. The patient was admitted to cardiac catheterization laboratory with diagnosis of cardiogenic shock secondary to acute anterior myocardial infarction. Patient was intubated, an aortic counterpulsation balloon was placed and PTCA of IVA was performed. During procedure numerous episodes of shockable rhythms (ventricular fibrillation and ventricular tachycardia) were treated following ACLS guidelines. After coronary reperfusion an episode of ventricular tachycardia followed by pulseless electric activity of more ten minutes was unresponsive to therapy. A bolus of 10 mcg/kg of levosimendan was injected in the left coronary artery followed by a continuous endovenous infusion (0,2 mcg/kg/min). After 30 seconds ROSC was obtained,, foretold by increasing etCO2 from 10 to 25 mmhg during chest compressions (figure) . Hemodynamic was mantained with low dosage of norepinephrine and continuous infusion of levosimendan. In intensive care unit first Bispectral index was 38. Patients was treated with targeted temperature management and then gradually weaned from vasoactives, aortic counterpulsation and ventilation, recovering good neurological condition and discharged with cpc score of 2.
CONCLUSION. To our knowledge, this is the first report of successful reversal of refractory cardiac arrest with intracoronary followed endovenous infusion of levosimendan. Only preclinical studies have analyzed the potentiality of levosimendan in cardiac arrest. Nan et al showed that a combination of levosimendan and epinephrine was superior to epinephrine alone to reverse bupivacaine-induced cardiac arrest in a rat model. (2)
There is evidence that intracoronary injection of levosimendan in cardiac surgery guarantees optimal drug spread, increasing contractility, global cardiac function, coronary perfusion pressure and reducing arrhytmic ischemic events (3). In this case intracoronary administration was possible because arrhytmic events followed coronary reperfusion during catheterization procedure. Intracoronary administration of drug is important to hypothesize the direct effect of levosimendan on arrhytmic unresponsive events and ROSC.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001341

INTRODUCTION. Introduction. SVCS results from compression of the superior vena cava. Lymphoma - one of the most frequent causes of the malignant SVCS.
The aim of the study was to identify the incidence of SVCS in lymphoma pts and features of the central venous access in lymphoma pts with SVCS.

METHODS. Materials and methods. 686 lymphoma pts (311 male, 375 female) were included in the prospective study. The pts suffered from Hodgkin's lymphoma (HL) (69 pts) and non-Hodgkin's lymphoma (NHL) (617 pts). In all pts SVCS was diagnosed clinically and was confirmed by CT scan or MRI. In pts with confirmed SVCS the central venous access was provided by non-tunneled central venous catheters (non-tCVCs) (Certofix DUO 7Fr, BBraun) and totally implantable central venous port system (PowerPort, Bard Access System). The indwelling time, the number of the replaced CVCs and the incidence of complications were analyzed. Statistic: SPSS ver.23 (IBM, Chicago, Il., USA). Pearson's chi-squared test and Fisher's exact test were used.
RESULTS. . SVCS was revealed in 70 (10.2%) of 686 lymphoma pts (9 pts with HL and 61 pts with NHL). Among lymphoma pts the frequency of SVCS was highest in pts with primary mediastinal large B-cell lymphoma (PMBCL). SVCS was revealed in 49 (51.6%) of 95 PMBCL pts. In SVCS pts venous access was provided by non-tCVC inserted in femoral vein (50 pts) and TIVAPS (20 pts) implanted into v. cava inferior through the femoral vein. TIVAPS reservoirs were implanted on the thigh. During lymphoma treatment most pts with non-tCVCs needed repeated catheterizations: median 3 (1-14) CVCs. Among pts with TIVAPS only in 3 pts TIVAPS needed repeated catheterizations; their TIVAPS were removed due to complications. The median indwelling times were 6 (1-129) catheter days for CVCs and 164 (1-280) catheter days for TIVAPS ($p<0.05$). Incidences of CVC related bloodstream infections (CRBSI) were 2.1/1000 catheter days for CVCs and 0.1/1000 catheter days for TIVAPS. Incidence of CVC associated thrombosis (CAT) were 4.1/1000 catheter days for CVCs and 0.5/1000 catheter days for TIVAPS. One patient had infection of the subcutaneous pocket (0.3/1000 catheter days). The reasons for non-tCVCs removal were the treatment completion (82.8%) and complications: CRBSI (7.1%), CAT (8.5%), malfunction (1.6%). The reasons for the TIVAPS removal were the treatment completion (85%), CRBSI (5%), infection of the subcutaneous pocket (5%) and CAT (5%).
CONCLUSION. SVCS was revealed in 10.2% lymphoma pts. Half of the PMBCL pts had SVCS. In PMBCL pts central venous access CT should be perform after assessment of vena cava superior patency by CT or MRI. In SVCS lymphoma pts implantation of TIVAPS into v. cava inferior is access of choice.
Key words:*lymphoma, superior vena cava syndrome, central venous catheter, vena cava inferior, totally implantable central venous port system.*

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001470

INTRODUCTION. Cancer immunotherapy is a modality of treatment that can favor survival; some oncological patients undergoing immunotherapy require critical care during the period of their disease. Immunotherapy itself and cancer can carry complications that need different organic supports that some oncologic patients in advanced stages are not typically considered for. Due to multiple factors that can affect the mortality of these patients, we made an analysis of mortality and its associations with organic support in patients that received immunotherapy before or during their stay in the intensive care unit (ICU).
OBJECTIVES. Describe the causes of admission to the ICU, causes of mortality, associated factors and the impact of different organic supports on mortality.
METHODS. Analysis of a historic cohort of patients with cancer diagnosis in III and IV clinical stages undergoing immunotherapy previous or during their stay in two critical care units.
RESULTS. 32 patients with a total of 38 admissions to the ICU, female 28.1%, male 71.9%, average age: 63.2%, pembrolizumab 50%, nivolumab 34.4%, ipilimumab 15.6%. 32% patients needed vasopressors, 9.3% inotropes, 25% renal replacement therapy, 56.2% noninvasive ventilation and 43.7% invasive ventilation. Main cause of admission was initiation of ventilatory support (39.6%); only 21.1% of all admissions were associated with a progression of the oncological disease.
All around mortality was 34.3%, only 15% of the 32 patients were considered to have side effects of immunotherapy. Mortality was mainly associated to the need of ventilatory support yet it was not meaningful in our analysis ($p=0.06$), the use of renal replacement therapy, vasopressors, inotropes was not directly associated with a higher incidence of mortality. The modality of immunotherapy was not itself associated with more complications or a higher incidence of mortality.
CONCLUSION. Patients under cancer immunotherapy are a new group of patients in the intensive care unit. We presented a historic cohort in terminal stage that needed critical care and analyzed mortality and possible associated factors. None of the modalities of organic support and types of immunotherapy were significant factors for mortality.
Although our cohort is small and our study is retrospective, our results suggests that these patients can undergo with critical care without conferring a major mortality factor. More studies are needed to determine if critical care alters the quality of life on these patients.

Cytokine release syndrome and other complications of cancer immunotherapy: a new reason for ICU admission

A. Garcia Roche, C. Díaz, I. Romera, A. Pacheco, R. Ferrer Roca
Intensive care department, Vall d'Hebron University Hospital, Barcelona, Spain
Correspondence: A. Garcia Roche
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001629

INTRODUCTION. Cancer immunotherapy has emerged as a promising treatment for many tumors. The expanding application of this new treatments to cancer will have profound consequences for the use of intensive care.
OBJECTIVES. Our aim is to describe the treatment and clinical evolution of oncohematological patients that required ICU admission after cancer immunotherapy.
METHODS. Retrospective study, including adult (+18 years) patients with cancer either hematologic or solid organ cancer, who received

immunotherapy and required admission to the ICU between 2017 and 2018. Qualitative variables are expressed as N(%).

RESULTS. Ten patients were admitted in this two years period. Four (40%) were men and the median age was 64 years. Seven (70%) had solid tumors and 3 (30%) had hematological malignancies. All of them were at an advanced stage of their cancer disease, and had received at least 3 lines of treatment previously.

The main indication for ICU admission was severe cytokine release syndrome (CRS) in 5 cases (50%): all of them were grade 3, and one with severe neurologic impairment (Glasgow Coma Score 10/15). Regarding the trigger of CRS, in two cases were hematologic patients after CAR-T cell therapy and the other three cases were after bispecific antibodies therapy (BiTe). All patients receive anti-IL6 treatment with Tocilizumab, and two receive corticosteroids also. The CRS was controlled in all five patients and all were discharge from ICU and hospital.

Four (40%) patients were admitted because immune-related events after checkpoint inhibitors: 1 myasthenia-like syndrome, 1 myocarditis, 1 severe pneumonitis and 1 hepatitis. Two required invasive mechanical ventilation support, one high nasal flow oxygen and the other one non-invasive mechanical ventilation. The median SOFA score at admission was 7 points. Management included corticosteroids in all of them, combined with other immunosuppressive therapies (tacrolimus, mycophenolate mofetil) in two of them, combined symptomatic and support treatment. The outcome was poor, three can be discharge from the ICU but only one survive and was discharge from the hospital.

The last patient was a preventive ICU admission to receive Tumor-Infiltrating lymphocytes (TIL) and IL-2 therapy. The patient present capillary leak syndrome with impairment of renal function, pulmonary and neurologic dysfunction (nightmares, hallucinations, somnolence...). The impairments resolved without specific treatment and can complete the treatment and discharge from ICU and hospital.

CONCLUSION. Adverse events associated to cancer immunotherapy treatments can be severe and require ICU admission. The treatment of these complications is mainly supportive but in some cases specific treatment is needed. A multidisciplinary approach with early ICU admission is recommended.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000717

INTRODUCTION. Candidemia has increased in the last decades in patients admitted to intensive care units (ICU). Candida bloodstream infection is life-threatening, recognition and treatment is frequently delayed, with clinical deterioration and death often preceding the detection of Candida in blood cultures.

Thus, it is crucial to maintain a high level of suspicion. Is important to know the epidemiology of candida infection, risk factors and tools that allow the selection of patients benefiting from empirical / preemptive therapy.

OBJECTIVES. Establish the incidence of candidemia; the prevalence and sensitivity pattern of different species; Identify possible risk factors; Evaluate the predictive value of tools such as candida score.

METHODS. Retrospective evaluation of the candidemia cases from January 2011 to December 2018, through the consultation of clinical files from the patients hospitalized in our ICU with candida in blood cultures.

Patients with ICU length of stay <24h and haematological malignancies patients were excluded.

Evaluation of risk factors. Candida score calculation. Characterization of the isolated candida species, sensitivity pattern, antifungals used, duration of therapy and outcome.

RESULTS. We enrolled 55 non-neutropenic patients with candidemia (54,5% males, average age 63,4±17 years, SAPS II 52,2±16,5). *Candida albicans* was the most prevalent species - 36 cases (65,5%) - followed by C. *parapsilosis* in 11 patients (20%). All *Candida albicans* isolates were susceptible to azoles. Fluconazole resistance rate among the non-albicans candida spp. was 7,3%. An echinocandin was used as empirical antifungal therapy in 61,8% of the cases and fluconazole in 30,9%. ICU mortality was 38,2% and cumulative mortality 30 days after ICU discharge was 47,3%. Candida score was 3,61±1,0. There was no difference in ICU mortality between patients with Candida score >3 or < 3 (p= 0,46). Despite the slight trend to higher mortality rate in patients with C. non-albicans vs albicans, we found no statistical relevance (p 0,09).

CONCLUSION. Candidemia in our ICU was mainly caused by *albican* species. Although echinocandins were the antifungal of choice, resistance rate to azoles was low. Our patients had a high candida score and a high overall mortality rate.

INTRODUCTION. Infections due to *Cryptococcus* species occur globally and can affect both immunocompromised (IC) and non-IC hosts. To date, many cases of cryptococcal infection have been reported, but concomitant influenza and cryptococcal infections are rare.

OBJECTIVES. To improve diagnosis and management of critically ill patients with influenza and cryptococcal infections.

METHODS. An unusual case of an avian influenza A (H7N9) infection with systemic super-infection with *Cryptococcus neoformans* presenting as ventilator-associated pneumonia (VAP) and bloodstream infection in a previously immunocompetent man during hospitalization was reported and the literatures were reviewed.

RESULTS. A review of the medical literature revealed only 3 reported cases regarding concomitant hospital-acquired cryptococcal infection and severe influenza. Adding our case to the review, a total of four cases are summarized and analyzed. All cases occurred in patients with severe influenza virus infection (2 cases with H1N1 and 2 cases with H7N9) from 7 to 25 days after admission. During the four patients' courses, there were 3 cases with cryptococcal pneumonia, 2 cases with cryptococcal fungemia, 1 case with cryptococcal pleurisy and 2 cases with cryptococcal meningitis, and 3 of them presented with disseminated cryptococcal infection. In the 3 cases with cryptococcal pneumonia, 1 case was diagnosed as hospital-acquired pneumonia (HAP), and 2 cases were VAP according to the diagnostic criteria of HAP and VAP. After the anti-fungual treatment, only one

case with H1N1 and cryptococcal infection survived, the other 3 cases including our patient all died.
CONCLUSION. Cryptococcal infection can occur in patients with severe influenza during hospitalization with a more severe condition, and the clinician should be aware of this infection.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001114

INTRODUCTION. Immunocompetent critically ill patients may be at risk for Citomegalovirus (CMV) reactivation as a result of immunosuppression associated with critical illness. Some studies have related this reactivation with poor outcomes.
OBJECTIVES. To describe the clinical profile of immunocompetent patients admitted to a tertiary ICU and tested for detection of CMV viremia, and address the prognostic implications of CMV viremia.
METHODS. Retrospective study, including adult (+18 years) immunocompetent patients who were tested for the presence of CMV viremia between 2014 and 2017. The CMV viral load was determined using the real time polymerase chain reaction RealStar® CMV PCR Kit 1.2. (Altona®). X-Square, Fisher´s test, T test, U Mann-Whitney and logistic regression were employed as required. Quantitative variables are reported as median (IQR) and categorical as frequency (%).
RESULTS. Eighty-one immunocompetent patients were tested for the presence of CMV viremia, with an age of 62 (43-68) years. Sixty (74%) were men. Sixteen (22%) had cirrhosis, 15 (21%) COPD, 6 (8%) chronic renal failure and 4 (5%) chronic heart failure. Thirty-five (43%) had septic shock and 22 (31%) were surgical patients. Twenty-eight (39%) were treated with high flow nasal cannula (HFNC), 64 (88%) required mechanical ventilation (MV), 52 (72%) vasoactive drugs (VAD) and 22 (31%) renal replacement therapy (RRT). Forty-nine (68%) were discharged from the ICU and 43 (60%) were discharged home. Nineteen (26%) were positive for CMV viremia and 13 (16%) were treated with ganciclovir. Hemoglobin levels, leukocyte count, platelet count, lymphocyte count, aspartate aminotransferase and alanine aminotransferase levels were similar in both groups (Table 1). Patients on VAD (OR: 8.7, IC95%: 1.1-71.1, p=0.043) or RRT (OR: 3.6, IC95%: 1.1-71.1, p=0.043) had a higher risk for CMV viremia, while use of MV (OR: 1.1, IC95%: 0.2-5.9, p=0.925) or HFNC (OR: 0.5, IC95%: 0.2-1.6, p=0.246) was not related. CMV viremia was not associated to ICU (OR: 1.4, IC95%: 0.45-5, p=0.594) or hospital mortality (OR: 1.4, IC95%: 0.5-5, p=0.464), length of mechanical ventilation (OR: 0.9 IC95%: 1-1, p=0.942), length of ICU (OR: 1.0, IC95%: 1-1, p=0.875) or hospital admission (OR: 1, IC95%: 1-1, p=0.837).
CONCLUSION. Patients without classical factors for immunosuppresion can suffer CMV viremia, with those on VAD or RRT suffering a higher risk. Despite the well known laboratory abnormalities related to CMV infection, these abnormalities have a great prevalence in ICU patients, so are not useful for suspecting CMV infection. In our cohort, CMV viremia was not related to mortality, length of mechanical ventilation or length of admission.

Table 1 (abstract 001114). See text for description

CMV viremia	Hemoglobin (g/dL)	Platelets (x10E)/L)	Leucocyte (x10E9/L)	Lymphocites (x10E9/L)	AST (UI/L)	ALT (UI/L)
Positive	8.7	131	12530	1200	48	37
Negative	8.6	105	9620	800	46	29

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001207

INTRODUCTION. Invasive pulmonary aspergilosis (IPA) is usually seen in immunocompromised patients, however over the past years numbers patients with flu and IPA as superinfection is increasing, while data on candida superinfection is scarce. While IPA independently increases mortality in patients with flu effect of candida superinfection on mortality remains unclear.
OBJECTIVES. We measured IPA and candida (C.) respiratory tract superinfection incidence in 2018/19 flu season in patients with influenza treated in ICU. Factors and patients characteristics that are linked to fungal superinfection were determined.
METHODS. Charts from consecutive patients diagnosed with flu hospitalized in tertiary medical ICU in academic hospital were analyzed. Flu was confirmed using molecular diagnostic test (PCR). Fungal superinfection was confirmed by immunoassays (galactomannan assay for IPA and beta-D-glucan for Candida), and by fungal growth on media plates from speciments. In 3 patients Aspergilus (A) growth was confirmed during bronshocsopy (**Figure 1**).
RESULTS. During the 2018/19 influenza season, 40 patients with flu were admitted (23 male, 17 female). In 11 fungal superinfection was confirmed (A. fumigatus in 3, C. albicans in 8 pts). In one patient Aspergilus and Mucor coinfection was demonstrated and in 3 patients more than 1 Candida species was isolated from various sites. None of microorganisms demonstrated significant in vitro resistance. 3 patients with IPA (100%) and 3 (38%) with Candida superinfection died. Selected data are presented in Figure 2. (**Figure 2**).
CONCLUSION. Fungal superfection was demonstrated in 27% of our patient with A. fumigatus and C. albicans being predominant species.

Candida and Aspergilus superfection is associated with increased mortality in influenza patients. Metlprednisolone use is associated with increased fungal infection rate. Inhalation corticosteroids use was not associated with increased fungal superinfection. Further investigation is needed for better understanding fungal superinfection in influenza patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000683

INTRODUCTION. Generally, clinical manifestations of pulmonary tuberculosis (PTB) are mild and some were asymptomatic. However, a series of cases of severe PTB characterized by acute respiratory failure and diffuse lung disease have been found in recent years in our hospital. Notably, such patients tend to have a short course of disease and a rapid disease progression with respiratory distress and severe hypoxia, which are similar to severe pneumonia and interstitial pneumonia and it is prone to misdiagnosis.
OBJECTIVES. To investigate the clinical features of diffuse type of severe PTB and improve diagnosis and management of the disease.
METHODS. A total of 17 cases of severe PTB, which were characterized by acute respiratory failure and diffuse lung disease and confirmed by etiological and (or) pathological examinations , were studied.
RESULTS. 11 of 17 cases (64.7%) were males and the patients were aged from 20 to 70 years with a median age of 36 years. Patients with and without immunocompromised underlying disease were 9 cases (52.9%) and 8 cases (47.1%), respectively. The most common symptoms were hyperpyrexia, shortness of breath, cough and sputum coughing. Typelrespiratory failure with a median oxygenation index of 138mmHg occurred in all the cases. The chest CT manifestations were characterized by diffuse small nodular or miliary nodules, ground-glass opacities (GGOs), consolidations and fibrotic reticular opacities. Among the 17 patients with PTB, the test of the lower respiratory secretions (sputum, alveolar lavage or bronchoscopic brushing smear) showed as followed: 8 cases (47.1%) were positive for acid fast bacillus (AFB) - smear, 11 cases (64.7%) were positive for mycobacterium tuberculosis (MTB) by bacterium culture, 14 cases (82.3%) were positive for MTB DNA by polymerase chain reaction (PCR). Additionally, the strains identification of MTB and the detection of rifampin (RFP) and isoniazid (INH) resistance in MTB were tested by gene chip technology in 6 cases, of which 5 cases (83.3%) were positive and confirmed as MTB complex without RFP and INH resistance. The transbronchial lung biopsy was performed in 8 cases and bone marrow biopsy in 2 cases and all the pathological examination revealed tuberculosis. There were 9 cases (52.9%) with coexisting extrapulmonary tuberculosis and 11 cases (64.7%) with one or more complications including secondary pulmonary infection (7 cases), acute respiratory distress syndrome (6 cases), acute left heart dysfunction (4 cases), hemophagocytic syndrome (3 cases), pneumothorax (3 cases), septic shock (2 cases), etc. 16 of 17 cases (94.1%) were cured with antituberculosis drugs and other therapy except one death after abandoning treatment.
CONCLUSION. Diffuse PTB was characterized by acute respiratory failure and could lead to various complications. The chest imaging showed bilateral diffuse infiltration distributing and the disease was easy to be misdiagnosed as interstitial pneumonia and severe pneumonia. In combination with bacteriology, pathology, PCR, gene chip technology and tracheoscopy can significantly improve the diagnosis ability of severe tuberculosis. Majority of patients can be obtained satisfactory results after timely diagnosis and early antituberculous treatment.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000213

INTRODUCTION. Leptospirosis is a common zoonotic infection in Thailand which widely presents as a mild to severe disease. The clinical characteristics of leptospirosis in our hospital were reviewed and the predictive factors of ICU admission were determined.
METHODS. A retrospective review of the medical charts was conducted in patients diagnosed as leptospirosis and hospitalized in our university hospital from 2007 to 2017. Patients with a positive test for serum immunofluorescence assay for leptospirosis were defined as definite cases and patients who had a Thai LeptoScore1 ≥4 were defined as possible cases. Patients were divided into ICU admission and non-ICU admission groups. All demographic data, clinical characteristics, and laboratory results were compared between the groups. Logistic regression was introduced to determine the predictive factors of ICU admission.
RESULTS. Sixty-eight patients were included. Forty-six (67.6%) patients were definite cases. Thirty-two cases (47.06%) were admitted to ICU and of these 20 (62.5%) had sepsis and septic shock. ICU patients had a shorter onset of symptoms (4.09 ± 1.67 vs. 6.44 ± 4.74 days, p = 0.008), higher Thai LeptoScore (7.64 ± 2.70 vs. 5.65 ± 2.37, p = 0.002), lower hematocrit (32.69 ± 7.50 vs. 36.59 ± 7.90 %, p = 0.04) and platelet count (88.69 ± 92.19 vs. 173.26 ± 150.13 x103/mm3, p = 0.01) and higher serum creatinine (4.24 ± 2.94 vs. 2.80 ± 2.09 mg/dL, p = 0.02) and total bilirubin levels (6.20 ± 6.33 vs. 2.98 ± 3.60 mg%, p = 0.01). ICU patients also had diffuse infiltration on chest x-rays (65.62% vs. 25%, p < 0.001), higher mechanical ventilation requirement (84.38% vs. 5.0%, p < 0.001), higher hemodialysis requirement (37.5% vs. 0%, p < 0.001), and higher inotropic support (90.63% vs. 11.1%, p < 0.001). The predictive factors for ICU admission were Thai LeptoScore (OR 1.36; 95% CI 1.10, 1.70, p < 0.001), requirement for mechanical ventilation (OR 63.24; 95% CI 5.79, 691.39, p < 0.001) and inotropes (OR 53.47; 95% CI 5.45, 524.47, p = 0.006). A Thai LeptoScore ≥7.5 could predict ICU admission (AUROC 0.72; 95% CI 0.59, 0.84, p < 0.001).
CONCLUSION. Predictive factors of ICU admission in leptospirosis were a high Thai LeptoScore and the need for mechanical ventilation and inotropes. A Thai LeptoScore ≥7.5 can predict ICU admission in patients with leptospirosis.

Enteral free water treatment for ICU acquired hypernatremia – a retrospective study

DV. E.a.j., VDV. P.h.j., L. T.
Intensive care, OLVG location East, Amsterdam, Netherlands
Correspondence: E. de vos
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000241

INTRODUCTION. ICU acquired hypernatremia (IAH) occurs frequently and is associated with increased morbidity and mortality (1). However the treatment of IAH remains controversial (2) and the relationship between sodium and body fluid volume appears to be complex (3,4).
OBJECTIVES. To determine the effect of enteral free water treatment on plasma sodium level in patients with IAH.
METHODS. A retrospective single centre study from 2008-2019 was conducted in adult patients with IAH treated with enteral free water. Patients with renal replacement therapy, diabetic ketoacidosis or hyperosmolar hyperglycemic state were excluded. Primary outcome was the change in plasma sodium (in mmol/L) after 5 days treatment (delta sodium). Responders were defined as a decrease in sodium level of ≥5 mmol/l. The volume of enteral free water and total sodium administration were also recorded. Descriptive statistics, Fischer exact and Mann-Whitney U test were used.
RESULTS. 409 consecutive patients (Table 1) were included. The median volume of enteral water was 4183 ml (IQR 3296 - 5310) after 5 days and mean sodium decrease was 1.4 mmol (SD 5.0). (Fig. 1). There was no significant correlation between the volume of enteral water and delta sodium r2=0.01 (Fig. 2). Responders (97) vs non-responders (312) did not differ significantly with the administration of furosemide or hydrochlorothiazide concerning sodium change. Responders had a significantly lower sodium intake compared to non-responders (842 mmol vs 894 mmol, p= 0.039).
CONCLUSION. The volume of enteral water was unrelated with sodium change over 5 days. The lower sodium intake in responders suggests that restricting salt intake is more effective then enteral free water treatment but further study is needed.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000276

INTRODUCTION. Fibrinogen plays an important role in hemostasis in the early phase of trauma. Numerous studies have shown that low fibrinogen levels were associated with hemostatic impairment, massive bleeding, and poor outcomes in severe trauma patients. Because fibrinogen levels deteriorate before other routine coagulation parameters in the early phase of severe trauma, aggressive supplementation of fibrinogen may improve hemostatic function.
METHODS. We conducted asingle-center retrospective cohort study with propensity score-matched analysis.Patients with severe trauma (injury severity score ≥ 16) who were admitted to the emergency department (ED) of Hokkaido University Hospital from January 2010 to July 2018 were eligible for inclusion in this study. Exclusion criteria were as follows: age < 18 years, cardiac arrest before arrival to the ED, cervical spinal cord injury not caused by a high-energy accident, and severe burn injury. The patients were divided into the FC and control groups. The FC group included trauma patients who received FC within 1 hour of arrival to the ED. The control group included patients who did not receive FC within 1 hour of arrival to the ED. Trauma and injury severity score, heart rate at admission to the ED, and age were included in the propensity score model. We compared the two groups using propensity score-matching to reduce selection bias and to balance characteristics and clinical variables that could potentially affect outcomes. The primary outcome was in-hospital survival rate.
RESULTS. The c-statistic of the propensity score model was 0.734. The Hosmer-Lemeshow chi-squared value was 7.036 (degrees of freedom=8), with a non-significant p value of 0.533, indicating the goodness of model fit. Propensity score-matching created 31 1:1-matched pairs. The characteristics of the two matched groups were appropriately balanced. In-hospital survival rate was higher in the FC group than in the control group (p=0.013 by log-rank test). The amounts of red blood cell and fresh frozen plasmaadministered within 24 hours after admission to the ED in the FC group were significantly higher than those in the control group.
CONCLUSION. This propensity score-matched analysis indicates that early administration of FCs improves in-hospital survival rates in severe trauma patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000308

INTRODUCTION. Intensive care unit (ICU) magnesium administration for the prevention of atrial fibrillation (AF) after cardiac surgery remains controversial. Previously we demonstrated that a strategy of bolus magnesium delivery followed by a continuous infusion resulted in a more sustained and stable serum magnesium level in comparison to a single bolus. However, the effectiveness of such approach has not been demonstrated in clinical studies.
OBJECTIVES. We aimed to evaluate the effectiveness of a post-operative 'bolus + continuous magnesium' strategy on the occurrence of AF (primary outcome) and other relevant clinical outcomes (secondary outcomes).
METHODS. We performed a before-and-after study in adult cardiac surgery patients admitted to the ICU of a tertiary metropolitan hospital. We enrolled patients with normal renal function and a serum magnesium level lower than 1.5 mmol/L on ICU arrival. Intervention group patients received a bolus of 10 mmol of magnesium-sulphate over 1 hour followed by a continuous infusion of 1.5 to 3 mmol/h until ICU discharge, aiming at a serum magnesium level of 1.5 to 2 mmol/L. Propensity score matching was performed to select control group patients.
RESULTS. We enrolled 99 intervention group patients and 99 control group patients. Both groups had similar baseline characteristics, except for a lower cardiac index at ICU admission in the intervention group. By 28-days after ICU admission, the occurrence of AF was reached by 25 patients (25.3%) in the intervention group and by 40 patients (40.4%) in the control group (OR 0.49 [95% CI: 0.27 to 0.92), P=0.023). The median ICU length of stay was longer in the intervention group than in the before-group (44.8 h [IQR: 22.2 to 68.2] vs. 24.9 h [IQR: 22.0 to 43.7), P=0.0007). There were no significant differences between the two groups regarding other secondary outcomes. A multivariable Cox regression model for 'time to AF' showed that the intervention was associated with reduced incidence of AF (HR 0.45 [95% CI: 0.25 to 0.77], P=0.004), and that the variables age, duration of bypass and requirement of vasopressors > 6 h were associated with increased risk of AF.
CONCLUSION. An ICU strategy of bolus followed by continuous magnesium administration after cardiac surgery was associated with a reduction in the occurrence of AF.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000340

INTRODUCTION. The Richmond Agitation-Sedation Scale (RASS) is widely used for assessing sedation level of the ventilated patients in intensive care unit (ICU), even though it has clinical limitations such as subjective and also intermittent measurements. The Patient State Index (PSI) has been a newly introduced processed EEG parameter and enables an objective and continuous monitoring of sedation levels by analyzing electroencephalograms. However, few studies have examined the correlation between PSI and RASS and the usefulness of PSI in assessing sedation levels in ICU patients is unknown.
OBJECTIVES. To analyze the correlation between PSI and RASS in critically ill ICU patients and the usefulness of PSI in assessing the sedation level.
METHODS. In the medical and surgical ICU at Tokyo Women's Medical University Hospital (Tokyo, Japan), PSI values continuously monitored with SedLine (Masimo, Irvine, CA, USA) and RASS were recorded every 2 hours for 24 hours in adult critically ill patients who required mechanical ventilation for 12 hours or more. Patients with a history of neurosurgery, cerebral infarction, or cerebral hemorrhage were excluded. Propofol, dexmedetomidine, midazolam, and fentanyl were used as sedatives and analgesics. The doses of sedatives and analgesics were adjusted to achieve the target RASS score set for

each patient, and the bedside doctors and nurses were blinded to the PSI values. The correlation between PSI and RASS was analyzed by Spearman's rank correlation coefficient. P-value <0.05 was considered significant.
RESULTS. In total, 382 PSI and RASS sets were recorded from 50 patients. The patient's age was 65.7 ± 10.3 years (mean ± standard deviation [SD]); the Acute Physiology and Chronic Health Evaluation (APACHE) II score was 15.3 ± 6.0 (mean ± SD); and 92% patients were postoperative. The Spearman's rank correlation coefficient between PSI and RASS was 0.783, and a positive correlation was observed ($p < 0.001$). Moreover, a RASS score of -3 or less (-3, -4, or -5) was defined as deep sedation and of -2 or more as light sedation. The PSI cutoff value for deep sedation was 53 (Area Under the Curve (AUC): 0.917, sensitivity: 0.824, specificity: 0.901).
CONCLUSION. In our prospective, single-blinded observational study, PSI showed a positive correlation with RASS, which is the gold standard for assessing sedation levels, and PSI was highly sensitive and specific in detecting deep sedation. PSI could be useful in assessing sedation levels in critically ill ICU patients.

INTRODUCTION. Cytoreductive surgery (CRS) with Hyperthermic Intraperitoneal Chemotherapy (HIPEC) is a viable treatment option for subjects with locally advanced abdominal cancer but has high risk complications that make postoperative management challenging for intensivists.
OBJECTIVES. To report our experience in the immediate postoperative care of subjects who underwent CRS-HIPEC. Subjects were managed following a protocol which included goal directed fluid therapy and minimally invasive hemodynamic monitoring.
METHODS. Retrospective, single-center observational study of patients who underwent CRS-HIPEC over a three year period (2015-2018).
RESULTS. A total of 55 patients were included. Mean (SD) age was 52.7 (±12.7) years and 69.1% were women. Mean (SD) Charlson comorbidity index and APACHE II score were 7.4 (±1.2) and 13 (±5.91) respectively. The most common indication was colon cancer (41,8%), followed by appendiceal mucinous neoplasm (25,4%) and ovarian cancer (20%). Mean (SD) PCI was 12.72 (±7.37). Complete cytoreduction (CC-0/1) was achieved in all patients. Mitomycin C was used as the main chemotherapy drug (49,09%) in digestive cancer, followed by oxaliplatin (25,4%) and cisplatin (18,1%) in gynecological cancer. The most frequent complications were anemia (60%) and thrombocytopenia (40%). 34.5% subjects presented acute kidney injury, but only 7 patients needed renal replacement therapy. Other severe complications included ARDS (3.6%) , peritonitis and intraabdominal bleeding (12.7%), subarachnoid hemorrhage (1.8%[n= 1]) and pulmonary thromboembolism(1.8%). Mechanical ventilation for more than 24 hours was required by 29% of the subjects and only 3 were tracheostomized. The median (IQR) LOS in the intensive care unit was 6 (5-9) days and the hospital stay of 13(9-22) days. Global ICU mortality was 5.45% [n=3].
CONCLUSION. Nevertheless the high rate of complications after CRS-HIPEC surgery, global ICU mortality was low and complications with protocolized fluid management were similar to other series published.

Sodium valproate versus continuous infusion of haloperidol in management of agitated critically ill patients

R. khalil, H. Khalid, A. Kamel, O. Mohamed, S. Mohamed
Critical care, Cairo University, Faculty Of Medicine, Kasr Al Ainy, Cairo, Egypt
Correspondence: R. khalil
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000375

INTRODUCTION. Agitation occurs in up to 70% of critically ill patients and is a significant source of distress for patients, families, and providers (Fraser GL, et al.2000). Sedatives are administered to 50% of intensive care unit (ICU) patients to alleviate agitation (1). Choice of sedative is complex and largely driven by patient context. No sedative has consistently been shown to be superior to the rest, and alternative agents are greatly needed (2).Most ICU patients, especially those requiring mechanical ventilation, are treated with opioids, propofol, and/or benzodiazepines (1&3). Use of these agents is limited by adverse effects (eg, hemodynamic derangement for safe administration (4). New therapies for treating agitation are rarely introduced into practice, with dexmedetomidine being the most recent in 1999. Consequently, providers have increasingly repurposed older pharmacologic agents as ICU sedatives (eg, clonidine, Phenobarbital, and valproate (depakene) (5 & 6).
Recently, valproate has been administered to critically ill patients to treat agitation and delirium, but there are few published reports to support this practice (7-9). Valproate is an emerging treatment for ICU agitation because it allows patients to interact with their caregivers; can be administered outside of the ICU; has both an intravenous (IV) and enteral formulation; has a low drug acquisition cost; and has not been associated with respiratory depression, hemodynamic derangements, or delirium. In this study we describe the use of depakene & haloperidol for agitation in critically ill patients and examine their safety.
METHODS. prospective study on 100 critically ill patients with agitation in kasralainy hospital over period from may 2016 to June 2017.patients were divided in to two groups, each group included 50 patients, 1st group patients received depakene orally and 2nd group patients received haloperidol by i.v infusion for 72h.Richmound agitation sedation score and doses of additional sedative drugs were noted and calculated daily in the first three days.
RESULTS. our study showed that valproate was equal in efficacy in controlling agitation; decreasing the RAAS significantly after 48h from initiation (2.52±0.61 Vs 0.28±0.54 with $p<0.001$) for depakene and (2.6±0.67 Vs 0.34±0.48 with $p<0.001$) for haloperidol. There was also decrease in the doses of additional sedative drugs used to control agitation (midazolam & propofol) after 48h from drug initiation.-both drugs therapy was associated with decrease in heart rate (89± 20 vs. 86.6±13.6 with $p=0.002$ for valproate and 99.8±23.3 vs. 91± 16.7 with $p<0.001$ for haloperidol) .theyhad no effect on blood

pressure. Haloperidol therapy was associated with significant QTc prolongation.
CONCLUSION. valproate was equal in efficacy as haloperidol infusion in controlling agitation in ICU and decreasing the doses of additional sedative drugs used after 48h from initiation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000380

INTRODUCTION. Intracerebral hemorrhage (ICH), sometimes unexplained, is one of the most feared complication after brain tumor surgery. Blood clot stabilization after surgery depends on factor XIII levels. Acquired or congenital factor XIII deficiency could be associated with hemorrhage after neurosurgery.
OBJECTIVES. To analyse the association between perioperative levels of factor XIII and ICH after neurosurgery.
METHODS. A prospective, longitudinal, 18-month study was conducted at a single third-level hospital in Spain. The study included all consecutive adults operated on brain tumor during 2013-2014 and postoperatory stay in intensive care unit. Informed consent was required. To evaluate factor XIII three blood samples were taken (A-presurgical or baseline, B-postsurgical and C-24 hours after surgery). Normal range considered was 70-140%. ICH was defined as bleeding that generates radiological signs of intracranial hypertension either by volume or by mass effect on the routine CT scan 24 hours after surgery. Mann-Whitney U Test and T-Test were used to inferential analysis. Ethics Committee approval was obtained.
RESULTS. The study included 109 patients. ICH was confirmed in 39 of them (35,78%). The average of factor XIII in sample A was 77,52% in patients without ICH vs 71,2% in patients with ICH, in sample B 70,14% vs 51,57% and in sample C 69,68% vs 52,14%, respectively. Inferential analysis determined significant association between factor XIII-B and C deficiency with ICH (both p0,000) and absence of association in patients without ICH.Their variation, compared to the baseline sample, was also significative (factor XIII A-B p0,000 and factor XIII A-C p0,004).
CONCLUSION. Factor XIII deficiency after brain tumor surgery increased ICH.
Further studies are necessary to demonstrate this association, in which case deficiency treatment could become a therapeutic target

Circadian melatonin rhythm in critically ill patients randomized to sedation or non-sedation: A NONSEDA substudy

J. Oxlund[1], T. Strøm[2], T. Knudsen[3], P. Toft[2]
[1]Sydvestjysk Sygehus, Esbjerg, Denmark; [2]Department of anesthesiology and intensive care, Odense University Hospital, Odense, Denmark; [3]Medicine, Sydvestjysk Sygehus, Esbjerg, Denmark
Correspondence: J. Oxlund

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000392

INTRODUCTION. Abolished circadian rhythm is associated with reduced cognitive function, delirium, and in turn increased mortality (1, 3, 6). Sleep disorders and poor sleep quality are frequent complications in the critically ill patient, especially when mechanically ventilated (4,5). The causes are multifactorial, but research suggests that changes in the biological 24-hour clock located in the nuclus suprachiasmaticus of the hypothalamus affect the circadian rhythm (2). Melatonin is secreted from this site and plays a physiological role in the regulation of sleep and daytime rhythm (7). No previous studies have investigated the melatonin level on sedated vs. non-sedated patients. This study investigates circadian melatonin rhythm on the largest population of critically ill patients.
OBJECTIVES. To evaluate the melatonin level in critically ill patients included in the NONSEDA trial and to investigate the correlation with delirium.
METHODS. This study was conducted as a sub study to the NONSEDA study where critically ill patients were randomized either to non-sedation or sedation with a daily wake-up trail. S-Melatonin was analyzed 3 times a day (14:00, 22:00 and 03:00 o'clock) for 4 days, starting on day 2 after intubation. Delirium was evaluated by CAM-ICU.
RESULTS. Seventy-nine of 100 patients included in the NONSEDA study at the Hospital of Southwest Jutland Esbjerg were included.
CONCLUSION. Circadian melatonin rhythm in patients allocated to non-sedation was closer to normal after 3 days of intensive care compared to sedated patients. During the study period the risk of delirium was significantly higher in the sedated group (OR 0,2). No correlation between abolished circadian melatonin rhythm and development of delirium was established in this study.

Correspondence: Y.L. Nguyen
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000394

INTRODUCTION. According to the latest recommendations of ESPEN, one of the following criteria define surgical patients at severe nutritional risk: a weight loss>10-15% within 6 months, BMI<18.5Kg/m2, subjective global assessment Grade C or NRS>5, preoperative serum albumin<30g/L(1). Sarcopenia measurement is now recommended in the nutritional assessment of oncological patients (2). In the setting of pancreatic cancer and surgical resection, patients are at risk to develop endocrine and exocrine pancreatic insufficiency, leading to malnutrition and a higher risk of developing a refeeding syndrome after starting nutritional support. To our knowledge, the prevalence of sarcopenia and refeeding syndrome in this population remains unknown.
OBJECTIVES. To describe the perioperative nutritional assessment, the prevalence of sarcopenia and of refeeding syndrome in subjects undergoing pancreatic oncologic surgery.
METHODS. A single-center observational study was conducted between July 2018 and March 2019. This study was endorsed by SFAR's CERAR. All subjects undergoing pancreatic oncologic surgery were included. Demographic, clinical, biological and CT data were collected on medical records. Total skeletal muscle surface area was evaluated on a single image at the third lumbar vertebra, using dedicated software, by a single researcher blinded to clinical data. Sarcopenia was defined by a lumber skeletal muscle index (total skeletal muscle surface normalized for stature) of less than 52.4 cm2/m2in men and 38.9 cm2/m2in women. The refeeding syndrome was defined by a hypophosphatemia £0.7 mmol/L occurring between J1 and J7 postoperatively. Data were presented median (IQR).
RESULTS. Thirty-two patients were included in our study. The sex ratio was 1/1, aged 67 yo (58; 74), a body mass index of 27 Kg/m2(22; 31), an albumin serum 34g / L (28; 39) and a skeletal muscle index of 48 cm2/m2(39; 54). 15% (n = 5) had preoperative chemotherapy, 3% (n = 1) had radiotherapy, 28% (n = 9) had diabetes, and 13% (n = 4) chronic renal failure. We did not find the global assessment grade or NRS. According to the ESPEN malnutrition assessment criteria, the rates of malnourished patients were 30% (n = 6) for weight loss, 3% (n = 1) for BMI and 33% (n = 1). 7) for serum albumin. According to the evaluation of muscle mass, 47% (n = 15) were sarcopenic. Nearly one third of the patients (n = 9) had preoperative nutritional supplementation. The prevalence of post-operative refeeding syndrome was 59% (n = 19).
CONCLUSION. The use of a single clinical or biological criterion to define malnutrition underestimates the prevalence of sarcopenia and the risk of post-operative refeeding syndrome in patients with pancreatic oncologic surgery. The calculation of the skeletal muscle index may help clinicians to optimize perioperative nutritional support management. Refeeding syndrome is common and affects more than one in two patients.

Assement of analgesic potency and feasability of serratus plane block in chest trauma patients

P. Brunet, K. Cogne, J. Pottecher, P. Diemunsch
Anesthésie - Réanimation chirurgicale, Hospital Hautepierre Hospitals Academics De Strasbourg, Strasbourg, France
Correspondence: P. Brunet
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000395

INTRODUCTION. Locoregional analgesia is one of the cornerstones of chest trauma management (epidural and paravertebral block)1. The serratus plane block is a regional analgesia method targeting the thoracic wall2. Several case reports described sustained pain relief in chest trauma patients. In a series of consecutive trauma patients presenting with rib fractures, admitted in an intensive care unit, we studied the effectiveness of the serratus plane block on analgesia, its feasibility and the incidence of complications.
METHODS. After the approval from the local ethics committee and informed consent we retrospectively studied the medical records of all consecutive patients presenting with a chest trauma and who benefitted from a serratus plane block according to the local practice between January 2018 and February 2019. The serratus plane block was performed in the supine or lateral position under ultrasound guidance. First, the local anesthetic (Ropivacaïne 0.2%) was instilled in the deep serratus plane followed by the insertion of a perineural catheter. Another instillation was performed in the superficial serratus plane. An elastomeric pump was then connected to the perineural catheter for continous infusion (Ropivacaïne 0.2% 10 mL/h).
RESULTS. The records of 13 patients were retrospectively analysed. The median age was 57 years [44;71], all patients were male. The trauma was the result of a car accident for 7 patients and of a fall for 5 patients. The rib fractures were bilateral for 7 patients, 9 patients presented a flail chest, 9 a pneumothorax, 5 an hemothorax. A chest tube was in place for 7 patients. 4 patients benefited from thoracic surgery. All a patients presented with an associated trauma, 8 orthopedic trauma, 4 neurosurgical trauma and 4 abdominal trauma. 9 patients required a surgical procedure. 10 patients received systemic analgesic alone before the serratus plane block, while 3 were under sedation. The values of Visual Analog Scale and morphine consumption are presented in Figure 1.No complication was observed.
CONCLUSION. Our results suggest that the serratus plane block is an effective locoregional analgesia method for pain management in chest trauma patients. A randomized clinical trial comparing the serratus plane block with the standard locoregional analgesia methods

is needed to define the place of this new analgesic technique in the management of chest trauma patients.

Type of volatile anesthetics in the long time general anesthesia for elderly patients does not affect incident postoperative delirium

K. NAKANO, T. Taniguchi
Department of anesthesiology and intensive care medicine, Kanazawa University, Kanazawa, Japan
Correspondence: K. NAKANO
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000434

INTRODUCTION. Postoperative delirium (PD) deteriorates morbidity, ICU length of stay, prolongation of existing hospitalization, and healthcare costs. Moreover, PD causes delayed functional recovery, cognitive dysfunction, and higher mortality. Several reports showed differences in general anesthesia methods affects incident PD. However, it is unknown whether type of volatile anesthetics affects incident PD.
OBJECTIVES. We evaluated retrospectively type of volatile anesthetics in long time general anesthesia for elderly patients affects incident PD.
METHODS. This study was a retrospective, single-center, observational study, which was approved by the ethics board of our hospital. 170 patients (110 male, 60 female, average age: 70 years old) aged at least 60, underwent surgery more than 8 hours by the general anesthesia method using volatile anesthetics, and admitted to the ICU at our hospital from April 2017 to September 2018. We excluded patients who underwent cardiac surgery or received total intravenous anesthesia (TIVA). After admission to the ICU, Intensive Care Delirium Screening Checklist (ICDSC) was measured to diagnose PD. Delirium defined four or more points. The subjects were divided into Sevoflurane group (S group) and Desflurane group (D group), and compared. The primary outcome was the difference in the incidence of PD between the two groups. The secondary outcomes were to identify explanatory factors, such as patient factors, surgical factors, and anesthetic factors that influence the onset of PD. The statistical method used the chi-square test or Fisher's exact test for comparison of incident PD between two groups. After univariate analysis, a multivariate analysis was applied to test for independent risk factors for PD. When$P$ value was <0.05, the test was considered statistically significant.
RESULTS. Data of 94 patients in S, 76 in D groups were analyzed. There were no significant differences in the patients' background between the two groups. Delirium developed in 16 patients. The incidence rates of PD in S and D group were 6.4% and 13.2%, respectively, and there was no significant difference between the two groups (P=0.186). With regard to PD onset, a causal relationship was recognized between age (P<0.01) and amount of bleeding (P= 0.0389).
CONCLUSION. In long time general anesthesia for the elderly, the type of volatile anesthetics is not significantly different in the incident PD. Further study is required to confirm the risk of PD with more number of patients and multiple center trial.

Goal-directed therapy reduces hemodynamic changes during elective laparoscopic colorectal surgery

V. Panafidina, I. Shlyk
Anesthesiology and intensive care, Pavlov First State Medical University of St. Petersburg, Sankt-Peterburg, Russia
Correspondence: V. Panafidina
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000457

INTRODUCTION. Goal-directed therapy is considered as an important option in perioperative care. However, most of the studies analyze the postoperative outcomes, but intraoperative hemodynamic changes seem to be a significant factor in development of hypoperfusion during operation. Moreover, laparoscopy effects on hemodynamic parameters are well known and its influence on cardiovascular physiology can be challenging.
OBJECTIVES. The aim of this study is to compare two different approaches to hemodynamic and fluid management during elective laparoscopic colorectal surgery.
METHODS. 102 patients with curable colorectal cancer were divided in 2 groups: observational (group №1, n = 46) and goal-directed therapy group (group №2, n = 56). All patients have a non-invasive monitoring of hemodynamic (EsCCO, Nihon Kohden, Japan). Management of hemodynamic and fluids in the group №1 were performed according to opinion and agreement of 2 experienced anesthesiologists. Hemodynamic optimization in the group №2 included some steps: first is Trendelenburg maneuver after induction and bolus of 500 ml of balanced crystalloid if stroke volume increased more than 15%, then assessment during pneumoperitoneum and infusion of small (3ml/kg) volume if intraabdominal perfusion pressure (IPP) less than 65 mm Hg, and, if patient is a non-responder, infusion of norepinephrine. Total infusion volume, mean norepinephrine dose, duration of vasopressors, lactate, BE, number of episodes of hypotension (MAP and/or IPP $\leq$ 65 mm Hg or decrease of SBP more than 20% from baseline), changes in HR more than 30% from baseline were measured. Data was analyzed using IBM SPSS Statistics 20.0. Continuous data variables were compared using *Mann-Whitney* U tests, results are reported as median (Q1; Q3).

RESULTS. Groups were similar in terms of demographic characteristics. Fluid volume were significantly less in the group №2: 2590 (2250; 2900) ml vs 3000 (2500; 3312) ml, *Mann-Whitney* U tests, p = 0.005. Norepinephrine time and dosage were similar between two groups. Lactate at the end of operation were lower in the group №2: 1,6 (1,2; 2,1) mmol/l vs 1,05 (0,7; 1,47) mmol/l in the group №1 and 2, respectively, *Mann-Whitney* U tests, p = 0.002. Hypotension were more often in the group №1: 2 (1; 5) episodes vs 1 (0; 1) in the group №2, *Mann-Whitney* U tests, p < 0.0001. Drop of SBP from baseline were significantly higher in the group №1: 35,4% from baseline (13%; 38%) and 21,8% (16,7%; 27,4%) in the group №2, *Mann-Whitney* U tests, p = 0.006.
CONCLUSION. Goal-directed hemodynamic and fluid therapy may be beneficial in terms of hemodynamic stability during elective laparoscopic operations in patients with colorectal malignances.

An Audit Evaluating Current Monitoring Practices of Low Molecular Weight Heparins and Unfractionated Heparin within the Critical Care Setting

A. Main-Ian[1], I. Welters[1], J. Hughes[2], P. Brown[3]
[1]Critical care, Royal Liverpool and Broadgreen University Hospitals NHS Trust, Liverpool, United Kingdom; [2]Pharmacy, Royal Liverpool and Broadgreen University Hospitals NHS Trust, Liverpool, United Kingdom; [3]Icnarc, Royal Liverpool and Broadgreen University Hospitals NHS Trust, Liverpool, United Kingdom
Correspondence: A. Main-Ian
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000517

INTRODUCTION. Unfractionated Heparin (UFH) and Low Molecule Weight Heparins (LMWH) are commonly used within critical care to provide therapeutic doses of anticoagulation. Limited evidence is available whether target concentrations are being met in critically ill patients, who are at particular risk of over- or underdosing due to reduction in bioavailability due to vasopressors, lack of weight-adjusted dosing and renal impairment. The Royal Liverpool University Hospital's current protocol demands monitoring of activated partial thromboplastin time (APTT) ratios after 6-8 hours for UFH infusions, and anti-factor Xa (anti-Xa) levels 4 hours post dose for subcutaneous LMWH when prescribed for patients with renal impairment or pulmonary embolism (PE). This audit evaluates whether target concentrations of therapeutic LMWH and UFH were met in patients admitted to the Intensive Care Unit (ICU) and how monitoring was performed in critically ill patients compared to guideline recommendations.
OBJECTIVES. Standards set included 100% post-dose monitoring at or within time-limits for all patients - receiving UFH; with renal impairment; with PE. 100% reaching satisfactory anticoagulation - within 24 hours for an UFH infusion; by the end of ICU admission or last dose of UFH/LMWH.
METHODS. Data was collected retrospectively over a two-month period. Patients who received therapeutic doses of UFH and LMWH were included. Data collected included anonymised patient demographics, renal function, drug used, indications and monitoring.
RESULTS. 144 patients were screened, and 30 patients receiving therapeutic anticoagulation were included in the audit. 86.7% of patients exceeded their ideal body weight. 16.7% had anti-Xa levels or APTT ratios measured within trust-formulary limits. 50% reached therapeutic levels of anticoagulation. 44.4% of patients with PE did not have anti-Xa levels/APTT ratios measured at all. 22.2% reached therapeutic levels of anticoagulation for PE. 77.8% of UFH patients reached therapeutic levels of anticoagulation within 24 hours. None of the patients receiving once daily (OD) LMWH had Anti-Xa levels checked 4 hours post first dose. 14.3% of OD and 12.5% of patients receiving twice daily LMWH reached therapeutic levels of anticoagulation during their admission. 64.3% of patients with acute kidney injury, 20% with chronic kidney disease and 33.3% with both achieved satisfactory levels of anticoagulation.
CONCLUSION. Due to inconsistent monitoring, the level of anticoagulation remained uncertain in patients with renal impairment. Patient safety could have been compromised from over- or underdosing. Only 22.2% of PE patients reached therapeutic levels which could exacerbate symptoms. We conclude that tighter adherence of the recommended frequency and timing of monitoring is required to avoid over- or underdosing in critically ill patients.

Incidence of Delirium amongst Neurosurgical and Non-Neurosurgical Patients in a Tertiary Trauma Centre

W. Flesher, A. Akbar, S. Kulkarni
Critical care unit, Royal Preston Hospital, Fulwood, United Kingdom
Correspondence: W. Flesher
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000518

INTRODUCTION. Delirium is a major cause of morbidity within the ICU environment1 and is associated with prolonged stay, longer time on mechanical ventilation2 and all-cause mortality3. In Royal Preston Hospital (RPH), a tertiary centre for neurosurgery in the Northwest of England, it has been anecdotally identified that neurosurgical patients represent a degree of delirium-related morbidity on the ICU disproportionate to the size of the group.
OBJECTIVES.

1. To quantify the incidence of delirium in the neurosurgical and non-neurosurgical ICU populations and
2. To audit compliance with existing Trust pathway for management of delirium.

METHODS. This was a retrospective audit of all admissions to ICU in RPH between 01/09/2018 and 30/11/2018. Patient notes were analysed to determine the primary reason for admission (whether neurosurgical or not), the number of days spent delirious based off the CAM-ICU assessment, the Richmond Agitation and Sedation Score (RASS), the type of delirium (hypoactive, hyperactive or mixed) and the treatment given (pharmacological or non-pharmacological).
RESULTS. 397 patients were included, comprising 346 non-neurosurgical and 51 neurosurgical patients. 100 (28.9%) non-neurosurgical patients and 29 (57%) neurosurgical patients had at least 1 delirious day on the ICU.
Neurosurgical patients represented 37.2% of all delirium days despite their small group size.
Further results of audit will be presented in the poster.
CONCLUSION. Neurosurgical patients have a disproportionately higher rate of delirium in this centre. We should consider neurosurgical patients to be an at-risk group for developing acute delirium and have a documented pharmacological and non-pharmacological plan as an anticipatory measure.
Our current statistics use delirium days as an outcome. This is a flawed statistic which is heavily skewed by neurosurgical long-stay patients. A different reporting measure is therefore required for ongoing audit purposes.

The use of neuromuscular blocking agent infusion and titration of sedation in a teaching hospital critical care unit

L. Buswell, J. Hanison
Critical care, Manchester Royal Infirmary, Manchester, United Kingdom
Correspondence: L. Buswell

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000602

INTRODUCTION. Neuromuscular blocking agent (NMBA) infusions in critical care are frequently used in acute respiratory distress syndrome (ARDS) where they provide a mortality benefit in early severe ARDS (1). Administration of such infusions requires a careful approach; monitoring paralysis with peripheral nerve stimulators and a train of four twitches (TOF); and monitoring depth of anaesthesia using clinical judgement and monitors such as Bispectral Index Score (BIS) (2).
OBJECTIVES. Firstly, to study rate of use of TOF and BIS monitoring amongst patients receiving NMBA infusion. Secondly, to look at titration of sedation after commencing NMBA infusion and physiological signs that could suggest awareness under anaesthesia.
METHODS. A retrospective review was performed of all episodes of cisatracurium infusion in Manchester Royal Infirmary general adult intensive care during a 23 month period. Data was gathered on use of BIS and TOF, looking at titration of sedation and change in physiological parameters after commencing NMBA infusion.
RESULTS. 104 patients received NMBA infusion, 18 more than once, with 130 episodes of NMBA infusion included for analysis. BIS monitoring was used in 95% of infusions but TOF monitoring in only 10%. Sedation was reduced after commencing NMBA infusion in 62% of episodes. A trend was seen towards increased sympathetic stimulation in the sedation reduction group. Comparing the group with reduced sedation to the group without reduced sedation, an increase of ≥20% in heart rate was seen in 44% Vs 18% respectively.
Pupillary dilatation was seen in 40% Vs 22% respectively. Similar effects of lesser magnitude were seen with reduction in noradrenaline dose and increase in systolic blood pressure.
CONCLUSION. BIS monitoring was used frequently in the unit but use of TOF monitoring was suboptimal; this is of some concern given potential for variations in dose response amongst a heterogeneous critical care population. Sedation was reduced after commencing NMBA infusion in the majority of patients. Although these parameters are non-specific in isolation for predicting awareness, there was a trend towards increased sympathetic stimulation in patients in the sedation reduction group. Given uncertainty about BIS monitoring as a sole indicator of depth of anaesthesia amongst patients undergoing NMBA infusion (3), this raises the question of whether patients are being exposed to the risks of accidental awareness under anaesthesia. A protocol is suggested to combine the use of clinical assessment, BIS and TOF monitoring to safely administer cisatracurium infusions (Fig 1).

A review of low tidal volume ventilation and 28-day mortality in a UK Intensive Care Unit (ICU) in all mechanically ventilated patients

N. Clayden, A. Rochester, M. Alice, T. Samuels
Intensive care unit, East Surrey Hospital, Redhill, United Kingdom
Correspondence: N. Clayden

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000621

INTRODUCTION. Low tidal volume (LTV) ventilation in mechanically ventilated patients has been associated with decreased mortality and a decreased number of days of ventilator use in patients with acute respiratory distress syndrome (ARDS).[1, 2] The recommendation is an initial tidal volume of 6ml per kilogram of ideal body weight (IBW).
OBJECTIVES. To review the use of LTV ventilation in all mechanically ventilated patients and determine whether there is an association with maintenance of LTV ventilation in the initial 24 hours of ventilation and patient mortality.
METHODS. Data were collected retrospectively from all patients who were mechanically ventilated on the intensive care unit at a UK district general hospital over a period of one month (January 2019). Data were collected at regular intervals over the first 24 hours of ventilation. All ventilated patients were included in this study regardless of whether they had a diagnosis of ARDS or not. Patients with inadequate data or being ventilated with airway pressure release ventilation mode (APRV) were excluded. Outcome was measured as 28 day mortality. Statistical analysis was carried out using R version 3.5.3 (R Foundation).
RESULTS. Of the 32 patients included in this study 22 patients survived and 10 were deceased at 28 days. The mean age of patients who survived was 60.8 years, compared to the mean age of those who died which was 68.5 years. We found the mean and median ideal body weight (IBW) adjusted tidal volumes were 8.1 and 8.4 ml/kg respectively. The graph illustrates that there is no significant difference between TV (ml/kg) against 28 day mortality ($p = 1.0$). It highlights the similar medians between each group and a larger interquartile range in the group of patients that survived.
CONCLUSION. In conclusion, in this cohort of patients, during the first 24 hours of admission, we are ventilating slightly beyond the range recommended by ARDSNet of 6-8ml/kg tidal volume. However, we found no association between mortality and tidal volume. Limitations of this analysis include a small sample size. In addition, we have not assessed other aspects of lung protective ventilation, such as

driving pressures and plateau pressures, which other studies have found to have an impact on mortality.[3] The original ARDSNet study compared LTV ventilation (6ml/kg of IBW) vs high tidal volume ventilation (12ml/kg of IBW).[1] The PREVENT trial compared LTV and intermediate tidal volume (10ml/kg) in patients without ARDS, finding no difference in the number of ventilator free days.[4] Further studies may be useful to assess the optimal tidal volume in different cohorts of patients, i.e. ARDS and non-ARDS.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000635

INTRODUCTION. Reverse triggering (RT) is a diaphragmatic contraction triggered by an insufflation initiated by the ventilator. This patient-ventilator dyssynchrony is potentially harmful through increased tidal volume, breath stacking or eccentric diaphragm contraction. The diagnosis at bedside is challenging for the clinician and automatic monitoring seems required.
OBJECTIVES. We aimed at validating the accuracy of an automatic detection based on the analysis of ventilator waveforms, (pressure and flow) against a visual assessment using flow, Paw and esophageal pressure signals (Peso).
METHODS. An algorithm was created to detect RT based only on flow and airway pressure (Paw) signals. This algorithm has been developed in collaboration between data scientists of Better Care® and researchers of Dr. Brochard's laboratory in Toronto and Parc Tauli University Hospital, using recordings from the BEARDS study having esophageal pressure (NCT03447288).
Two researchers visually reviewed 16 recordings from 16 different patients with ARDS included in an observational physiologic study (BEARDS). Reverse triggering was defined by visual assessment as a patient effort starting less than 1.5 sec after a machine triggered breath and generating a Peso deflection ≥ 2cmH2O. This threshold was chosen has having a potential clinical relevance. The automated algorithm was based on flow and Paw and detected events in the same tracings without using esophageal pressure: we compared automatic detection to visual assessment (gold standard). Sensitivity, specificities, predictive values, accuracy were calculated.
RESULTS. We included recordings from 16 patients (mean±SD age of 61±12, SOFA 10±3, 63% male, 81% with pneumonia). At time of recording, they had been intubated for a median [IQR] of 4 [1-7] days and 93% were receiving sedation or analgesia (Midazolam: 56%; Propofol: 19%; opioid: 94%). Their total duration of mechanical ventilation was 9 [7-14] days and 63% were discharged alive from the ICU.
Sixteen recordings were assessed: under pressure control ventilation (n=6), volume control ventilation (n=6) and pressure support ventilation (n=4); 3735 breaths were evaluated of which 752 breaths (20.1%) were considered as RT by visual assessment. The automatic detection had a global accuracy of 95%: sensitivity of 85%, specificity of 97%, positive predictive value of 90% and a negative predictive value of 96%. Individual patients' tracing assessment showed an accuracy of the automatic detection ranging from 77% to 100%.
CONCLUSION. An automatic detection algorithm can reliably detect breaths with reverse triggering and a potential clinical relevance using only ventilator waveforms. This is an essential first step to describe and understand the clinical impact of this frequent patient-ventilator dyssynchrony.

INTRODUCTION. Nebulization is widely used in intensive care unit (ICU), by up to 99% of intensivists in an epidemiological study (1). However, even if vibrating mesh nebulizers are actually developed, efficiency of such administration route remain relatively poor, around 20% of nebulized dose under mechanical ventilation (MV) being deposited in the respiratory tract (2). Moreover, aerosol deposition is impacted by numerous factors such as gas humidification, position of the nebulizer in the circuit etc. Consequently, a preclinical *ex vivo* respiratory model was developed to study regional aerosol deposition under MV.

OBJECTIVES. To study the impact of humidification and vibrating mesh nebulizer position in the circuit in order to assess and then optimize lung deposition under MV.
METHODS. A preclinical *ex vivo* respiratory model was used, under controlled volumetric ventilation. Aerosols were performed with a vibrating mesh nebulizer (Aerogen Solo, Aerogen Ltd, Galway Ireland) with or without humidification. Experiments were performed at least in triplicate for each experimental condition. Without humidification, the nebulizer was placed just after the inspiratory valve. When heated humidifier was used, the nebulizer was placed either previous it or between endotracheal tube (ETT) and the Y piece adapter or 15 cm before this latter one. A quantitative 99mTc-DTPA scintigraphic study was then performed to determine nebulized fraction and deposited fractions on each part of the system and the circuit.
RESULTS. Efficiency of the nebulization was achieved with a mean nebulized dose higher than 95% of nominal dose. The respiratory tract deposited fraction of the nebulized dose varied considerably: 18±4% without humidification, and from 25±3% to 57±8% depending of the nebulizer position on the humidified ventilator circuit (*i.e.* 25±3% prior the humidifier, 43±11% between ETT and Y piece adapter and 57±8% upstream the Y piece adapter). These results are strongly correlated to change of aerosol droplet sizes for the different experimental conditions studied. Moreover, the aerosol distribution varied equally in the repartition between tracheal and pulmonary deposition but was not significantly different for the ETT deposition.
CONCLUSION. Nowadays, mesh nebulizers allow an increase in nebulized dose under MV, potentially leading to significant improvements of aerosol therapies. Consequently, determining factors as humidification and nebulizer position could have a higher impact on the delivered dose to the respiratory tract. This study showed very important differences in the dose delivered to the respiratory tract with potential significant impacts for patients in ICU.

INTRODUCTION. The use of prone positioning for patients with moderate to severe ARDS has been shown to improve oxygenation and survival (1). Despite evidence demonstrating benefit, many patients with ARDS do not undergo prone positioning - one large study found prone position was used in only 16.4% of eligible patients (2). Prohibitive reasons are likely to be multiple and include human factors and lack of a protocolised approach.
OBJECTIVES. To review the effect of introducing protocolised practise in prone positioning over an 8 month period in one DGH ICU.
METHODS. Following the results of a previous study (3) at the same unit, a protocol was introduced to guide timing and procedure for prone positioning. During the 8 months following the introduction of the protocol, data were collected regarding aetiology of ARDS, severity at initiation of prone position (determined by P/F ratio), arterial blood gas (ABG) results, outcome (Hospital Discharge/ITU Discharge/Death), demographics and adherence to protocol.
RESULTS. During the study, 11 patients underwent prone positioning (1.4 episodes per month). In the previous 2 year study (3), there were 14 patients (0.6 episodes per month). 2 patients from this study underwent a second episode of prone position soon after being returned to supine - i.e 13 episodes in total. 11 out of 13 cases (84.6%) were classified as severe ARDS with a P/F ratio of <13.3 kPa. The remaining 2 (15.4%) were moderate ARDS (13.3kPa-26.6kPa). The mean age was 55.3 (SD 10.4 years), 8 male and 3 female. The mean duration of prone position was 15.3 hours (SD 4.1 hours); the protocol targeted 16 consecutive hours of proning. Prone position was implemented as per protocol in 92.3% of cases and intra-proning checks (head turn etc.) were correct for 84.6% of proning episodes. Improvement in oxygenation after 6 hours of prone position was observed in 92.3% of cases. In terms of outcome, 7 (63.6%) patients survived to hospital discharge, 3 (27.3%) survived to ITU discharge and 1 (9.1%) died. In-hospital mortality was 36.6%, which compares with 50% observed in the previous study (3).
CONCLUSION. Introduction of a protocol has increased awareness and utilisation of prone positioning in our unit. Protocolisation has also yielded high rates of correct pre-prone and intra-proning checks, meaning there is standardisation of the way prone position is used within the unit. The improvements observed in oxygenation in this patient cohort echo what is also seen in the wider literature (1). Although a reduction in mortality was observed after the introduction of a protocol, given the size of this study this would not be statistically significant. Guidance in the protocol on when to initiate prone positioning may be useful, as the majority of patients (84.6%) underwent prone positioning when ARDS was severe and may have benefitted from earlier proning. A future study involving a larger cohort aiming to prone at an earlier, less severe stage would be useful and may demonstrate improvement in patient outcome.

INTRODUCTION. Tracheostomy (TT) is performed in ITU patients requiring prolonged ventilation as a means to facilitate weaning. However, the optimal timing of TT has been debated. The TracMan RCT 2013 failed to demonstrate beneficial effects of early TT on 30-day mortality or ITU length of stay. Orthotopic heart transplant (OHT) patients are often complex and require prolonged mechanical ventilation, yet there is limited data available for this cohort. We wanted to see if there was a benefit to early TT in heart transplant patients who were likely to require prolonged mechanical ventilation.
METHODS. We retrospectively reviewed 153 consecutive patients who underwent OHT in our centre between 2013 and 2018. 47 patients required TT. We compared the baseline factors and outcomes

of those who underwent early-TT(<10days) versus those who underwent late TT (>10days).
RESULTS. Over one third of OHT patients required TT (TT group; n= 47; 31.5%) during their ITU stay. Risk factors for tracheostomy were previous stroke/TIA (OR 3.52;95% 1,41-8.79), left ventricle assist device support prior to OHT (OR2.14; 95% 1.06-4.34; p=0.034), cardiopulmonary bypass time (OR 1.1;95%; 1-1.01; p=0.022). Other baseline factors were normal.
20/47(42.6%) patients underwent early TT, whilst 27/47(57.4%) patients underwent late TT. Mean time from ITU arrival to TT was 6.5± 2.4 days in the early group versus 15.3±6.3 days in the late group(p< 0.001). There were no life-threatening complications related to procedure. Early-TT was more common in female patients with 90% of early-TT being done in female patients(p=0.006), but there were no other differences in baseline factors. Patients who developed primary graft failure were significantly more likely to have a TT, 14.7% versus 51.1%(p<0.001), and it was more likely to be performed late p<0.001. However, total duration of mechanical ventilation (25.4±38.4 vs 35.4± 24.7days; p=0.284), and ITU length of stay was also comparable (early-TT 27.5±27 days vs late-TT 38.1±19.5 days; p=0.122). All-cause early mortality within 30-days of OHT was comparable between early-TT 15% vs Late-TT 7.4% (p=0.438). Although there was a trend to increased 1-year survival in the early-TT group versus the late-TT group, this wasn't significant (25% vs 48.2%; p=0.104).
CONCLUSION. The timing of TT in critically unwell patients has been debated, and previous trials have failed to show major benefits to favour early TT. In comparing early-TT versus late-TT, we have found that female patients are more likely to have early-TT, whilst developing PGF would appear to be a factor favouring a decision for late-TT. Despite these differences, there was no difference in over duration of mechanical ventilation, or short-term survival outcomes. Though early-TT appears to show a trend towards improved 1-year survival, the sample size may have been too small to demonstrate significance.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000726

INTRODUCTION. Ventilator-induced lung injury significantly increases patient morbidity and mortality. To reduce the underlying pathophysiological mechanisms different ventilation strategies are applied. Flow-controlled ventilation (FCV) is a new ventilation mode to establish a continuous, stable flow throughout the ventilation cycle resulting in a slow and steady change of intrapulmonary pressure during in- and expiration, to minimize applied and also dissipated energy (both related to lung injury) and to individualize ventilation based on measurements of dynamic lung mechanics [1].
OBJECTIVES. Aim of this porcine study was to investigate FCV compared to best "standard of care" pressure-controlled ventilation (PCV) with corresponding lung-protective ventilator settings.
METHODS. Animals were randomly assigned to FCV or PCV. FCV (with Evone®, Ventinova, Eindhoven, The Netherlands) was established at compliance-guided pressure settings (PEEP and peak), fixed FiO2 of 0.3 and flow adjusted to maintain normocapnia (paCO2 = 35-45 mmHg) at an I:E ratio of 1:1. PCV ventilation (with Evita XL®, Dräger, Lübeck, Germany) was performed with at least a PEEP of 5 mbar adjusted to transesophageal pressure, peak pressure set to achieve a tidal volume of 6 - 8 ml/kg, fixed FiO2 of 0.3 and respiratory rate adjusted to maintain normocapnia at an I:E ratio of 1:1.5. After ventilation for 10 hours a CT-scan was carried out in order to visualize and quantify lung tissue aeration by Hounsfield unit analysis.
RESULTS. 12 pigs were enrolled in the study (FCV and PCV n=6). Baseline characteristics were comparable in both groups. Animals in the FCV group showed a significant reduction of respiratory minute volume needed to maintain normocapnia (6.0±0.5 vs. 12.7±0.8 l/min,p<0.0001; fig. 1) thereby achieving significantly better oxygenation (paO2 = 120.0±6.1 vs. 96.6±7.4 mmHg, p=0.0097; fig. 2) compared to the PCV group. CT scans of FCV animals obtained at the end of the experiment showed a significantly higher portion of normally ventilated lung tissue (73.7±3.9 vs. 68.1±5.1 %, p=0.0068) compared to PCV animals.
CONCLUSION. In this porcine study FCV significantly improved gas exchange and maintained better aeration of lung tissue.

INTRODUCTION. Assessing the ability to clear secretions and protect airway with effective cough is an important part of pre-extubation evaluation in patients who have passed spontaneous breathing trial (SBT). We hypothesized that passive cephalic excursion of diaphragm, peak velocity of the diaphragm, or both during cough expiration measured by ultrasound might predict extubation outcome.
OBJECTIVES. The aims of this study are 1) to identify associations of the ultrasonographic indices with simultaneously measured cough peak expiratory flow (CPEF) and 2) to investigate the predictive values of the ultrasonographic indices for extubation outcome in patients who have passed SBT.
METHODS. A total of 323 mechanically ventilated patients who passed SBT were enrolled in the study. Diaphragm excursion and max velocity were measured during voluntary and involuntary cough by ultrasound in the supine position. CPEF was also measured using the ventilator flow waveforms simultaneously with the ultrasonographic measurement.
RESULTS. Diaphragmatic excursion during voluntary cough has a significant correlation with CPEF (r=0.491, p<0.001). The areas under the curves (AUCs) of diaphragmatic excursion and CPEF during voluntary cough for extubation failure are 0.753 (95% CI 0.623 - 0.894, cutoff value 1.6 cm) and 0.715 (95% CI 0.54 - 0.89, cutoff value 50 L/min) respectively. There was no significant difference in predictive accuracy between diaphragmatic excursion and CPEF (p=0.61). Diaphragmatic excursion during involuntary cough or peak velocity of the diaphragm during voluntary or involuntary cough did not predict extubation outcome.
CONCLUSION. Passive cephalic excursion of the diaphragm during voluntary cough measured by ultrasound is as accurate a predictor of extubation outcome as CPEF in patients who have passed SBT.

INTRODUCTION. Veno-venous extracorporeal membrane oxygenation (V-V ECMO) can support arterial oxygenation in case of refractory hypoxemia. With total ECMO blood flow (QB) being delivered through the ECMO return cannula, the fraction of QB recirculating into the drainage cannula constitutes the recirculation fraction (R*f*), which does not contribute to systemic oxygenation and has to be substracted from QB to determine the effective extracorporeal flow (QEFF; QEFF = QB – R*f* x *QB*) [1]. Routine calculation of R*f* is cumbersome and requires mixed venous blood samples. A new ultrasound technique supports bedside measurements of Rf without the need for a pulmonary artery catheter [2].
OBJECTIVES. We investigated whether the bedside quantification of R*f* enables the optimization of ECMO blood flow (QB). Theoretically, QB can be reduced by R*f* without compromising systemic oxygenation. Reduction of QB can minimize adverse effects related to very negative inlet pressures like hemolysis or vessel damage.
METHODS. In a prospective clinical trial (ClinicalTrials.gov Identifier: NCT03200314), we measured R*f* in patients on V-V ECMO suffering acute respiratory distress syndrome (ARDS) using a saline ultrasound dilution technique. In the case that R*f* was greater than 10%, QB was reduced by the volume flow of R*f*. Following a safety protocol, reductions of QB were stopped when pulse oximetry saturation (SpO2) fell below 90%. Likewise, QB was increased when SpO2 fell below 88%.
RESULTS. Eighteen patients were examined (52 ± 16 years old, 2 ± 1 days on ECMO; mean ± SD). Mean QB was 4 ± 0.7 l/min with a R*f* of 15 ± 9 % (0.7 ± 0.48 L/min). R*f* exceeded 10% of QB in 11 patients (21 ± 7%, 0,9 ± 0.46 L/min). QB was reduced in 7 of these 11 patients by 0.6 ± 0.17 L/min (to 3.3 ± 0.77 L/min; $p < 0,05$) resulting in a new R*f* of 10 ± 5 %. QB reduction resulted in a decrease in arterial oxygenation (before reduction: SpO2 98 ± 2 %, arterial partial pressure of oxygen, PaO2 101 ± 24 mmHg; post reduction: SpO2 96 ± 3 %, PaO2 85 ± 23 mmHg; $p < 0.05$). Despite a R*f* > 10%, QB was not reduced in 3 patients with SpO2 < 90% and increased in one patient with SpO2 < 88%.
CONCLUSION. Ultrasound-based estimation of blood recirculation in a V-V ECMO setting provides an objective measure supporting the reduction of recirculation to optimize ECMO blood flow within safe limits of arterial oxygenation.

INTRODUCTION. Lung and diaphragmatic injury can be related to an unsuitable respiratory drive (1).
It's usually handled by the airway occlusion pressure or by the esophageal pressure (2).
OBJECTIVES. To assess the usefulness of tracheal pressure (Ptrach) to monitoring the respiratory drive.
METHODS. We studied 18 patients under pressure support ventilation with different levels of assistance and a maximum sensitivity of the inspiratory trigger. Esophageal (Pes), airways pressure (Paw), Ptrach and flow were registered at 560 Hz. A total of 151 cycles were analyzed. Ptrach was measured using a specific dedicated Intratracheal catheter. P100 was measured in Paw between 0 and 300 milliseconds (ms) after occlusion, selecting the segment with greater slope, at 100 ms. The cycles prior to occlusion were analyzed to measure the Ptrach 100, from nadir to backwards selecting the greater slope segment.
The results are expressed as mean±SD, median (IRQ), or percentage. The comparisons by t-student. Bland-Altman and linear regression analyses were performed.
RESULTS.
CONCLUSION. Tracheal pressure may be useful for continuous monitoring of respiratory drive. The good fit agrees as the respiratory drive increases.

"Alveolar Tidal Flooding" – a new concept addressing edema liquid shear stress in ventilator-induced lung injury

J. Matuszak, A. Tabuchi, J. Grune, WM. Kuebler
Institute of physiology, Charité – Universitätsmedizin Berlin, Berlin, Germany
Correspondence: J. Matuszak
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000789

INTRODUCTION. While mechanical ventilation is a mainstay of therapy for the acute respiratory distress syndrome (ARDS), it can simultaneously trigger adverse complications, most prominently ventilator-induced lung injury (VILI). This fatal association necessitates the need for optimized ventilation strategies, and for a better understanding of alveolar dynamics and the mechanisms underlying alveolar epithelial injury in the mechanically ventilated, injured and edematous lung.
OBJECTIVES. In previous studies, we observed a variety of abnormal dynamics (alveolar dyskinesias) including pendelluft, alveolar stunning and inversed ventilation, but never anatomical collapse and reopening of alveoli [1, 2]. Therefore, we propose that during ventilation of injured lungs, edema fluid will – according to LaPlace´s law - cyclically shift in and out of the alveolus as a function of ventilation pressure. We suspect that the cyclic flooding of alveoli with edema liquid, termed by us "alveolar tidal flooding" (ATF), rather than anatomical opening-and-collapse of alveoli contributes critically to the development of alveolar damage during VILI by exerting excessive shear stresses upon the alveolar epithelium.
METHODS. We tested this concept by direct visualization of alveolar dynamics with lung intravital microscopy (IVM) in a murine model of alveolar edema [3]. Onset, extent, and time course of ATF in injured lungs as well as the cyclic fluid shifts in and out of the alveolar space will be analyzed under a range of ventilation settings with variation of IPP, PEEP, and driving pressure (ΔP). Further the cellular damage exerted by ATF will be assessed with characteristic markers.
RESULTS. ATF was detectable in fluid-filled, yet not in control lungs. ATF frequency increased as a function of inspiratory plateau pressure (IPP) at PEEP = 0 cmH20, and decreased in turn with higher PEEP. We compared the effects of three ventilation settings with different IPP and PEEP values (IPP /PEEP: 18/1; 24/7; 30/13 cm H2O) but same driving pressure in a mouse model of edema. In line with the driving pressure hypothesis, no significant differences in wet-to-dry weight ratio, oxygen saturation, serum pH and lung compliance were detected between groups. Further studies comparing different driving pressure, as well as flooded and unflooded lungs are presently ongoing.
CONCLUSION. We think understanding of this physiological principle will have direct impact on clinical care in terms of optimized ventilation strategies to prevent ATF.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000805

INTRODUCTION. Two distinct hypo- and hyper-inflammatory subphenotypes have been identified in patients with ARDS. The hyper-inflammatory sub-phenotype is associated with fewer non-pulmonary organ failure free days and increased mortality 1. Necroptosis is a form of programmed cell necrosis mediated through activation of receptor interacting serine/threonine kinase-3 (RIPK3) signalling. Furthermore, necroptosis is associated with greater degree of inflammation through extensive cell lysis and release of damage associated molecular patterns, leading to more severe systemic inflammation.
OBJECTIVES. To establish if plasma markers of necrosis and necroptosis are different between the sub-phenotypes in ARDS in the placebo arm of the HARP-2 cohort 2. HARP-2 was a randomised, controlled clinical trial evaluating simvastatin in patients with ARDS.
METHODS. We measured RIPK3 (necroptosis marker) and Cytokeratin-18 (CCK18, epithelial necrosis marker) by Sandwich ELISA (Cusabio & Cytokeratin-18, M65 PEVIVA respectively) in blinded samples from 30 patients (N=15 per endotype as defined at ARDS diagnosis) from the HARP-2 clinical trial over a 14-day time course.
RESULTS. Levels of RIPK3 and CCK18 were significantly higher in the plasma of the hyper-inflammatory ARDS endotype as compared with the hypo-inflammatory endotype. This elevation was maintained across 14 days.
CONCLUSION. We found that markers of necroptosis and epithelial necrosis were raised in patients with ARDS with a hyper-inflammatory endotype. These data implicate necroptosis in the development of the hyper-inflammatory endotype of ARDS. This pathobiological mechanism may provide an opportunity for pharmacological blockade and improved outcomes in this hyper-inflammatory cohort.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000837

INTRODUCTION. Long-term mechanical ventilation is the most common situation where tracheostomy is indicated for patients in Intensive Care Units (ICU). Percuteneous dilatational tracheotomy (PDT) was first described in 1985 and now is a well-established procedure that can be performed at the bedside by an intensivist with less surgical equipment required.
OBJECTIVES. The use of a laryngeal mask airway was compared with the existing endotracheal tube in terms of the safety, effectiveness and duration of the procedure. Our aim was to compare the safety and effectiveness of bronchoscope guided percutaneous tracheostomy performance via endotracheal tube (ETT) vesrus Laryngeal Mask Airway (LMA) in critically ill adults patients
METHODS. 287 patients 18-83 yrs of age, 132 females and 155 males with body mass index 31±6 kg/m^2 underwent PDT with bronchoscopy assistance due to prolonged endotracheal intubation between December 2009 and March 2019. The procedures of percuteneous dilatation tracheotomy with guide wire dilator forceps (GWDF) were done bedside with bronchoscopic guidance under general anaesthesia in the (ICU). Operative and post operative complications were observed. In 57 patients (23 females and 29 males) the ETT tube was changed to LMA 20 min before the procedure. The rest of the patients underwent PDT via the pre-existing ETT. Bronchoscope was used in both groups during procedure.
RESULTS. Overall complication rate was low and occurred in 56 patients, there was no procedure-related mortality. 18 accidental extubations were noted in PDT via ETT group. Subcutaneous emphysema without pneumothorax occurred in twelve patients (2 in LMA group and 10 in ETT group), nine patients had transient hypotension related to sedation (1 in LMA group and 8 in ETT group) and seventeen patients had peristomal oozing (3 in LMA group and 14 in ETT group). The mean time for procedure completion was 15 minutes for the EET group and 12 minutes for the LMA group, and no patient required conversion to surgical tracheotomy
CONCLUSION. Use of LMA seems to shorten the duration of the procedure with better visibility field through bronchoscope and this shortens the period during which the airway is insecure. On the basis of the limited number of patients investigated it is not possible to draw any conclusions as to which procedure is superior in terms of the likelihood of occurrence of mortality and adverse events

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000842

INTRODUCTION. Measurement of esophageal pressure (Pes) allows quantification of respiratory muscle activity, and transdiaphragmatic pressure (Pdi) represents a specific measure of diaphragm contractility. However, acquisition and interpretation of the relevant waveforms remains a complex procedure, limiting wide implementation of the technique in everyday ICU clinical practice. Ultrasonography, on the other hand, is an increasingly popular tool in the diaphragmatic assessment of ICU patients. However, no association has so far been described between Pes or Pdi and sonographically acquired indexes of diaphragmatic function, such as diaphragmatic displacement (DD).
OBJECTIVES. The purpose of this study was to investigate a possible correlation between Pes and Pdi values with diaphragmatic displacement, in patients during a T-piece weaning trial.
METHODS. In fifteen patients undergoing a T-piece weaning trial, we recorded diaphragmatic displacement along with simultaneous Pdi and/or Pes recording. When assessing displacement along with Pdi recording, we studied two consecutive stages: i) breathing normally, and ii) breathing normally with performance of sniff-like maneuvers. When assessing displacement along with Pes recording, we again studied two different breathing conditions: i) breathing normally, and ii) breathing with resistances of 40cmH2O/L.
RESULTS. A total of 1360 breaths were studied at all different breathing conditions (approximately 350 breaths/study condition). Statistical significant correlations were observed in all stages. Pearson correlation coefficient for the Pdi – DD relationship was r=0.57 (p< 0.001) and r=0.67 (p<0.001) for normal breathing and breathing with sniff-like maneuvers respectively. Pearson correlation coefficient for the Pes – DD relationship was r=0.65 (p<0.001) and r=0.8 (p<0.001) for normal breathing and breathing with resistances respectively.
CONCLUSION. Our results suggest a statistically significant correlation between the amplitude of diaphragmatic motion and the derived changes in esophageal and transdiaphragmatic pressures. More research is needed to confirm the potential of this non-invasive index of diaphragmatic function to provide information once considered strictly provided by esophageal pressure catheters.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000856

INTRODUCTION. The evaluation of muscular effort, measured by PTP and Wob, during mechanical ventilation, requires the use of esophageal pressure, scarcely used in clinical practice. We evaluated a new method based on the tracheal pressure, easier to use and, more convenient than esophageal.
OBJECTIVES. Assess the usefulness of tracheal pressure (Ptrach) to monitoring Wob and PTP.

We are designed a method for getting muscular inspiratory effort from tracheal pressure, based on respiratory mechanic related to resistances of the endotracheal tube (Rett) and Elastance of the respiratory system (Ers) obtained from the time constant (τ). A new signal is generated as Alveolar pressure (P Alv), by subtraction from the tracheal pressure the product of the instantaneous volume and Ers.
METHODS. We have studied 12 patients mechanically ventilated during pressure support ventilation (PSV) at three different levels of assistance. We recorded the signals of Flow (V'), Airway pressure (P Aw), Esophageal pressure (P Eso), Tracheal pressure (P Trach, sampling at 561 Htz. A total of 310 cycles were selected. Pressure drop across the ETT (DPETT) was obtained by subtraction of P trach to Paw. The ratio DPETT change to the corresponding change in flow was calculated to obtain the ETT resistance (Rett) using linear regression. Time constant (τ) was determined by exponential regression from exhaled volume. Ers was calculated as the ratio of the Rett to τ. The work of breathing (WOB, J/L) and effort as product pressure-time product (PTP, cmH2O*s/min) were calculated, according to the P Eso and P Alv. The results are expressed as mean±SD, the comparisons by t-student; the relationship and agreement by linear regression and Bland-Altman analysis.
RESULTS.
CONCLUSION. This method using tracheal pressure is a good approach to continuous monitoring muscular effort.

Table 1 (abstract 000856). Agreement of the measurements between both methods.

All Data	Means (SD)	Means Difference	Limits agreement, CI 95%	Regression equation	R
WOB_Peso vs WOB_P Alv *(J/L)*	0.26 (0.12) 0.20 (0.09)	-0.05 (0.07)	-0.19 to 0.08	WOB P Alv = 0.0455 + (0.613 * WOB Pes+)	0.83
PTP Peso vs PTP P Alv *(cmH2O*s/min)*	92.72 (34.56) 72.59 (27.76)	-20.12 (23.21)	-66.53 to 26.29	Ptp/min Av = 17.236 + (0.597 * Ptp/min Esof)	0.74

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000867

INTRODUCTION. Prone position reduces mortality among patients with moderate to severe acute respiratory distress syndrome. We aimed to evaluate whether the radiographic extent in high resolution computed tomographic (CT) has predictive value for prone positioning response and its role in outcomes prediction.
METHODS. This study was conducted in a medical center from October 2014 to June 2016. Patients with moderate to severe acute respiratory distress syndrome underwent prone-position were included. Each lung was divided into three representative levels (apex, hilum and base lung) and each levels was divided into three sections (sternal, central and vertebral part). Each area was rated on a six-point scale of 0–5 for the extent of consolidation or ground glass opacity (GGO). Prone-responders are patients whose PaO2/FiO2 ratio (PF ratio) increases by at least 20% or by ≧ 20mmHg.
RESULTS. Among 52 patients, 34 (65.4%) patients was prone responders and 18 (34.6%) patients were non-responsive. The consolidation difference between dorsal and ventral section at basal lung level was higher in prone responder than non-responder (5.3±2.6 vs 2.0±2.5, p<0.001). If the dorsal section had ≧ 4 points of consolidation score than ventral section at basal lung, the sensitivity/specificity/positive-predictive-value/positive-predictive-value of prone response prediction were 73.5%/77.8%/86.2%/60.9%, respectively. Neither prone oxygenation response nor dorsal-ventral consolidation difference at base lung was independently associated with 60-day mortality, but a CT GGO score more than 14 was an independent factor associated with 60-day mortality (Odds ratio =4.46, p=0.030).
CONCLUSION. The results indicated that high vertical consolidation difference (≧ 4 points) at base lung level was a helpful predictor in predicting prone response. High extent of GGO change (≧ 14 points) significantly correlated to 60-day mortality in patients with moderate to severe acute respiratory distress syndrome.

Circulating neutrophil and endothelial-derived microvesicles differentiate ARDS subphenotypes

INTRODUCTION. ARDS has recently been proposed to consist of 'hypo-' and 'hyper-inflammatory' subphenotypes. Patients with ARDS with a hyper-inflammatory phenotype have a higher mortality.
Microvesicles (MVs) are plasma membrane-derived extracellular particles of 0.1-1μm size, produced in response to cell activation, and retaining the antigenic characteristics of their parent cells. Circulating MVs in ARDS represent the status of intravascular cell activation, either within the systemic (e.g. from underlying sepsis, trauma or burns) or pulmonary (e.g. from ventilator-induced lung injury) circulation. We hypothesised that ARDS subphenotypes may be differentiated by these circulating MVs.
OBJECTIVES. To test our hypothesis, we analysed the profiles of MVs in platelet-poor plasma samples from patients with ARDS from the HARP-2 clinical trial**(1)**, according to their allocation to a hypo- or hyper-inflammatory subphenotype**(2)**.
METHODS. Plasma samples from 30 ARDS patients (15 hypo-, 15 hyper-inflammatory as defined at ARDS diagnosis) were analysed at baseline (<48h ARDS onset) and day 7. Samples were analysed in a blinded manner by flow cytometry for endothelial-(CD146+), neutrophil-(CD66b+), monocyte-(CD14+), and total leukocyte-derived (CD45+) MV counts.
RESULTS. Endothelial- and neutrophil-derived MVs were significantly increased at baseline in the hyper-inflammatory group. MV counts decreased in both MV subpopulations at day 7 (Table 1).
CONCLUSION. These results demonstrate that a significant early release of endothelial- and neutrophil-derived MVs into the circulation occurs with 'hyper-inflammatory' but not 'hypo-inflammatory' ARDS, suggesting that intravascular inflammation, either within the systemic or pulmonary circulation, plays a crucial role in defining ARDS subphenotypes and early ARDS pathophysiology. Further research into the cargoes and biological effects of these MV subpopulations, and the contribution of ventilator-induced pulmonary microvascular inflammation to MV production in ARDS, is warranted.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000893

INTRODUCTION. In hemodynamically stable patients with acute respiratory distress syndrome (ARDS), a conservative fluid management strategy has been shown to improve lung function and shorten the duration of mechanical ventilation (1). However premature initiation of diuresis can increase non-pulmonary organ failure such as acute kidney injury. Previous study demonstrated high E/E′ and weight gain predict poor tolerance of negative fluid balance (NFB) defined as development of hypotension or AKI, or need for fluid expansion (2), but no study has investigated whether urine output in response to a small dose of diuresis predicts the poor tolerance of NFB. We hypothesized that urine output after the administration of small dose of diuresis are predictive to the poor tolerance of NFB in patients with acute respiratory failure.
OBJECTIVES. We aimed to investigate whether the amount of urine output after a small dose of furosemide administration predicts the poor tolerance of NFB in acute respiratory failure patients.
METHODS. This study was a prospective observational study. All mechanically ventilated and hemodynamically stable patients with evaluations of hypervolemia for whom diuresis were planned were included. A small amount of furosemide was administered (10mg for eGFR>50, 20mg for eGFR 30-50), and the urine output was examined for 4 hours, which is a part of the traditional practice in our hospital to predict tolerability to NFB although no study has validated the practice. Before administrating the furosemide, we performed transthoracic echography to investigate several parameters, such as E/E′, inferior vena cava diameters. After 4 hours of the meseaurement, the patients were diuresed to achieve an NFB of more than 1000ml in 24 hours with additional doses of furosemide as needed. The primary outcome of this study was the tolerance to NFB. Tolerance to NFB was defined as absence of hypotension, acute kidney injury, or need for fluid expansion.
RESULTS. A total of 60 mechanically ventilated patients were included in the intensive care unit at Tokyo Bay Urayasu/Ichikawa medical center. 48 patients (80%) had a tolerance of NFB and 12 patients (20%) did not. The urine output following the furosemide administration in patients who did not have tolerance of NFB showed significantly lower urine output than that of patients with tolerance to NFB in each of the first 4 hours (p<0.01). The area under the receiver operator (AUC) characteristic curves for the urine output in the first 4 hours following FST to predict tolerance to NFB was 0.826. The cutoff point of 500ml has the sensitivity of 0.85, and the specificity of 0.75. The AUC of the urine output was higher than those of E/E′ (AUC=0.626) and an amount of positive fluid balance (AUC=0.633).
CONCLUSION. The urine output in response to a small dose of furosemide could predict poor tolerance of NFB in patients with acute repiratory failure. Further studies to validate this finding are needed.

The Maximum Diameter of the Left Ventricle May Not Be the Optimum Target for Chet Compression during Cardiopulmonary Resuscitation: A Preliminary Observational Study to Report Clinical Outcomes Challenging the Traditional Assumption

SB. Chon[1], GY. Park[1], WS. Oh[2], S. Kim[1]
[1]Department of emergency medicine, CHA Bundang Medical Center, Seongnam, Republic of Korea; [2]Department of internal medicine, Kangwon National University School of Medicine, Chuncheon, Republic of Korea

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000021

INTRODUCTION. Researchers have assumed that compressing the point (P_max.LV), beneath which the left ventricle (LV) diameter is maximum, would improve cardiopulmonary resuscitation (CPR) outcomes. Defining the mid-sternum, the currently recommended chest compression, as the reference (x=0), the lateral deviation (x_max.LV) of personalized P_max.LV has become estimable using posteroanterior chest radiography (chest_PA) (Fig 1).[Ref. 1]
OBJECTIVES. We aimed to investigate whether out-of-hospital cardiac arrest (OHCA) victims, whose x_max.LV was closer to the mid-sternum (where x=0) and thus had their P_max.LV compressed closer during CPR, showed better chances of return-of-spontaneous-circulation and survival-to-discharge (Fig 2).
METHODS. A retrospective, cross-sectional study was performed on adult OHCA victims with available chest_PA checked before the cardiac arrest. For each clinical outcome, multivariable logistic regression was performed grouping x_max.LV into tertiles and adjusting the variables selected among the core elements of the Utstein template showing possible differences (p>0.10) in univariate analysis.
RESULTS. Among 309 cases (age: 65.6±15.8 y, female 106 (34.3%)), 141 (45.6%) achieved ROSC and 48 (15.5%) survived to discharge. Compared with the third tertile of x_max.LV (58~87 mm), its first (-15~47 mm) and second (47~58 mm) tertiles whose P_max.LV were closer to the mid-sternum, were negatively associated with return-of-spontaneous-circulation (OR: 0.461 (0.250, 0.849), p=0.013; and OR: 0.429 (0.236, 0.782), p=0.006, respectively) and survival-to-discharge (OR: 0.272 (0.086, 0.861), p=0.027; and OR: 0.131 (0.035, 0.492), p=0.003, respectively).
CONCLUSION. OHCA victims with P_max.LV located closer to the mid-sternum showed worse chances of return-of-spontaneous-circulation and survival-to-discharge. This challenges the traditional assumption identifying P_max.LV as the optimum compression point.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000028

INTRODUCTION. Cardiovascular accidents are the leading cause of death. A cardiopulmonary resuscitation (CPR) of quality has well shown that can reduce the mortality; despite this, survival rate has not changed significantly during last years.
OBJECTIVES. Aim of this study is to test a new wearable glove to provide lay people with instructions during out-of-hospital CPR.
METHODS. After ethical committee approval, we performed a blinded, controlled trial on an electronic mannequin AmbuMan (Ballerup, Denmark) to test the performance of adult volunteers, non-healthcare professionals performing a simulated CPR both, without and with glove, following the glove instructions. The group without glove, also called "no-glove" is intended as control group. Each compression performed on theelectronic mannequin AmbuMan was recorded by a connected laptop computer, drawing a depth frequency curve over the time. Primary outcome was to compare the accuracy of the two simulated CPR sessions in terms of depth and frequency of chest compression performed by the same lay volunteers. Secondary outcome was to compare the decay of performance and percentage of time in which the candidate performed accurate CPR. Finally, the participants were asked if the glove was useful for CPR maneuvers. The difference between the two groups in regard to change in chest compression depth over time due to fatigue, defined as decay were also analyzed.
RESULTS. 571 chest compressions were included: 293 in control group, 278 in glove group (Table 1). Mean depth of compression in the control group was 55.17 mm versus 52.11 mm in the glove-group (p=0.000016). Compressions with an appropriate depth were not statistically different (81.9% vs 73.6%, p=0.017). Mean frequency of compressions in the group with glove was 117.67 rpm vs 103.02 rpm in the control group (p<0.00001). The percentage of compression cycles with an appropriate rate (>100 rpm) was 92.4% in the group with the glove versus 71% in the control group, with an observed difference of 21.4% between the two groups, which was statistically significant (p<0.0001, CI=95%). A mean reduction over time of compressions depth of 5.3 mm (SD 10.28) was observed in the control group versus a mean reduction of 0.83 mm in the group wearing the glove (SD 9.91), but this mean difference in the decay of compressions delivery was not statistically significant (f-ratio=5.680, SS=579.61, df=1, MS=579.61, p=0.018).
CONCLUSION. The use of the glove was effective in reducing by more than 20% the inappropriateness of the frequency of chest compressions during CPR. The visual and acoustic feedbacks provided by the device were useful in dictating the correct rhythm for non-healthcare professionals, translating in a significantly more accurate CPR.

Right ventricular dysfunction after out of hospital cardiac arrest

SN. Voorrips, JC. Winkelhorst, IT. Bootsma, F. De Lange, EC. Boerma
Department of intensive care, Medical Centre Leeuwarden, Leeuwarden, Netherlands
Correspondence: S.N. Voorrips
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000035

INTRODUCTION. In addition to poor neurological outcome, circulatory failure has been described as an important determinant of prognosis after out of hospital cardiac arrest (OHCA). The role of left ventricle dysfunction after cardiac arrest has been established in multiple studies [1]. However, data on right ventricle (RV) dysfunction in this setting remains scarce.
OBJECTIVES. To investigate a potential association between RV failure and mortality after OHCA.
METHODS. A retrospective single-centred study was conducted. All patients ≥18 years, admitted to the ICU with return of spontaneous circulation (ROSC) after OHCA between 2011 and 2018 were included. By protocol, all OHCA patients were equipped with a pulmonary artery catheter that enables near-continuous assessment of RV ejection fraction (RVEF). (Vigilance® CCO/SvO2/CEDV Monitor, Baxter Healthcare Corporation, Irvine, CA). Resuscitation characteristics, hemodynamic variables and 1-year all-cause mortality were recorded. Primary endpoint of the study was 1-year all-cause mortality in different RVEF-subsets (group A: <20%, group B: 20-30%, group C: >30%). RVEF was calculated as an average over the first 24h of ICU admission. Data are presented as median [IQR].
RESULTS. N=238, divided over group A: 47 (20%), group B: 123 (52%), group C: 68 (29%); 77% male, median age 66 [55-73]. Patients with the lowest RVEF had a significantly longer time to ROSC and the incidence of a non-shockable rhythm and adrenaline administration was significantly higher. However, presumed aetiology and the percentage of patients with an intervention of the right coronary artery were not different across groups. 1-year all-cause mortality was significantly different across groups (group A: 64%, group B: 43%, group C: 32%; p<0.01). In a Kaplan-Meier survival analysis there was a significant separation between groups (X2=18.90; p=<0.001; fig.). However, in multivariate analysis, with statistical correction for potential baseline confounders, this association between RVEF (as a continuous variable) and 1-year all-cause mortality was not independent (OR 0.99, CI 0.93-1.06, p=0.81).
CONCLUSION. The incidence of patients with an RVEF of <20% after OHCA was 20%. 1-year all-cause mortality was significantly higher in patients with the lowest RVEF in the first 24h after OHCA. However, after correction for potential baseline confounders this association did not remain statistically significant.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000082

INTRODUCTION. Development of acute kidney injury (AKI) after out-of-hospital cardiac arrest (OHCA) is a well-known predictor for mortality and poor neurological outcomes in both adult and paediatric populations [1,2]. However, the natural course of AKI in terms of its recovery rate after OHCA is uncertain. If we know the natural course of AKI after OHCA, it will be helpful in making appropriate clinical decisions such as determining the initiation time for renal replacement therapy and making a prognosis in OHCA patients with AKI development. We hypothesized that recovery from AKI may affect the survival discharge and neurological status at discharge in OHCA patients treated with targeted temperature management (TTM).
OBJECTIVES. This study investigated the clinical course of AKI after OHCA and determined whether recovery from AKI impacted the outcome of OHCA.
METHODS. This retrospective multicentre cohort study included adult OHCA patients treated with TTM between January 2016 and December 2017. AKI was diagnosed using the Kidney Disease: Improving Global Outcomes criteria [3]. The primary outcome was the recovery rate after AKI and its association with survival discharge.
RESULTS. A total of 3,697 OHCA patients from 6 hospitals were screened and 275 were finally included. AKI developed in 175/275 (64%) patients and 69/175 (39%) patients recovered from AKI. In most cases, AKI developed within 3 days of return of spontaneous circulation [155/175 (89%), median time to AKI development: 1 (1–2) day] and patients recovered within 7 days of return of spontaneous circulation [59/69 (86%), median time to AKI recovery: 3 (2–7) day]. The median duration of AKI was 4 (2–7) days. Duration of AKI was significantly longer in the AKI non-recovery group than in the AKI recovery group [5 (2–9) vs. 1 (1–5) days, $P < 0.001$]. Most patients were diagnosed with AKI Stage 1 initially [120/175 (69%)]. However, the number of Stage 3 AKI patients increased from 30/175 (17%) to 77/175 (44%) after the initial diagnosis of AKI. The rate of survival

discharge was significantly higher in the AKI recovery group than in the AKI non-recovery group [45/69 (65%) vs. 17/106 (16%), $P < 0.001$]. Recovery from AKI was a potent predictor of survival discharge in multivariate analysis (adjusted odds ratio, 12.622; 95% confidence interval: 3.390–46.993; $P < 0.001$).
CONCLUSION. The recovery rate from AKI after OHCA was 39% and recovery from AKI was a potent predictor of survival discharge in adult OHCA patients treated with TTM.

An exploratory, observational study regarding extracorporeal cardiopulmonary resuscitation for non-shockable out-of-hospital cardiac arrest developed after emergency medical service arrival (SOS-KANTO 2012 study report)

T. Yoshida, S. Fujitani, M. Yoshida, K. Tsutsumi, Y. Masui, Y. Taira

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000088

INTRODUCTION. The prognosis of non-shockable out-of-hospital cardiac arrest (OHCA) patients is poorer than that of shockable OHCA patients[1]. The advantage of extracorporeal cardiopulmonary resuscitation (E-CPR) for OHCA has been suggested[2], but as most studies involved shockable OHCA patients with a relatively favorable outcome[3], the usefulness of E-CPR in patients with non-shockable OHCA remains to be clarified.
OBJECTIVES. The purpose of this study was to examine the application of percutaneous cardiopulmonary support (PCPS: V-A ECMO) as E-CPR and its outcome-improving effects in patients with non-shockable OHCA developed after EMS arrival.
METHODS. Of 16,452 patients accumulated in the SOS-KANTO 2012 study (OHCA patients admitted to 67 emergency hospitals in Kanto region (central Japan) from January 2012 until March 2013 were registered), the subjects (n=531) were selected. We retrospectively analyzed the background and clinical outcomes by dividing the subjects into two groups: the PCPS group and the non-PCPS group.
RESULTS. Thirty-eight patients (7.2%) was undertaken PCPS and not for 493 patients (92.8%). On univariate analysis of background factors, the age was significantly younger (p<0.001), ADL before the onset were significantly more favorable (p=0.002), the body weight was significantly heavier (p=0.02), and the interval from onset until hospital arrival was significantly shorter in the PCPS group than in the non-PCPS group (p=0.001). The incidences of ACS, non-ACS cardiac disease, and pulmonary embolism were significantly higher in the PCPS group than in the non-PCPS group (p<0.001, p=0.004, P<0.001). The 3-month survival/favorable cerebral function outcome rates were significantly higher in the PCPS group than in the non-PCPS group (p=0.003, p=0.001). On multivariate analysis corrected for background factors, the execution of PCPS and interval from onset until hospital arrival were independent prognostic factors for favorable cerebral function outcome at 3 months (OR 7.62, 95%CI 1.641 - 35.38 / OR 1.08, 95%CI 1.004 - 1.194).
CONCLUSION. In this study, the outcomes at 3 months were significantly more favorable in the PCPS group than in the non-PCPS group, although there were differences in the background factors. Even in patients with non-shockable OHCA, E-CPR may improve the outcome if patients are carefully selected.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000119

INTRODUCTION. In patients resuscitated from out-of-hospital cardiac arrest (OHCA), severe metabolic acidosis occurs due to whole-body ischemia and anaerobic metabolism. Lactate level at hospital admission is often used as a marker og ischemia and prognosis. However, hyperlactatemia does not alone explain the metabolic acidosis after OHCA, since other metabolic products is formed during ischemia. Base excess, which is an easily obtainable measure of the total metabolic acid-base status, could potentially have additional prognostic information compared with lactate.
OBJECTIVES. We aimed to investigate and compare the prognostic value of base excess and lactate at hospital-admission and during intensive care after OHCA.
METHODS. We included 939 consecutive, comatose OHCA-patients in the targeted temperature management (TTM)-trial, which randomly allocated patients to TTM at 33°C and 36°C for 24 hours. Base excess and lactate were prospectively measured at hospital admission and at several time points during TTM and mortality was reported in all patients after 180 days. Receiver operation characteristic (ROC) curves for admission base excess and admission lactate were computed in respect to 180-day mortality with calculation of optimal cut-off values to predict ICU mortality. Repeated measurements models were used to assess differences in base excess during TTM between survivors and non-survivors.
RESULTS. We excluded 5 (1%) patients with no base excess data which left 934 patients (99%) eligible for analysis. The admission-base excess measurement was missing in 62 (6%) patients. Patients were 64 (±12) years old, 81% were men and 89% had a witnessed OHCA. At hospital admission, mean base excess was -9.09 (±6.15) mmol/L and median lactate was 6.0 (3.0-9.5) mmol/L. Comparing survivors and non-survivors, admission-base excess was less negative in survivors (-7.63±5.59 versus -10.57±6.53, p=0.01). Furthermore, during TTM, not including the admission values, base excess remained significantly less negative in survivors (β = 1.31 [95% confidence limit, 1.85 – 0.78 mmol/L]; pgroup <0.0001). Pairwise comparison of ROC-curves showed no difference in predictive value between base excess (area under the (AU) ROC = 0.66 (95%-CI 0.62-0.69)) and lactate (AUROC = 0.64 (95%-CI 0.61-0.68)) (p = 0.88). The optimal base excess cut-off value to predict mortality was <-9.35 mmol/l (sensitivity 61%, specificity 69%, Youdens Index: 0.28). For lactate the optimal cut-off value to predict mortality was >5.65 mmol/L (sensitivity 63%, specificity 59%, Youdens Index: 0.21). In a multivariate Cox regression model adjusted for confounders including admission-lactate, admission-base excess <-9.35 mmol/L was independently associated with mortality (hazard ratio: 1.83 [95%-CI 0.44-2.32], p<0.0001).
CONCLUSION. Admission base excess below a cut off -9.35 mmol/l was independently associated with mortality. Lactate and base excess had identical predictive value and can be used interchangeably in the patient-assessment at hospital-admission after OHCA.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000223

INTRODUCTION. Choosing the appropriate candidate who can get benefit from early coronary angiography(CAG) and targeted temperature management(TTM) is still challenging. Simplified CAHP (sCAHP) score is a validated tool to predict neurological outcomes following out-of-hospital cardiac arrest (OHCA).
OBJECTIVES. To evaluate whether the effect of CAG and TTM is modulated by the sCAHP score in OHCA patients.
METHODS. Consecutive OHCA patients were evaluated from 2011 to 2017 in a tertiary medical center. The optimal cutoff value of sCHAP score for neurological prognosis was estimated by generalized additive model (GAMs).
RESULTS. There were 412 patients included in the study and 94 patients (22.8%) had favorable neurological outcome with cerebral performance category (CPC) 1-2. The optimal cutoff value of sCAHP for differentiating high risk from low risk was 185 by GAM plot. There was interaction between the sCAHP score and TTM in regression analysis for predicting the favorable neurological outcome. TTM was associated with favorable neurological outcome only in the patients with sCAHP score < 185 (odds ratio (OR) 2.13, 95% confidence interval (CI) 1.10–4.13, p=0.02). Improvement of survival outcome was associated with TTM independent of sCAHP scores (OR 2.66, 95% CI 1.54–4.59, p<0.001). Early CAG was associated with favorable neurological (OR 4.43, 95% (CI) 2.28–8.60, p<0.001) and survival outcome (OR 3.47, 95% CI 1.93–6.25, p<0.001) irrespective of low or high sCAHP scores.
CONCLUSION. Early CAG should be considered for all OHCA patients, irrespective of the immediately predicted neuroprognosis after ROSC. The appropriate selection of candidate for TTM needs further studies, especially for those with worse predicted immediate neuroprognosis.

Manual Chest compression quality during intra-hospital transportation is not inferior to Corpuls-CPR

G. Jansen[1], K. Kipker[1], E. Latka[2], R. Borgstedt[1], S. Rehberg[1]
[1]Anaesthesiology, Prostestant Hospital of the Bethel Foundation, Bielefeld, Germany; [2]Fachbereich rettungswesen, Studieninstitut für kommunale Verwaltung Westfalen - Lippe, Bielefeld, Germany

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000227

INTRODUCTION. High-quality chest compressions (CC) with minimized interruptions are one of the most essential prerequisites for an optimal outcome of resuscitation. Therapy of reversible causes of cardiac arrest, such as coronary angiography, often requires intra-hospital transport (IHT) during ongoing resuscitation. There is concern for a relevant decline of compression quality while moving patients. Therefore, automatic CC devices have been developed by the industry. As guidelines only recommend these devices under certain circumstances, such as transport during resuscitation, manual CC remains the gold standard [1].
OBJECTIVES. The present study investigated manual CC quality during IHT in two different provider positions in comparison with the automatic CC device Corpuls-CPR.
METHODS. 20 paramedics were enrolled into a manikin study (Laerdal Resusci Anne QCPR) with four groups: a reference group (RG) with the provider kneeling beside the manikin on the floor and 2 groups performing CC during a simulated IHT: kneeling in bed beside the patient (group 1, figure 1) or squatting above the patient in bed (group 2,figure 2). Each participant completed each scenario. In comparison, 20 simulated IHT were performed using the Corpuls-CPR (GS Elektromedizinische Geräte G. Stemple GmbH) (group 3, figure 3). Indicators of CC quality (pressure point and depth, compression frequency, complete relief and sufficient pressure depth) were measured as defined in the European Resuscitation Council Guidelines 2015 [1].
RESULTS. The RG was able to perform high quality CC. Compared to the RG, there were no statistical differences in CC quality in groups 1-3. Notably, CC quality was similar in the manual groups 1 and 2 as compared to Corpuls-CPR in group 3. Detailed results are shown in table 1.
CONCLUSION. Carrying out guideline-compliant CC [1] during IHT is feasible with multiple provider positions. A manual CC in this context is not inferior to a mechanical CC with the Corpuls-CPR. These results suggest that even in the absence of automatic devices high quality CC are possible during intra-hospital transportation.

Characterization of Peri-operative Paediatric Cardiac Arrest - A 10-year Review of 22,650 Anaesthesiologic Procedures in a German Tertiary Hospital

G. Jansen[1], E. Lang[1], J. Popp[1], B. Schmidt[1], M. Barthel[2], S. Rehberg[1]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000231

INTRODUCTION. Cardiac arrest (CA) in the peri-operative care of paediatric patients is a dreaded event [1,2]. The incidence ranges between 3-21 per 10,000 paediatric anaesthetic procedures, depending on the investigated patient population. [1,2]
OBJECTIVES. The aim of our study was to characterize the causes of perioperative paediatric CA at a German tertiary care hospital between 2008-2018.
METHODS. The anaesthetic database was screened for perioperative paediatric CA during all anaesthesiologic procedures in patients <16 years of age. We defined the peri-operative period from anaesthesia induction until the end of care of the team of anaesthesists care. CA was defined as the necessity of performing chest compressions. In each case the cause of CA was documented and it was assigned to one of the 3 peri-operative phases: induction of anesthesia, intraoperatively and postoperatively until the end of anaesthesiologists´ care.
RESULTS. During the 10 year observation period,18 perioperative paediatric CA were observed in a total of 22650 general anaesthesia procedures according to an incidence of 7,9 ± 4,2 per 10,000 paediatric anaesthetics (CI 95 4,2-11,6). In 17 cases a surgical procedure was performed, while in one case a bronchoscopy was the reason for anaesthesia. Five CA occurred during induction of anaesthesia, eleven intra-operatively and two in the post-operative phase. The causes of CA are displayed in Table 1. Two children died intraoperatively as a result of liver haemorrhage and one child at the post-anaesthesia care unit as a result of malignant hyperthermia. After 30 days seven children with perioperative CA had died during the hospital stay as a result of their underlying condition, nine of the resuscitated children survived.
CONCLUSION. Paediatric peri-operative CA is a rare event. During anaesthesia induction, CA mainly occurs in association with a difficult airway. Intraoperatively, acute shock events (haemorrhage, sepsis) and complications with the endotracheal tube are the most common causes of paediatric perioperative CA.

Multi-vessel versus culprit-only revascularization in cardiac arrest survivors with multi-vessel coronary artery disease: A multi-center cohort study

CK. Wu[1], CW. Sung[2], CH. Huang[1], WJ. Chen[1], SN. Wu[1], WT. Chang[1], T. Ming-Sham[1]
[1]Department of emergency medicine, National Taiwan University Hospital and College of Medicine, Taipei, Taiwan; [2]Department of emergency medicine, National Taiwan University Hospital Hsin-Chu Branch, Hsinchu, Taiwan
Correspondence: C.K. Wu
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000264

INTRODUCTION. Conflicting results existed as to the recommendation of complete revascularization for multi-vessel coronary artery disease (CAD) in patients with ST-elevation myocardial infarction (STEMI). In survivors successfully resuscitated from cardiogenic arrest with multi-vessel CAD, whether multi-vessel revascularization or culprit-only revascularization benefit outcomes more remains undetermined and worth further investigation.
OBJECTIVES. To evaluate whether multi-vessel revascularization following return of spontaneous circulation (ROSC) is associated less in-hospital mortality and poor neurological recovery than culprit-only revascularization.
METHODS. Two hundred and seventy-three non-traumatic, adult (ages ≥ 18) cardiac arrest patients with sustained ROSC and underwent emergent coronary angiography (CAG) within 24 hours following cardiac arrest were retrospectively recruited from three hospitals from 2012 to 2017. Patients with definite coronary artery stenosis (< 70%) (n=72) or 1-vessel stenosis (n=74) or failed percutaneous coronary intervention (PCI) (n=37) were excluded. Multi-vessel PCI was defined as revascularization of more than one major vessel during the index CAG, and culprit-only PCI as revascularization of the infarct-related artery only. In-hospital mortality and neurological function at hospital discharge were compared between groups.
RESULTS. A total of 90 patients were enrolled in the final analysis and classified into multi-vessel (n=45) and culprit-only (n=45) groups. No significant differences of baseline characteristics, CPR events, and post-arrest care was noted between these two groups. Twenty-five patients (55.6%) in the culprit-only groups failed to survive to discharge while 17 patients (37.8%) in the multi-vessel group did (adjusted HR = 0.54, 95% CI = 0.28 – 0.98, p = 0.04). There were 27 patients (60.0%) in the culprit-only groups discharged with poor neurological recovery (cerebral performance category: 3-5) while 25 patients (55.6%) in the multi-vessel group (adjusted OR = 0.89, 95% CI = 0.29 – 1.98, p = 0.78). Consistent decrease of in-hospital mortality in patients receiving multi-vessel revascularization was noted with CPR duration ≥ 10 mins.

CONCLUSION. In cardiac arrest survivors with multi-vessel CAD, multi-vessel revascularization is associated with less in-hospital mortality as compared with culprit-only revascularization.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000335

INTRODUCTION. The incidence of cardiac arrest after cardiac surgery is around 1,4-2,7%, while reported survival rate is 30-56%.
OBJECTIVES. Aim of our study is to investigate whether cardiac surgical patients who survived after cardiac arrest during the first 48 hours, are more likely to experience major postoperative complications
METHODS. We retrospectively studied patients who suffered cardiac arrest during the first 48 h after cardiac surgery , from June 2012 to March 2019.The following complications were investigated: Post op atrial fibrillation(AF), Acute Kidney Injury based on KDIGO criteria(AKI), need for renal replacement therapy(RRT), postop stroke, sternal wound infection and low cardiac output syndrome(LCOS).We compared cardiac arrest survivors with the rest of the cohort excluding patients who died during hospital stay. Cardiopulmonary resuscitation was conducted according to the Cardiac Advanced Life Support(CALS) protocol. Chi square test was used for the statistical analysis.
RESULTS. From a total of 86 pts who suffered cardiac arrest, 42 survived (group A, mean age 67,2± 10,8 and mean Euro Score II 3,5± 3,1). Group B consisted of 3217 patients (mean age 65,3± 10,6 and mean Euro Score II 2,2±3,1) who underwent cardiac surgery and discharged from hospital. Results are shown in table 1.
CONCLUSION. Cardiac arrest survivors after cardiac surgery have higher incidence of postoperative stroke, atrial fibrillation, AKI, AKI requiring RRT, and Low Cardiac Output Syndrome compared with the rest of patients who discharged from hospital. No statistical significant difference was found regarding sternal wound infections.

INTRODUCTION. Post-CA ischemia/reperfusionn of the gastrointestinal tract is suspected to provoke endotoxin translocation, contributing to shock and organ failure (1, 2). However, incidence, characteristics and consequences of these GI ischemic injuries are unknown
OBJECTIVES. Main objective: to assess the incidence of upper digestive tract ischemia in a prospective cohort of patients resuscitated from an out-of-hospital cardiac arrest (OHCA).
Secondary objectives: to determine the incidence of severe digestive ischemia; to determine if upper digestive digestive tract ischemia (severe or not) is associated with occurrence and duration of post-CA resuscitation shock, and with favorable neurological outcome.
METHODS. The ENTRACT study was a prospective, interventional, non-controlled, multicentric study. Included patients underwent a gastroscopy 2 to 4 d after OHCA if still intubated. Digestive ischemia was determined by the gastroenterologist who performed the gastroscopy. Severe lesion were defined as ulceration or necrosis. Post-CA shock was defined by the needs for vasopressors despite appropriate fluid management and vasopressors-free days over the first 10 days. CPC 1/2 at hospital discharge defined a favorable outcome (FO). Patients with and without digestive ischemia were compared. Multivariate regression analysis were performed to identify variables associated with digestive ischemia.
RESULTS. 221 patients were included, 214 were suitable for complete analysis. Mean age was 62, 74% were male. CA was witnessed in 90%, initial rhythm was VT/VF in 53%, median no-flow was 5 (0-9) min and low flow 21 (15-30) min. 121 (57%, CI95% 50-63%) patients had at least one ischemic lesion lesion of upper digestive tract (103 (85%) didn't present any digestive symptoms before endoscopy). Fundus was the most frequent localization of ischemia followed by antrum, duodenum and esophagus. Ischemic lesions were severe in 55/121 (45%) patients and mild in 66 (mucosal oedema/erythema). Patients with digestive ischemia, compared to patients without, had similar demographic characteristics but were less frequently treated with proton pump inhibitor (PPI) before CA (16% vs 31%). CA characteristics were similar except that patients with digestive ischemia received more epinephrine (2(1-4) vs 1(0-3) mg) despite similar low-

flow. Multivariate regression identified peripheral artery disease (OR 0.3 (0.09-0.94)) previous PPI (OR 0.49 (0.23-1.03)) and hypochloremia (OR 0.9 (0.84-0.97)) as protective factors whereas hematocrit (OR 1.04 (1.00-1.09)) and epinephrine dose during CPR (OR 1.17 (1.03-1.32) were associated with upper digestive ischemia. 138 (64%) patients presented post-resuscitation shock and 82 (38%) had a FO. These proportions were similar between the 2 groups as well as vasopressors free days. In pre-specified sub-group analysis, patients with severe digestive ischemia had a lower rate of FO (26% vs 41% and 36% for patients with moderate or no digestive ischemia, p=0.04). Analyses on post-CA shock and on organ failure are ongoing.
CONCLUSION. In this multicentric study, upper digestive tract ischemia was frequent after CA (57% of the patients) and associated with epinephrine dose during CPR. Digestive ischemia involved mainly the stomach, necrosis was rare. Severe ischemia seems to be associated with outcome. Main limitation is that patients extubated or dead before d2 were not included.

INTRODUCTION. The aim of this study was to identify predictive factors for successful weaning in patients who received extracorporeal cardiopulmonary resuscitation (ECPR) after cardiac arrest.
METHODS. Between December 2015 and November 2018, we retrospectively analyzed all patients who had in-hospital cardiac arrest (IHCA) and out-of-hospital cardiac arrest (OHCA) and were treated with venoarterial extracorporeal membrane oxygenation (VA-ECMO) at our institution. We divided the patients into two groups (weaned and unweaned) and compared the patients' baseline characteristics, low-flow time, and laboratory findings between the two groups.
RESULTS. Of the 151 patients included in the study, 30 (19.9%) had OHCA and 121 (80.1%) had IHCA. Seventy-three patients (48.3%) were successfully weaned from VA-ECMO, while 78 (51.7%) were not. The mean low-flow time was 24.9 ± 16.9 minutes in all the patients, 20.9 ± 15.9 minutes in the weaned group, and 28.6 ± 17.1 minutes in the unweaned group (p = 0.005). Multivariate analysis revealed shorter low-flow time as an independent predictor of successful weaning from VA-ECMO, whereas IHCA and age did not predict successful weaning from VA-ECMO.
CONCLUSION. Low-flow time was a significant predictor of successful weaning from VA-ECMO in the patients who received ECPR in this study.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000428

INTRODUCTION. Current treatments for out-of-hospital comatose cardiac arrest patients have improved the survival rate and neurologic prognosis. However, early neurologic prognostication still remains a challenge. We assumed that initial serum ammonia and lactate levels may be associated with the patients neurologic outcome.
OBJECTIVES. This is a single-centered prospective study comprising 213 patients with 14 exclusions. Blood samples were taken after the return of spontaneous circulation (ROSC). Neurologic prognosis was evaluated using cerebral performance scale (CPC). Patients were divided into two groups: Good neurologic outcome (CPC 1, 2 = 80) and Poor neurologic outcome (CPC 3, 4, 5 = 133).
METHODS. Variables were compared using Chi-square or T-Test. All variables found to be significant by univariate analysis then underwent multivariate logistic regression analysis for determine whether each variable has an independent relationship with poor neurological prognosis. The primary model was constructed by extracting statistically significant variables and performing multiple logistic regression analysis. The secondary model consisted of the discriminative power of the primary model for the prediction of neurological prognosis, and the concentration of serum ammonia and blood lactate, respectively.
RESULTS. Serum ammonia and lactate levels in the poor outcome group were significantly higher than those of the good outcome group. On multivariate logistic regression analysis, age (OR, 1.029; 95% CI, 1.003-1.055; p =0.027), non-shockable rhythm (OR, 12.682; 95% CI, 5.855-27.471; p < 0.001), and time from collapse to ROSC (OR, 1.062; 95%CI, 1.037-1.088; p < 0.001) were the most significant predictive variables for poor neurologic outcomes, and comprised our primary prediction model for poor neurologic outcomes. Secondary model consisted of either or both of ammonia and lactic acid in the primary model. These two models were compared and no significant differences were found.
CONCLUSION. In conclusion, serum ammonia and lactate levels were associated with prognosis of the out-of-hospital comatose cardiac arrest patients but did not provide incremental prognostic value.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000490

INTRODUCTION. Current basic life support guidelines recommend two minute shifts for compression between two rescuers (1). However, rescuer fatigue coupled with a decay in the quality of chest compressions occurs within one minute.
OBJECTIVES. To compare alternating rescuers in one-minute and two-minute chest compressions, in terms of: chest compression quality metrics and rescuer fatigue.
METHODS. This prospective randomized cross-over study was conducted at Songklanagarind hospital, Hat Yai, Songkhla, Thailand. The study enrolled sixth year medical students and residents. All participants were randomly grouped into pairs to perform 8 minutes of chest compression, utilizing both the one-minute and two-minute scenarios on a mannequin model. The primary end-points were: chest compression depth and rate. The secondary end-points included rescuer's fatigue, respiratory rate and heart rate.
RESULTS. One-hundred and four medical students and residents participated in this study. In the one-minute group, compared with the two-minute group, there was significant, higher mean (SD) compression depth [mm] (45.8 (7.2) vs 44.5 (7.1), P=0.01), but no difference in the mean (SD) compression rate [per min] (116.1 (12.5) vs 117.8 (12.4), p = 0.08). The rescuers in the one-minute group were lower in the fatigue visual analog scale (P<0.001), change in respiratory rate (P<0.001), however, there was no difference in the change of heart rate (P=0.59), compared with the two-minute group.
CONCLUSION. There was statistically significant, higher compression depth and lower rescuer fatigue in 1-minute chest compression groups, compared with 2-minutes. (Thai Clinical Trials Registry TCTR20170823001)

Hospital survival following out of hospital cardiac arrest - is it all due to pre-hospital patient selection?

P. May[1], W. A.[1], M. J.[1], B. G.[2], P. M.[1]
[1]Intensive care, Frimley Park Hospital, Frimley, United Kingdom; [2]Accident and emergency, Frimley Park Hospital, Frimley, United Kingdom

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000549

INTRODUCTION. Out of hospital cardiac arrest (OHCA) affects 60,000 people in the UK annually and good outcomes rely on a 'chain of survival', which has pre-hospital and in-hospital components. Our 700-bedded UK DGH has a 24-7 Cardiac Cath Lab service, receives 100 OHCA patients each year, and is served by two ambulance services – South East Coast (SECAMB) and South Central (SCAS).
OBJECTIVES. To quantify our hospital survival after OHCA and contrast this with local ambulance service data.
METHODS. We analysed prospectively collected data from all adult post-OHCA patients admitted via ED over a 5-year period (01/01/12-31/12/16) using Trust electronic databases, and compared this with nationally published ambulance service data.
RESULTS. [Presented as median (range) or percentages] Of 499 patients identified: age 71 (20-96); primary rhythm VF 40%, VT 3%, PEA 29%, asystole 19%, none recorded 9%; died in ED 45%, admitted to ICU 43%; admitted to a ward 12%; survived 25%. Of VF patients: age 68 (20-93), admitted to ICU 59%, survived 44%. Of VT patients: age 76 (57-91), to ICU 38%, survived 38%. Of PEA patients: age 72 (23-96), to ICU 28%, survived 7%. Of asystole patients: age 74 (25-96), to ICU 26%, survived 3%. Monthly OHCA ambulance service survival data during study period: SCAS 15.4% (5.5-26.9), SECAMB 7.6% (0.7-12.3), national 8.5% (6.3-10.6). Of the 31192 ambulance arrivals in 2016: conveyed by SECAMB 77%, conveyed by SCAS 23%.
CONCLUSION. 1) Our data show that patients presenting with VF are younger, more likely to be selected for ICU support and survive to hospital discharge: a relationship that is well known. 2) The national incidence of cardiac arrests presenting with shockable rhythms is 20%; in our population this was 43%. 3) Our overall survival rate is well above average (observed 25%; expected 8.5%), which could be be explained, in part, by selection bias by pre-hospital teams, who consciously select in patients with favourable outcomes (those in VF and most likely to benefit from a heart attack centre) and unconsciously select out those with unfavourable outcomes via unsuccessful resuscitation. 4) Both SECAMB and SCAS follow national guidelines and are able to pronounce life extinct (PLE) at the scene. However, they have dramatically different survival data; reasons for which we will continue to investigate. We hypothesise that, among others, differences in data collection and/or PLE thresholds may be at play here. 5) SCAS conveys <¼ of our patients, so excess survival directly attributable to SCAS should have minimal impact on our outcomes. 6) Increased VF prevalence does not completely explain the extent of survival benefit that we observed.

INTRODUCTION. There is controversy on admission of critically ill elderly patients in ICU as older age has been associated with poor clinical outcome.
OBJECTIVES. We analyzed patients above the age of 80 admitted to our ICU during the past four years and evaluated clinical outcomes.
METHODS. Retrospective cohort study of patients aged 80 and above admitted to the ICU of Hospital de Mostoles in Madrid, Spain, from January 2014 to December 2018. We collected data from electronic medical records on demographics, functional status prior to admission, Simplified Acute Physiology Score III (SAPS III), admission cause, need of mechanical ventilation, vasopressor support, continuous renal replacement therapy (CRRT), mortality in ICU, hospital mortality and mortality up to one year after ICU discharge.
RESULTS. 347 patients aged 80 and over were admitted to our Unit during the study period. Mean age was 83 years, 47% women and 68,7% totally independent for activities of daily living according to the Barthel index. The most common cause of admission was cardiovascular, 48.1%, including cardiac arrest, acute coronary syndrome, pulmonary embolism and arrhythmias. Mean SAPS III score was 57,70. Vasopressor support was administered in 37% of patients, invasive mechanical ventilation 25% and non-invasive mechanical ventilation or high flow oxygen cannula in 19%. Only 2% of patients required CRRT. Median ICU stay 3 days. ICU mortality was 19.6% and overall hospital mortality 28,53%; 10% died within the first year after ICU discharge.
In the univariate analysis, a statistical association with mortality was found with vasopressor support, OR 4.86, 95% CI (2.75-8.61) and both invasive and non-invasive mechanical ventilation with OR 78, 95% CI (26,5-230) and OR 7.29, 95% CI (2.1-24.5) respectively. For each unit increase in SAPS III, there was an increased odds of death of 1.1 (95% CI 1.07–1.13). Similarly, the odds of dying in patients partially dependant for activities of daily living was 3,09 (95% CI :1-17-8.15) whereas totally independent subjects showed OR 1.07 (95% CI: 1.01-1.13). Finally, age revealed no association with increased risk of mortality (OR 0.96 with a 95% CI 0.88-1.05) and male sex had a lower risk of dead (OR 0.45 with a 95% CI 0.26-0.77). The multivariate logistic regression analysis determined that only functional status (partially dependent OR 3.09, 95% CI 1.17-8.15) and length of hospital stay (for each day increase OR 1.07, 95% CI 1.01-1.13) were associated with mortality at one year.
CONCLUSION. Admission of elderly patients to ICU should be considered after a careful evaluation of their functional status and comorbidities. As expected, patients requiring more ICU support (invasive mechanical ventilation, vasopresssors) have higher mortality. Age by itself does not seem to predict poor clinical outcome.

Correspondence: E. SANCHO
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000775

INTRODUCTION. The use of peripherally inserted central venous catheters (PICC) is increasing in the ICU due to the easy peripheral access and the lower number of complications related to insertion. Some studies indicate a higher frequency of venous thrombosis related to PICC than to central venous catheters (CVC). However, there are no conclusive data on the incidence of catheter-related venous thrombosis (CRVT) in critically ill patients. Despite there are different diagnosis possibilities, the gold standard technique is the ecography.
OBJECTIVES. The aim of the study is to investigate the incidence of catheter related venous thrombosis (CRVT) in ICU and compare this incidence between patients with PICC and CVC (jugular or subclavian). A secondary objective is to locate the role of ultrasound screening for the early diagnosis of the CRVT. Additionally, the study describes the characteristics of the patient, the canalized vein, the clinical expression, and the relationship of these variables with the appearance of CRVT.
METHODS. The study was carried out as a prospective, open, non-randomized cohort study of consecutive patients between March and November 2018. PICC and CVC used were polyurethane 7F catheters. All PICC were placed by trained nurses. Resident or senior doctors placed CVC. Clinical (daily) and ultrasound (3 established exams) follow-up was applied to each patient during the first 20 catheter days (or until the catheter was removed). All data concerning the patient, the anticoagulation treatment and the diagnosis of other non-thrombotic complications related to the catheters was collected.
RESULTS. A total of 150 patients have been analyzed; 83 patients underwent PICC placement, and CVC was used in 67 patients. Both groups were comparable in terms of baseline characteristics. We found a significantly higher incidence of CRVT in the PICC group: 25% (n=21) vs 8,9% (n=6) in the CVC group (p = 0,001). PICC patients had an increased risk of thrombosis OR=3,20 (IC95% 1,18-8,69). Moreover, thrombosis appeared at day 4,81 in average in PICC patients, while appeared at day 7,83 in CVC patients (p=0,0029).
Just 8 of the 27 patients with thrombosis had clinical signs of phlebitis, while 19 (70,3%) of patients had subclinical thrombosis, only diagnosed by ecography. Then, the PPV of phlebitis is just 29,6%.
CONCLUSION. In our cohort, PICC catheters have an increased risk of thrombosis and this thrombosis appeared before than thrombosis related with CVC. Phlebitis was not a reliable sign of thrombosis, most patients with thrombosis had no clinical features. Ultrasound screening should be performed regularly in critically ill patients wearing central catheters.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000777

INTRODUCTION. Frailty is characterized by age-associated declines in physiologic reserve and function across multiorgan systems, leading to increased vulnerability for adverse health outcomes.
OBJECTIVES. To asses the impact of frailty in the outcomes of patients suffering from a cardiac arrest during their hospital stay.
METHODS. A descriptive, observational and retrospective study was conducted from January 2015 to June 2018. We analyzed all calls to the ICU resuscitation team in Guadalajara Hospital in this period. Demographic variables (age and sex), frailty, causes of CPA, limitation of CPR and outcomes were determined. Frailty assessment was performed using the Clinical Frailty Scale (CFS). Frailty divide patients in 2 categories: prefrail and frail (PF-F) (CFS > 3) and non-frail (NF) (CFS ≤ 3).
For statistical analysis of the data, quantitative variables are expressed as means ± standard deviation and qualitative variables as percentages. Categorical variables were assessed using the chi-square test and continuous variables were assessed using t-Student or U-Mann-Withney tests. Multivariate analysis was performed using a logistic regression model. A p-value <0.05 was considered statistical significance
RESULTS. 105 calls for CPA were recruited. 17 patients were excluded because CFS could not be determined. We studied 88 patients with a main age of 74.9 ± 10,9 years, with a higher proportion of men (68.2%). In our sample, 69.3 percent of patients were considered PF-F (61/88) (Image 1). In-hospital mortality was 94,3% (83/88), with no statistically significant difference in age, sex, limitation of CPR and causes of CPA. People with frailty are significantly more likely to die.
Multivariant analysis, adjusted by age, sex and CPR cause showed that only CFS>3 (PF-F patients) was a significant independent prognosis factor of mortality (OR 10,43; IC 95% 1,11 - 98,35; p=0,04).
CONCLUSION. Frailty is a significant independent prognosis factor of mortality in patients suffering from a CPA. Assessing frailty may help clinicians in CPR or non CPR decision-making.

'Development of a Quality Assurance Framework for Focused Echocardiography in Intensive Care

S. Curry, N. Jones, A. Roscoe, K. Salunkey, A. Rubino
Intensive care, Royal Papworth Hospital NHS Foundation Trust (new Cambridge site), Cambridge, United Kingdom
Correspondence: S. Curry
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000811

INTRODUCTION. The use and availability of point-of-care care ultrasound is increasingly being recognised as a valuable diagnostic and monitoring tool in the Intensive Care Unit (ICU). When used at the bedside, ultrasound-guided vascular access, drain insertion and ultrasound-guided regional anaesthesia have been shown to enhance the safety and are now considered standard practice. Equally, the use of focused transthoracic echocardiography (TTE) has become readily available for real-time haemodynamic assessment and monitoring of patients with sepsis, congestive heart failure, shock and traumatic injuries. Separate from the scope of a comprehensive TTE study, a focused TTE study is intended to answer specific questions related to the ICU patient. Limited to acquisition of four basic cardiac views and one view of each lung base, a focused scan can serve as a rapid assessment of the cardiac structure and function in acutely unwell patients. However, there are currently no robust quality assurance systems in place for ensuring responsible practice in the use of focused echocardiography by intensive care clinicians after the initial training period. To assess the quality of focused TTE studies completed on our ICU we conducted a retrospective analysis of our current practice to establish the level of consistency and reproducibility of focused TTE studies.
METHODS. A retrospective analysis of focused TTE studies conducted on Royal Papworth Hospital ICU. Data collection included repeated audit cycles of 3-months duration between April 2016 – Feb. 2018. All focused TTE studies conducted on Royal Papworth ICU during the audit periods were included. Focused TTE studies were analysed using a 22-point audit tool to assess technical quality, reporting, documentation and upload to the local PAC system. Data were analysed using Chi-squared tests, with a p-value <0.05 regarded as significant.
RESULTS. Data were collected from 409 focused TTE studies during four audit cycles. Inclusion of patient details and attachment of ECG was similar between audit cycles (64.4%). Studies with four recorded cardiac views improved from the first audit cycle (31%), with the highest percentage of complete images obtained during April-June 2017 (53%). The subcostal view was the least obtained view across all cohorts, with more than 50% of all studies missing a subcostal image. Chamber function, pericardial collections and hypovolaemia were assessed on average the same across all cohorts (>90%). Assessment of pleural collections declined from 2016 (69%) to 2018 (48%). A decrease in the number of studies uploaded to the PAC system was also observed, with only 4% of studies uploaded in June-Aug 2017.
CONCLUSION. Basic echocardiography training for intensive care clinicians is regarded as valuable screening tool, which can be used quickly and effectively in the management of patients in acute settings. However, variation in practice related to incomplete studies, reduced number of standard images obtained and poor compliance with clinical documentation were highlighted in this retrospective analysis. In response to these findings, we have implemented a structured system of senior review and on-going audit during monthly quality assurance meetings. BSE accredited Cardiologists and Cardiac Physiologist contribute to a quality assurance scoring system and provide direct feedback on quality of echocardiography images and on the accuracy of reporting, enabling qualitative review of focused TTE studies that was not possible in the previous quantitative audit parameters.

INTRODUCTION. Among the several physical, cognitive and psychological consequences of ICU stay, the activities ot daily living (ADL) are indicative tasks of the ability to lead an independent life, such as housework, shopping, self-medication.
OBJECTIVES. To assess the capacity of the dependence degree for basic daily activities in adult ICU survivors.
METHODS. Cross-sectional descriptive study by evaluating adult ICU survivors in a University Hospital, for 2 years. The sample was composed by patients who returned for the multiprofessional follow-up clinic 3 months after ICU discharge. The data were collected through consultation and application of the Katz index.
RESULTS. A total of 287 patients were evaluated (mean age 46.3 y; 56.8% male; 36% trauma as ICU admission cause). The pre-ICU dependence status was: 95.8% independent; 0.8% partial dependence; 3.5% total dependence. Table 1 shows the post-ICU dependence degree and some variables.
CONCLUSION. Although most post-ICU patients were independent, the incidence of dependence was relatively high, particularly in older and non-trauma patients. The evaluation of ADL may be an important marker of outcome in this group, as well as the quality of care performed during hospitalization.

Table 1 (abstract 000824). Dependence degree for basic activities of daily living in ICU survivors, n=287

	Independent	Dependent, partial	Dependent, total

Does early lactate serum levels predicts mortality in very old critically ill patients?

R. Carvalho De Menezes[1], I. Bonifácio Brige Ferreira[2], M. Lisboa Otero[1], G. Andrade Agareno[3], AMDS. Cerqueira Junior[1], L. Pamplona Neto[1], S. Agareno De Souza Filho[1], NM. Filgueiras Filho[3]

INTRODUCTION. Lactate is considered to be a useful prognostic biomarker in critically ill patients. However, few studies address the association of lactate with mortality specifically in octogenarian patients, a population that deserves to be individualized given changes in clinical presentations of diseases, functional reserve, social demands and, among others that occur over the years.
OBJECTIVES. To assess the accuracy of lactate in predicting mortality in very old patients.
METHODS. A retrospective cohort study with very old patients (≥ 80 years) with a length of stay > 24 hours in a general ICU during the period August 2015 to August 2018. Lactate serum level was obtained within the first 6 hours of admission. The D'agostino test was used to determine normality in lactate values. In order to evaluate the median levels of lactate between the populations that were discharged and those who died and its accuracy, the Mann-Whitney U Test and the Area Under Receiver Operating Characteristic Curve (AUROC) were respectively used.
RESULTS. A total of 691 patients were analyzed, 65% (451) of whom were women, the mean ± SD and the maximum age was 87 ± 4.9 and 103 years. The mean Simplified Acute Physiology Score 3 (SAPS3) was 55.7 ± 9.4 and mean Charlson Comorbidity Index was 1.78 ± 1.73, without the assignment of points for age. Overall mortality was 28% (194), 7-day mortality was 13% (92), and there was 20% (144) of patients with an elevated lactate (≥ 2 mmol/dL). In comparison to those who survived (1.1; IQR: 0.8 – 1.8), the median lactate was higher in patients who died in all period (1.5; IQR: 1.1 – 3.05) [p < 0.0001] and in those who died in 7-day (2.0; IQR: 1.3-4.4) [p < 0.0001]. However, lactate did not demonstrate a good accuracy in determining the outcome of the patients, either to determine death during ICU stay (AUROC: 0.63) or even early death (AUROC: 0.73).
CONCLUSION. In the very old critically ill patients of our cohort, lactate had a poor correlation with mortality.

Mortality and readmission rates of patients discharged in-hours and out-of-hours from a British ICU over a three year period

J. Cumberworth, M. Chequers, O. Boyd, B. Philips
Department of intensive care medicine, Royal Sussex County Hospital, Brighton, United Kingdom
Correspondence: J. Cumberworth
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000839

INTRODUCTION. We have previously reported higher in-hospital mortality in patients discharged from the ICU out-of-hours compared to in-hours.1 When patients discharged for end-of-life care or organ donation were excluded, the discrepancy in mortality rates was much smaller. This could be explained because organ donation procedures are frequently undertaken at night and the mortality rate is 100%. We hypothesised that later discharge of patients undergoing organ donation or other end of life care might be a major influence on the frequently reported finding of apparent excess mortality in out-of-hours discharges.2 This new study seeks to establish in-hospital mortality rates for those discharged in-hours and out-of-hours over a 3 year period, with those discharged for organ donation or end-of-life care excluded.
METHODS. This is a single centre retrospective cohort study. Discharge data were collected for all patients admitted to our unit from 01/07/2015 to 31/07/2018. Patients were excluded if they did not survive to ICU discharge or if they had an APACHE II score of 0. Readmissions were defined as patients readmitted to ICU within the same hospital stay; the first admission for these patients was included. Patients discharged for end of life care or organ donation were identified and excluded. Data collected included age, sex, APACHE II score, nature of admission, length of stay, hospital outcome and readmissions to ICU.
RESULTS. 3943 patients were included. The patients discharged out-of-hours were significantly older and had higher APACHE II scores, but there was no significant difference in mortality rate or readmission rate (table 1). Out-of-hours was defined as 22:00 to 07:00.
CONCLUSION. There was no excess mortality in patients discharged out-of-hours once the effect of end-of-life or organ donation patients had been excluded. These groups should be considered separately to other patients surviving to ICU discharge, as their prognosis is equivalent to those who have not survived. This cohort of patients may be disproportionately discharged out of hours. The inclusion of patients discharged from ICU but for end-of-life on the ward may explain the previously reported, but unexplained, finding of higher mortality rates in patients discharged from ICU out of hours.

INTRODUCTION. Cortisol levels and the responsiveness of cells to steroids are important in regulating the glucocorticoid (GC) activity. GC actions are mediated by the glucocorticoid receptor (GCR) and its dysfunction leads to tissue resistance to GCs.
OBJECTIVES. To evaluate the expression of *GCR-α* and *GCR-β* in peripheral polymorphonuclear cells in relation to cortisol and adrenocorticotropin (ACTH) in critical illness for a 13-day period.
METHODS. Forty-two mechanically ventilated, steroid-free patients were studied. Blood samples were collected on admission in the ICU and on days 4, 8, and 13, to measure *GCR* expression, cortisol and ACTH. Twenty-five age- and sex-matched subjects were used as controls.
RESULTS. Acutely, in critically ill patients *GCR-α* mRNA expression was 10-fold that of controls ($p< 0.0001$), while *GCR-β* mRNA levels were 3-fold the expression of controls ($p< 0.0001$). Cortisol was elevated and ACTH was within normal limits. During the sub-acute phase, the expression of the isoforms was lower compared to controls, cortisol remained high and ACTH increased.
CONCLUSION.*GCR* expression and hypothalamic-pituitary-adrenal axis function undergo a biphasic response during critical illness; acutely, the expression of both GCRs is increased, however, *GCR-α* expression dominates and there is probably no GC resistance. During the sub-acute phase, the expression of both isoforms decreases and there is dissociation between low *GCR* expression and high cortisol, implying an abnormal stress response. Elevated cortisol is preserved through both ACTH and non-ACTH pathways.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000866

INTRODUCTION. To improve the quality of care provided to patients and their relatives in the ICU, assessing their satisfaction with the care they receive is important, being communication a crucial item to take into account.
OBJECTIVES. To evaluate whether the quality of communitation by the healthcare personnel in the Intensive Care Unit perceived by patients and relatives influences their level of satisfaction.
METHODS. Information was collected from June to September 2018 through a survey adapted to patients and family members. The questionnaire included a 7-score Likert scale conformed by different items aimed at assessing the quality of communication between patients and relatives and the healthcare personnel in the ICU. The dimensions are based on the work of Mora Lourido (2015). We conducted a difference analysis of means using the student's T, to check the differences in patients and relatives' satisfaction.
Subsequently, a multivariate linear regression analysis was performed to analyze the influence of perception of the quality of communication on satisfaction with the quality of care in the ICU.
RESULTS. In the scale of quality of the communication there are six variables shown in the previous table. In the regression analysis of the quality of the communication on the patients and relatives' satisfaction, we find that "Sincerity" is the variable that has the greatest influence on satisfaction (β=0.316, t=4.220, p=0.000), followed by the "Satisfactory communication" (β=0.247, t=2.787, p=0.006), being the rest of the variables not relevant to explain the satisfaction of patients and relatives.
The value of the F statistic indicates that, globally, the model is acceptable (F=52.905, p=0.000) and that it explains 59.1% of the total variance.
CONCLUSION. A high perception of the quality of the communication positively influences the satisfaction with the quality of the service on the part of patients and relatives. The most important factor in satisfaction is the sincerity in communication, followed by satisfactory communication. The communication by the healthcare personnel in the ICU is so important that it is able to explain 59.1% of the variability of satisfaction with the quality of the service, which is why it is a fundamental aspect to which health professionals should give importance.

Identification of predictors for postoperative deterioration

E. Mestrom[1], T. Bakkes[2], N. Ourahou[1], P. De Andrade Serra[2], S. Turco[2], E. Korsten[1], RA. Bouwman[1]
[1]Intensive care, Catharina Ziekenhuis, Eindhoven, Netherlands; [2]Signal processing systems, Technical University, Eindhoven, Netherlands, Netherlands
Correspondence: E. Mestrom
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000877

INTRODUCTION. An unplanned Intensive Care Unit (ICU) admission is a serious complication in postoperative patients. Identification of patients at risk of postoperative deterioration is crucial to support the anesthesiologist's decision on patient direct admission to a higher-acuity facility, such as the ICU or the surgical ward. Currently, no evidence-based criteria exist.
OBJECTIVES. To identify predictors for postoperative deterioration, which could aid allocation of postoperative patients to the appropriate level of care.
METHODS. Retrospective data collection of surgeries was performed between January 2013 and December 2017. Only first surgery per patient per hospital admission was included for analysis. All possibly relevant preoperative, intraoperative and early postoperative factors were collected. An unplanned ICU admission was used as criterion for postoperative deterioration.
RESULTS. A total of 27369 postoperative patients were selected. An unplanned ICU admission complicated recovery of 187 (0.7%) patients. These patients were significantly older (65 versus 54 years), more often male (52.4 % versus 37.5%), known to have higher ASA scores (38.4% ASA III versus 16.6%) and underwent longer surgeries (273 versus 159 minutes). Multivariate analysis resulted in 9 variables as best predictors of unplanned ICU admissions, consisting of age (OR 1.02; 95% CI 1.00-1.03), general in combination with epidural anesthesia (OR 3.31; 95% CI 2.26-4.84), surgical specialism (OR 2.76; 95% CI 1.89-4.03), ASA score 3 (OR 2.02; 95% CI 1.43-2.87), administration of phenylephrine (OR 1.71; 95% CI 1.21-2.42), or erythrocytes

(OR 2.45; 95% CI1.23-4.89), or plasma (OR 5.11; 95% CI 1.20-21.9), tachycardia (OR 2.15; 95% CI 1.53-3.03) and duration of surgery in minutes (OR 1.005; 95% CI 1.004-1.006). The ROC curve of this model resulted in AUC of 0,865.

CONCLUSION. Combining preoperative, intraoperative and early postoperative factors results in good prediction of unplanned ICU admissions. The model could improve decision support for the patients' allocation after surgery.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000878

INTRODUCTION. Renal ultrasound is increasingly used in critically ill patients, although studies show different levels of performance for predicting various conditions, such as acute kidney injury (1, 2). Performing renal ultrasound may be difficult in critically ill patients due to suboptimal positioning, pain or wounds. Previous studies however did not report data on feasibility, which could provide an overly optimistic impression.

OBJECTIVES. To explore the feasibility and image quality of renal ultrasound in a population of critically ill patients.

METHODS. This is a predefined substudy of SICS-II (3), a large prospective observational cohort in patients acutely admitted to the Intensive Care Unit (ICU). Patients underwent a protocolized ultrasonography exam within 24 hours of ICU admission by researchers who were not involved in patient care. All researchers were trained by experts before the start of the study and the first 20 study exams were supervised. We primarily assessed the right kidney and attempted to visualize the left kidney if image quality of the right kidney was considered insufficient. If necessary, the radiologist, who was not involved in patient care, was asked to perform the ultrasound. We recorded renal length, and arterial and venous doppler measurements. Images were validated by an expert radiologist who was blinded for patient characteristics.

RESULTS. So far, 403 patients were included in the SICS-II. In 81 out of 403 patients, no images were available, as ultrasound was not attempted due to severe abdominal pain, bandages or large wounds in 47 patients, and image quality was insufficient in 34 patients. In the remaining 322 patients, the right kidney was imaged in 90% of exams and the left kidney in the remaining 10%. Renal length could be obtained in 315, arterial doppler in 270 and venous doppler in 244 of the 322 patients, respectively. In 201 of the 322 patients (62%), all indices were obtained. So far, validation was completed for the first 125 exams (39%, validation is ongoing). The radiologist approved 84% of renal length measurements, 94% of arterial doppler measurements and 90% of venous doppler measurements (figure 1).

CONCLUSION. Renal ultrasound could be performed in 322 out of 403 patients. Kidney length could be measured in almost all patients, while doppler seems successful in around 80% of patients. When obtained, at least 84% of measurements were of sufficient quality as judged by an independent expert.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000894

INTRODUCTION. Auscultation has historically been an essential component of physical examination in critically ill patients but may be challenging. A more advanced modality like lung ultrasound (LUS) seems easy to use and has shown to be superior to chest x-ray and comparable to CT scan in detecting interstitial syndrome (1).

OBJECTIVES. In this sub-study of a large observational study, we aimed to explore the level of agreement between auscultation and LUS for interstitial syndrome.

METHODS. This post-hoc analysis included all patients with LUS out of the SICS-I study (2). In SICS-I, patients acutely admitted to Intensive Care Unit (ICU) within 24 hours after admission were eligible for inclusion, consisting of physical examination and LUS by trained

researchers not involved in patient care. Physical examination was performed first and included auscultation of six regions bilaterally for crepitation and rhonchi, if either was present, auscultation was considered abnormal. LUS consisted of the BLUE protocol (3) using a phased array probe targeting six scan-sites on the patient´s chest. Interstitial syndrome was defined as three or more B-lines in at least two scan-sites bilaterally. We evaluated sensitivity, specificity, negative predictive value and positive predictive value of the results of auscultation. We performed a sensitivity analysis to assess whether the diagnostic accuracy differs in patients with or without mechanical ventilation.

RESULTS. From the 1075 SICS-I patients, 926 (86%) had LUS performed in at least 2 scan sites and 535 of these patients (57%) were mechanically ventilated during the examination. A total of 302 patients (32%) had abnormal auscultation, and 307 patients (33%) had interstitial syndrome on LUS. Specificity of auscultation to diagnose interstitial syndrome on LUS was 76% (95%CI 72-79), sensitivity was 49% (95%CI 44-55), positive predictive value 50% (95%CI 45-54) and the negative predictive value was 75% (95%CI 72-77). Overall diagnostic accuracy was 67% (95%CI 64-70). Amongst those mechanically ventilated, the specificity was 73% (95%CI 68-78), sensitivity was 47% (95%CI 39-55) and accuracy was 65% (95%CI 61-69). Among those not mechanically ventilated, the specificity was 79% (95%CI 73-84), sensitivity was 52% (95%CI 43-61) and accuracy improved to 70% (95%CI 65-74).

CONCLUSION. The diagnostic accuracy of auscultation for interstitial syndrome on LUS was poor. Even though diagnostic accuracy and specificity of auscultation was better in patients who were not mechanically ventilated, a wide variation existed between auscultation and LUS. This leads on to whether routine use of LUS, as opposed to auscultation, should become a necessity rather than an optional skill set in the assessment of critically ill patients.

INTRODUCTION. It is widely known that COPD exacerbations lead to lung function Decline. Short-term Health-related quality of life (HRQL) after intensive care is poorly reported and a relevant concern for COPD patients, their relatives and providers of health care.

OBJECTIVES. To describe HRQL change in acute exacerbation of COPD ICU-admitted patients 3 months after discharge from a medical Tunisian ICU.

METHODS. We analyzed a prospective collected database including consecutive patients admitted for AE/COPD in a 9-bed medical ICU between February 1, 2017 and March 30, 2018. Patients' quality of life was assessed using Web-based version of the St George's Respiratory Questionnaire score (SGRQ) recorded at admission and within three months of ICU discharge via phone calls. The SGRQ variables (symptoms, activity, impacts) were compared before and after 3 months of ICU discharge using Wilcoxon test.

RESULTS. Among 102 patients admitted for AE/COPD during the study period, 75(73.5%) were included in the second evaluation. General characteristics were: age, 66.4±9.5 years old; sex ratio, 7/1; Charlson index>3, 40(53.3%); COPD GOLD D, 65(86.7%); median SAPSII score, 27 [22-34]; initial invasive mechanical ventilation, 20 (26.7%); median length of stay, 10 [6-16] days. Median SGRQ total score recorded at admission for the included patients was 33.8 [25.4-44]. The phone evaluation contact was performed in 71 (94.6%) patients. There was statistically significant increase in the total SGRQ score at admission compared to the total SGRQ score recorded after 3 months of ICU discharge 33.8 [25.4–44.] vs 55.8 [41.4-78], p<0.0001. Autonomy impairment increase was significant for all items of the SGRQ score (Symptoms 43 [41.4-78] vs 56.05 [45-74], p<0.001; Activity 47.6 [46-61.5] vs 66.1 [59.4-86], p<0.001 and impacts 21.4 [13.2-35] vs 47.7 [33.6-75], p<0.001).

CONCLUSION. In this study, ICU stay was associated with a significant decline in the short-term HRQL in this cohort of Tunisian COPD ICU survivors.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000909

INTRODUCTION. Mechanical ventilation (MV) is used during respiratory failure to reduce work of breathing and improve gas exchange. However, its efficacy depends on the visco-elastic properties of the respiratory system(1).

OBJECTIVES. To identify discriminative properties of respective airway pressures to predict difficult weaning process.

METHODS. A retrospective charts' review of MV patients admitted to a medical ICU of Farhat Hached hospital from November 2015 to February 2018. Difficult weaning process was indirectly expresse d by prolonged MV (≥ 7 days), Ventilator freedays (VFD), and a composite outcome defined as death and/or length of stay ≥14 days. Were collected patients' characteristics at admission and respective airway pressures (Peak, plateau, driving and intrinsic PEEP) at admission and at day 4. High airway pressure (NDHP) is defined as the number of days spent with high pressures : Peak ≥40 and/or plateau ≥30; and/or driving pressure ≥15 and/or; intrinsic PEEP ≥6) were extracted from medical records. Univariate and multivariate regression analyses were performed to identify factors independently associated with mortality.

RESULTS. 304 mechanically ventilated patients were collected within the study period. 199(65%) were non-COPD patients. They were 50± 18 years aged; ARDS, 25(12.6%); pneumonia, 14(7%) Pulmonary edema, 11(5.52%); SAPS II, 35.1±15.7; pH, 7.31±0.14; PCO2, 42.4±19.9; PaO2/FiO2, 210.6±109.2mmHg; MV duration, 8.9±9.4days; tracheostomy, 18(9%); length of stay, 10±10 days. Mortality, 114(57%). Mean airway pressures were respectively for peak, plateau, driving and intrinsic PEEP at admission : 30.2±8.9, 20.2±6.22, 13.5±4.9, 2.7±4.2 cmH2O and at day 4 : 30.9±8.9, 20.8±7, 13.7±5.8, 2.4±3.8 cmH2O. Univariate analysis and multivariate logistic regression showed the following factors associated to : 1) 28VFDs, peak at day 4 (OR, 1.06; 95%CI, [1.01- 1.13]; p=0.03), 2) prolonged MV, NDHP (OR, 1.35; 95%CI,

[1.13- 1.60]; p=0.001) 3) composite outcome, plateau at day 4 (OR, 1.52; 95%CI, [1.21- 1.91]; p=0.000).
CONCLUSION. Peak pressure, Plateau pressure and number of days spent with high airway pressures may alter significantly the weaning process in MV non-COPD patients.

INTRODUCTION. Objective: To evaluate the relationship between psychological symptoms (particularly Posttraumattic stress disorder [PTSD]) and the memories (real or illusory) reported by ICU survivors.
METHODS. Prospective cohort study for 7-year period in the Post-ICU multiprofessional outpatient office of a University Hospital, attending adult patients 3 months after ICU discharge. In order to evaluate the ICU memories, a cheklist was used, consisting of 9 items grouped in 4 domains of memories: treatment-related; environmental; related to emotional experiences, and illusory memories (dreams, nightmares and hallucinations). PTSD symptoms were evaluated using the IES-R. Levels of anxiety and depression were measured using HADS.
RESULTS. During the study period, 834 patients were evaluated by outpatient clinic/ psychology team: 61.8% male, mean age 45.4 y, mean APACHE II 19.8, 81% used MV, 39% used continuous sedation, mean ICU length of time 10.5 days. Most patients (54.6%) described some type of ICU memory (40.0% memories of real events; 2.6% illusion memories, such as dreams, nightmares and hallucinations; 13.0% a combination of memories of real events and illusions). The most frequent memories of real events were: discharge to the ward, family visit, see other patients and feel thirsty. Remarks related to the endotracheal tube, such as aspiration and extubation were reported by only 24.7% of the patients. Among patients with post-ICU memories, the incidence of psychological disorders was high, particularly those with PTSD symptoms (Table 1).
CONCLUSION. The presence of ICU memories may be an additional factor for the onset of PTSD symptoms, three months after discharge from the ICU. Early identification of patients at risk for PTSD after an ICU stay may improve the patients' long-term psychological outcomes.

Table 1 (abstract 000910). See text for description

	Total Outpatient Patients	No ICU Memory	With ICU Memories	p-value - ICU Memory x Psychological Disorder
n	843	383	460	
Any kind of psychological disorder	30.6%	36.0%	63.9%	p<0.001
Anxiety symptoms	24.4%	40.3%	59.7%	0.8819
Depression symptoms	19.0%	49.1%	50.9%	0.3030
PTSD symptoms	18.1%	11.1%	88.9%	p<0.001

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000915

INTRODUCTION. Early mortality and severity prognostication in the critically ill is a challenge in intensive care medicine. The conception of large, trial validated Scores, as the SAPS II or the SOFA Score, offered a tool to more efficiently tackle this task. Nevertheless, these Scores were not intended for individual patient assessment. It has been shown that MR-proADM on admission is a marker of poor outcome prediction in septic ICU patients [1]. However, there is no data regarding the use of MR-proADM in a general medical ICU population.
OBJECTIVES. To propose MR-proADM as an admission prognostic biomarker for ICU and 28-day mortality, as well as for therapy refractory multi-organ dysfunction during the course of the ICU stay.
METHODS. Between January 2018 and February 2019 all patients, aged ≥18 and with given consent, admitted to the Medical ICU of the University Hospital Zurich were prospectively included. Blood samples for MR-proADM testing were obtained and the standard monitoring and laboratory analytics recorded on the moment of admission, the next 7 consecutive days and on the day of ICU-discharge.
RESULTS. The studied population, comprising 475 patients, presented with an age of 63 [52-72] years, a SOFA Score of 7 [4–10], a SAPS II of 43 [30–58] and a Charlson Comorbidity Score of 3 [1–5] at admission. In ICU mortality was 17% and 28-day mortality 24%. Admission MR-proADM was 2.38 [1.34–5.17] nmol/l. MR-proADM was highest on ICU admission and decreased on average by 31% until discharge. Kinetics of MR-proADM were independent of age and sex. Patients with KDIGO stage ≥ 2 presented overall higher MR-proADM levels.
MR-proADM values at admission correlated with a higher ICU and 28-day mortality ($p < 0.0001$). The AUROC of admission MR-proADM (0.73) in its prediction of ICU mortality was comparable to those of the SAPS II (0.71) and SOFA Score (0.78) (both calculated for the initial 24h in ICU). Admission MR-proADM was more specific (Cut-Off: 5 nmol/l, LR+: 4.1) than SAPS II and SOFA regarding the prediction of persistence of multi-organ impairment (organ specific SOFA subscores > 2) after 7 days. The AUROCs for admission MR-proADM showed a good predictive capacity for death or continued ICU-stay (AUC: 0.72, Cut-off: 6 nmol/l, LR+: 3.2) and for status at home (AUC: 0.7, Cut-off: 1.3 nmol/l, LR+: 3.0) after 28 days. Daily measurement of MR-proADM during the subsequent ICU days did not improve the predictive power of admission MR-proADM, except MR-proADM levels at discharge, which presented an AUROC of 0.85 (Cut-Off: 4.9 nmol/l, LR+: 10.7) for the prediction of 28-day mortality.
CONCLUSION. We, for the first time, show that in a general medical ICU population, admission MR-proADM is a sensitive and specific prognostic marker for sustained ICU dependency by day 7 and 28-day mortality and hence a triage tool to identify those patients with prolonged ICU dependency and poor outcome.

Mortality review process in the intensive care unit (ICU): Are we learning from the past?

J. Macallan, A. Cavalier, M. Alice, T. Samuels, F. Lamb
[1]Critical care, East Surrey Hospital, Redhill, UK
Correspondence: J. Macallan
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000916

INTRODUCTION. Mortality review meetings are used in healthcare to review patient deaths and to allow learning from these cases. National guidance recommends that these meetings are multidisciplinary, held at least quarterly and provide non-judgemental discussion of events to allow improvements in care to be identified (1). Local guidance suggests that unexpected deaths should all be discussed in detail (2). Our ICU uses a dedicated, bespoke mortality database for review and presentation of these cases.
OBJECTIVES. To examine our current mortality review process using our database and to assess the recommendations produced by these cases.
METHODS. A retrospective search of cases entered into the mortality database of our ICU in a district general hospital in the UK. Cases were entered between January 2017 and March 2019. Recommendations from cases that have been presented were reviewed.
RESULTS. A total of 326 deaths were entered on to our mortality database. Cases were classified into five different categories based on whether the death was expected or not. This ranged from category 1 (anticipated due to terminal illness/ death pre-hospital arrival) to category 5 (unexpected resulting from medical intervention). 244 cases (74.8%) have been categorised, 25.2% cases are currently unclassified. Of the 326 cases entered, 202 (61.9%) have been presented at a mortality review meeting. The median number of days between death and presentation was 117 (IQR 77- 203). 77 out of 202 cases (38.1%) had recommendations for further action or suggestions for future management. 14 cases had more than one recommendation with a total of 94 recommendations made. These have been reviewed and grouped into themes (Table 1).
CONCLUSION. The largest category of recommendations is “feedback to another team”. Our tailored database facilitates this through recording documentation and providing a presentation that can be delivered independently. The database approach also enables us to easily identify which deaths are classified as unexpected so that these can be selectively reviewed in-depth and presented as per recommendations. Reviewing every death would represent a large additional workload. Currently a quarter of deaths have not been categorised and there is a considerable time lag in presenting several of the cases. Even with our database approach, we may still be missing important leaning points. Future work should focus on reducing the interval from death to presentation through regular meetings and finding out how other ICUs manage the workload of preparing cases for mortality review.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001176

INTRODUCTION. Obesity and overweight are associated with an increased risk of mortality in the general population, however, in some pathological processes such as respiratory distress syndrome (ARDS) have an unexpected behavior known as "obesity paradox".
OBJECTIVES. The objective of this study is to assess the relation between obesity and mortality in patients admitted to the ICU with diagnosis of sepsis.
METHODS. Prospective observational multicenter study. The incidence of obesity in septic patients admitted to the ICU during a period of five years and it relation to mortality was studied. Obesity was defined as an IBM ≥ 30 kg / m2. Multivariable logistic regression was used to evaluate the adjusted relationship between obesity and mortality. The levels are expressed in median and interquartile range (IQR)
RESULTS. Among 621 patients admitted in five different hospitals in Spain with the diagnosis of sepsis, 221 (35,6%) were considered obese. Mean age was 63,7±14,4 (61,78-65,6); 41,6% were men. The global mortality was 33% and 34,1% in the obesity group (ns). Mortality subgroup analysis by origin did not show significance differences between non-obese and obese patients respectively: surgical patients: 24% vs 26,3%; abdominal focus septic patients 24,2% vs 24,6% ; bacterial pneumonia 41,3% vs 45,3% severe pneumonia caused by H1N1 virus 32,3% vs 37,5%. Kaplan-Meier survival analysis showed no significant survival variations in septic patients with and without obesity . Also the ICU and hospital stay did not differ significantly. Severity scores (APACHE II, SAPS II, SOFA), biomarkers (MR-proADM, PCR, PCT and lactate), iron metabolism and immunity (lymphocytes subsets CD14+ and HLA-DR) did not differ significantly neither among septic group vs obesity group. In the survival subgroups in obese patients, the SOFA score was higher in the non survivor than in the survivors: 12 (5-11) vs 8 (5-11) ($p < 0.001$) and the Apache II score 27 (21- 35) vs 19 (12-25) ($p = 0.0001$). In the multivariate analysis (Cox proportional-hazards regression) the Apache II score at admission was statistically significant predictors for mortality in obese patients. Multivariate analysis showed that obesity was not significantly associated with an increase in mortality in septic patients.
CONCLUSION. Despite obesity is a common find in septic patients admitted to the ICU it does not related to an increase in mortality.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001177

INTRODUCTION. Due to its pleiotropic activities vitamin C combined to steroids has been recently proposed as a potential beneficial strategy in patients with septic shock. In 2017 we decided to introduce in our institutional protocol for management of septic shock the use of vitamin C in patients receiving low-dose steroids because poorly responsive to vasopressors. In this pre-post analysis, we

compared clinical outcome of septic shock patients treated and non-treated with vitamin C.
METHODS. Forty-one patients admitted to our ICU in 2017 and 2018 with septic shock and treated by low dose steroids (i.e. hydrocortisone, 240 mg/day) and vitamin C (1,5 g every 6 hours) were matched by a propensity score including age, SAPS II score and comorbidities with 41 control patients admitted to our ICU in 2015-2016 with septic shock and treated by low-dose steroids without vitamin C. 30-day and in-hospital mortality, length of vasoactive drug therapy and mechanical ventilation, and occurrence of renal failure requiring replacement therapy were used as clinical outcome for the comparison. P< 0,05 was used for clinical significance.
RESULTS. SAPS II score, age, comorbidities, source of infection and incidence of infection by multidrug resistant bacteria were similar in vitamin C treated (T) and in controls (NT). 30-day (46% T vs 49% NT) and in-Hospital (54% T and 61% NT) mortalities, duration of vasopressors (5±5 days T vs 5±4 days NT) and mechanical ventilation (6± 10 days T vs 8±9 days NT) were similar (p> 0,05) in the treated and in controls. A trend for reduction of renal replacement therapy were observed in treated patients (34%) compared to controls (46%).
CONCLUSION. In patients with septic shock treated with low-dose steroids, the addition of vitamin C seems to reduce the occurrence of renal failure without any significant improvement in survival rate and vasopressor time.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001181

INTRODUCTION. Different features of iron metabolism can affect bacterial growth and host response to infection. Important alterations have been described in severe viral infections.
OBJECTIVES. We studied the metabolism of iron in patients with severe sepsis from pulmonary origin due to influenza virus pneumonia admitted to the ICU.
METHODS. Prospective observational multicentre study. We recruited patients admitted consecutively to the ICU from five different hospitals in Spain with a diagnosis of severe sepsis due to influenza A and B virus pneumonia. Epidemiological data, immunological parameters, biomarkers levels (RCP, PCT, MR-proAdrenomedullin) and iron metabolism parameters were collected at admission. Data were compared with a control group (CG) of patients with pneumonia due to the different influenza viruses with less severity and who were not admitted to the ICU.
RESULTS. 156 patients were included: 95 patients suffered severe pneumonia caused by influenza virus (N1H1, N2H3 and B) and 61 patients were included in the control group (CG). The mortality of the group admitted to the ICU was 30.52% (29/95). Iron levels at ICU admission were 68 mcg / dl; similar values in both groups. Ferritin levels at admission were 194.8 ng / ml *versus* 95.4 ng / ml in the CG ($p = 0.0047$).
Regarding the different types of influenza, Ferritin levels were significantly higher in patients with pneumonia due to influenza A N1H1, both in the severe and those not admitted to the ICU: N1H1 648 ng / ml; N2H3 74.9 ng / ml; influenza B 64.25 ng / ml. In the survival subgroups Ferritin levels were higher in the non survivors than in the survivors in the total group and in the subtypes of influenza N1 H1 (2225 ng / ml vs 421 ng / ml) and influenza B (274 ng / ml vs 60 ng / ml).
The Area Under the ROC Curve (AUC) for severity prognostic (ICU admission) was 0.732 ($p < 0.0001$) for Ferritin levels in patients with influenza A N1H1, 0.561 for type A N2H3 and 0.509 for type B. The Area Under the ROC Curve (AUC) for mortality prognostic at admission was 0.786 ($p = 0.0001$) for Ferritin levels in patients with influenza A N1H1.
For ferritin levels of 830 ng / ml and above, there was an increase in mortality ($p < 0.0001$) in Kaplan-Meier survival curve. In multivariate analysis (Cox proportional-hazards regression), ferritin levels at admission were statistically significant predictors for mortalityin patients with influenza A N1H1v .
CONCLUSION. Ferritin levels at ICU admission help us to determine the unfavorable evolution in the Emergency Department and the risk of mortality in patients with pneumonia due to influenza A N1H1 virus but not for pneumonia due to other types of influenza viruses

INTRODUCTION. The analysis of lymphocyte subpopulations in BAL by flow cytometry has represented an important advance in the understanding of the physiopathology and in the diagnosis of certain pulmonary diseases. However, its usefulness for diagnosis and prognosis in mechanical ventilation (MV)critical septic patients has not been described.
OBJECTIVES. To study the lymphocyte populations in BAL in different types of critical septic patients admitted to the ICU with pulmonary infiltrate and to evaluate their diagnostic and prognostic usefulness.

METHODS. Observational and prospective study. We recruited mechanically ventilated patients admitted to the ICU with the diagnosis of sepsis with pulmonary infiltrate. Epidemiological data, APACHE II, SAPS II, SOFA, immunological parameters, biomarker levels in blood were collected at ICU admission. BAL bronchoscopy was performed for microbiologic and cellular study. Lymphocyte subpopulations in blood and BAL were studied by flow cytometry. The results were compared with a control group of patients with normal BAL. Multivariate logistic regression was used to evaluate the relationship between the immunophenotype and mortality.
RESULTS. 57 patients were analyzed: 43 mechanically ventilated patients and a control group of 14 without infectious disease (control group (CG)) . ICU mortality was 41,8%; mean age of 59.9 ± 13.24, with 55.8% of male patients, Apache II 18 ±7. Mechanically ventilated patients were classified according etiology: 21 bacterial pneumonia, 9 Influenza A N1H1, 3 fungal pneumonia and 9 Acute respiratory distress syndrome (ARDS) without pulmonary infection. The BAL immunophenotype of MV patients, showed a significant increase in B and NK lymphocytes and a decrease in double negative T lymphocytes (CD3+/CD4-/ CD8-) compared to the CG. In the analysis of mortality in the total group of patients in VM showed no significant differences in the CD4+T cells percentage and the CD4 / CD8 ratio. Nevertheless, In the bacterial pneumonia group, CD4+T cells percentage was significantly higher in the non-survivors (46% vs 18% p = 0.0284) and also the CD4 / CD8 ratio (1.2 vs 0.2 p = 0.0218). The Area Under the ROC Curve (AUC-ROC) for mortality prognostic was 0.778 (p = 0.0114) for CD4+ T cells percentage and 0.790 for the quotient CD4 / CD8. For CD4+ T cells levels equal to or greater than 36% and CD4 / CD8 ratios greater than 7 in BAL of patients with bacterial pneumonia, an increase in mortality (p <0.0001) was found in the Kaplan-Meier survival curve. The multivariate analysis (Cox proportional hazards regression), the percentage of CD4+ T cells in BAL was a statistically significant predictor for mortality similar to the Apache II score at admission in bacterial pneumonias in MV admitted to the ICU.
CONCLUSION. The appearance of NK, B lymphocytes and the disappearance of CD3+/CD4/CD8- (double negative) T cells in BAL of patients intubated with pulmonary infiltrate is suggestive of pulmonary infectious disease. The increase of CD4+ T cells and consequent increase of the CD4 / CD8 ratio in BAL in patients with bacterial pneumonia has a predictive value of poor prognosis.

INTRODUCTION. The early administration of sepsis bundles including appropriate antibiotics has been demonstrated to improve patient outcomes. However, there is a growing concern of the indiscriminate use of antibiotics and omission of microbiology investigations in patient management (1). Additionally, there is no recent description of the microbiology of sepsis on the wards or the real-life antibiotic choices used in sepsis in Wales.
OBJECTIVES. The primary objective of the study was to investigate antibiotic prescribing practices on general wards and emergency departments (ED) in at-risk population of patients in acute hospitals in Wales. Secondary objective was the evaluation of microbiology investigations of sepsis patients.
METHODS. Secondary analysis of patient episodes was performed on patient population recruited into three annual 24-hour point-prevalence studies on the general wards and ED across all Welsh acute hospitals in years 2016-2018. We recruited patients after written informed consent with a NEWS ^{3} 3 and proven or suspected infection documented in the clinical notes; methodology described in detail in our previous studies (2, 3). Data were collected on patient demographics; as well as radiological, laboratory and microbiology data within 48 hours of the study. For statistical analysis Mann-Whitney U and Chi-square tests were used as appropriate.
RESULTS. We screened 19,453 patients over the three 24 hours study periods and recruited 1252 patients who fulfilled the entry criteria. We had information about the antibiotics use for 1195 patients. 775 (64.9%) patients were treated with intravenous antibiotics. The antibiotics used were broad spectrum, with Piperacillin/Tazobactam being the most commonly used (40.5% of patients treated with Abx, 314/775). The vast majority of patients did not undergo microbiology investigations. Only in 33.65% (421/1252) of all recruited patients healthcare providers obtained blood cultures, in 25.64% (321/1252) urine cultures, in 8.63% (108/1252) sputum cultures, in 6.79% (85/1252) wound cultures and in 15.25% (191/1252) other cultures. Analysing only patients who received Abx we found that only 49.75% (300/603) had blood cultures, 13.81% (70/507) sputum cultures, 35.47% (210/592) urine cultures, 9.01% (53/588) wound cultures and 13.42% (104/775) other microbiology investigations. Out of the recruited patients 59.1% (740/1252) fulfilled SEPSIS-3 criteria. Patients with SEPSIS-3 criteria were significantly more likely to receive Abx than the non-septic cohort (p<0.0001). Nevertheless, 33.78% (250/740) of patients fulfilling SEPSIS-3 criteria did not receive any Abx. Patients who were screened for sepsis using an official tool were also significantly more likely to receive Abx in comparison to non-screened patients (p<0.0001) and to obtain blood cultures (p= 0.001) but no other microbiology investigations.
CONCLUSION. Our study shows that antibiotics prescription practice is not guided by microbiology investigations. Significant proportion of sepsis patients are still at risk of not receiving appropriate Abx treatment and microbiology investigations, which may be improved by more thorough implementation of sepsis screening tools.

INTRODUCTION. The early detection of sepsis (SE) and septic shock (SS) with automated electronic models (AEM) is a problem due to the high percentage of false positives (FP), which generates fatigability to clinicians (1).
OBJECTIVES. To compare an AEM published and commonly used in our Electronic Health Record (EHR) (2) with those generated from AI and ML techniques for the detection of SE/SS.
METHODS. Retrospective observational study comparing predictive models for the detection of SE/SS in patients of 14 years of age or more in all hospital areas (ED, wards and ICU). We value according to SEPSIS.2, because it was the definition used during the study period. The AEM is based on 15 clinical-analytical variables with different weights and a discrimination score that we usually use (2). In contrast to others based on ML techniques that used different structured and unstructured databases (free text) of the EHR. All cases were evaluated and validated prospectively by the Multidisciplinary Sepsis Unit. The Mann-Whitney-Wilcoxon test was used to identify statistically significant clinical and analytical variables, as well as wrapper techniques, with a significance level of 0.01. And to obtain relevant unstructured data Natural Language Processing (NLP) techniques such as the Dunning test were applied. The total sample was divided into 2 groups: the 5/7 proportion of the total of randomly selected records constituted the training set and the rest of the records (2/7) formed the test set.
RESULTS. From January 2014 to October 2018, we included 218,562 patients, mean age of 67.5 years and 57% males, where 9301 (4.6%) patients had SE/SS. The ML models included 244 structured and unstructured variables associated with SE/SS. We have identified 75 clinical and analytical variables in our ML models compared to 15 in the EAM (p<0.0,01). Interestingly, three variables normally associated with sepsis such as Glascow Coma Score (GCS), mean arterial blood pressure (MAP) and platelet count were not significantly related to SE / SS in ML predictive models. And neither the MAP nor the platelet numbers were significantly associated in the predictive model of the AEM, which does not include the GCS in its score. There were 28,294 patients with AEM alerts, where there were 62% of false positive (FP) cases and 12% of false negatives (FN). We have obtained 3 models with ML, being that the best (named BISEPRO) identified 11,2% FP and 0,9% FN cases compared to AEM (p=0,001 in both analyzes). The AUC-ROC, sensitivity and specificity to detect SE/SS of the best ML model was 0.95 (95% CI 0,94-0,96), 0,94, 083 compared to the AEM with 0.86 (95% CI 0,83-0,88), 0,78 and 0,68, respectively. But the three models of ML were significantly superior to that of the AEM both to detect SE / SS and with lower cases of FP and FN.
CONCLUSION. ML predictive models were significantly higher for SE/SS detection than traditional automated ones, lowering FP by more than 50%.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001201

INTRODUCTION. The Surviving Sepsis Campaign recommends targeting a mean arterial pressure (MAP) of at least 65 mm Hg during initial resuscitation of patients with septic shock. However, the impact of such MAP target on cerebral perfusion remains unknown.
OBJECTIVES. To assess the effects of changes in MAP on cerebral autoregulation (CAR) in critically ill septic patients.
METHODS. Prospective study of 32 patients with septic shock without intracranial disease; severe arrhythmias; treatment with extracorporeal membrane oxygenation; or supra-aortic arteriopathy. MAP was progressively increased at three levels: 70±5 mmHg (low-target group), 80 ±5 mmHg (middle-target group) and 90 ±5 mmHg (high-target group). Transcranial Doppler (DWL, Germany) was performed at each target group, insonating the left middle cerebral artery (LMCA) with a 2MHz probe. LMCA blood flow velocity (FV) and arterial blood pressure (BP) signals were simultaneously recorded for at least 6 minutes; Pearson´s correlation coefficient between BP and FV (MXa) was calculated using MATLAB (MathWorks, USA). Impaired CAR was defined as MXa > 0.3.
RESULTS. In the 32 patients (median age: 69 [60-78] years), actual MAP were 70 (range: 55-80), 78 (63-88) and 90 (80-103) mmHg in the low-, middle- and high-target group, respectively. At different time-points, mean MXa was 0.29 (±0.36), 0.27 (±0.34) and 0.20 (±0.32), respectively (p=0.55). In patients with intact CAR (n=17), increasing MAP resulted in a significant increase of MXa over time (ANOVA; p= 0.03), in particular from low- to middle-target levels (p=0.02). In patients with altered CAR (n=15), increasing MAP resulted in a significant decrease of MXa over time (p=0.003), in particular from low- to high-target levels (p=0.006).
CONCLUSION. Targeting higher MAP in septic shock patients can improve cerebral autoregulation when it is altered at baseline.

INTRODUCTION. Healthcare-acquired sepsis is known to be associated with higher mortality than community-acquired sepsis. More specifically, mortality associated with intensive care unit (ICU)-acquired sepsis is extremely high. However, little is known about patient characteristics, pathogens, treatments, and outcomes according to admission sources among patients with severe sepsis and septic shock in Japan.

OBJECTIVES. To describe characteristics and outcomes according to admission sources in patients with severe sepsis and septic shock in Japan.
METHODS. We included adult patients (≥16 years old) with severe sepsis and septic shock, based on the sepsis-2 criteria published in 2003,[1] who were admitted to the ICU in the Focused Outcomes Research in Emergency Care in Acute Respiratory Distress Syndrome, Sepsis, and Trauma (FORECAST) study [2]. It conducted at 59 ICUs in Japan from January 1, 2016 to March 31, 2017. Patients whose admission sources data was missing were excluded. We compared baseline and infection characteristics, treatments such as initial antibiotics, and outcomes among patients from different admission sources which were emergency departments (ED), inside ICUs, and wards.
RESULTS. Overall, 1182 patients were included in this study. There were 676 (57.2%), 49 (4.1%), and 457 (38.7%) patients admitted to the ICU from EDs, inside ICUs, and wards, respectively. The median [interquartile range (IQR)] age of patients in the EDs, inside ICUs, and wards was 75 [66–83], 69 [61–81], and 71 [61–79] years old, respectively ($p < 0.01$). There was no significant difference in gender, Charlson comorbidity index, having shock, APACHE II and SOFA scores according to admission sources. The most common infected sites were as follows: the lungs (33.4%), abdomen (23.4%), and urinary tract (21.7%) in patients from the ED; the abdomen (34.7%), lungs (20.4%), and skin and soft tissue (10.2%) in patients inside the ICUs; the abdomen (29.3%), lungs (28.7%), and urinary tract (14.9%) in patients from wards. Common pathogens obtained from the blood culture were: *E. coli* (30.8%), *Staphylococcus* species (MSSA or CNS) (17.2%), and *Klebsiella* (9.7%) in patients from EDs; *Klebsiella* (20.0%), *E.coli* (16.0%), and *Pseudomonas* (12.0%) in patients inside ICUs; and *E.coli* (18.4%), *Staphylococcus* species (12.4%), and *Klebsiella* (9.8%) in patients from wards. In opportunistic pathogen positivity of blood cultures, MRSA was 1.4%, 4.0% and 3.8% and *Pseudomonas* was 1.4%, 12.0% and 2.6% in patients from the ED, inside ICUs, and wards, respectively. In regard to initial antibiotic's selection, more than 70% patients were administered carbapenem or PIPC/TAZ and approximately 20% of patients were administered vancomycin as initial antibiotic regardless of admission sources.There was no significant difference in in-hospital mortality rates according to admission sources (22.1% from EDs, 35.6% inside ICUs, and 24.2% from wards, $p = 0.108$).
CONCLUSION. In this multicenter study in Japan, in-hospital mortality was not different according to admission sources. The initial antibiotic selection was similar irrespective of admission location although infection characteristics such as common pathogens were different according to admission locations.

Fulfillment of the Sepsis Resuscitation Bundle is associated with lower then expected mortality: experience of a chilean University Hospital

A. Hernández, D. Pérez, A. Gajardo, F. Cayupi, N. Medel, C. Luengo
[1]Critical care unit, department of medicine, University of Chile Clinical Hospital, Santiago, Chile
Correspondence: C. Luengo
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001213

INTRODUCTION. Sepsis and septic shock are related to high mortality. The Hospital Clínico Universidad de Chile applies the recommendations of the Chilean Society of Intensive Care Medicine which include the sepsis bundle proposed by the Survival Sepsis Campaign (SSC) in order to reduce morbidity and mortality in septic patients. However, the adherence to these recommendations including the SSC-bundle fulfillment and it's possible impact t is unknown.
OBJECTIVES. To assess the adherence to fulfill the SSC bundle and its impact on in-hospital mortality and length of stay (LOS) in Intensive Care Unit (ICU) in a cohort of ICU patients with severe sepsis or septic shock.
METHODS. Retrospective cohort study based on patients' records. All patients diagnosed with severe sepsis or septic shock, according to the 2001 International Sepsis Definitions Conference, and who entered the ICU at Hospital Clínico Universidad de Chile between January and December 2017 were included (n = 91). We assessed the fulfillment of the SSC bundle, compared expected versus (*vs*) actual mortality, according to the Acute Physiology And Chronic Health Evaluation II (APACHE II) and Sequential Organ Failure Assessment (SOFA) (at day 1) scores, and ICU LOS in patients who fulfilled it *vs* those who did not. Comparisons were performed using Fisher's exact test and Mann Whitney's U test. In addition, logistic and linear regression models were performed to evaluate the effect of bundle compliance on mortality and LOS adjusting by age, sex, SOFA score, and lactate levels.
RESULTS. Patients were 61.4 ± 16.4 years old (yo) (49.5% older than 65 yo), 57.1% were men; 40.7% sepsis were diagnosed at the emergency room, and abdominal and respiratory foci were the most frequent sepsis sources (41% and 32 %, respectively). APACHE II and SOFA scores were 19 [IQR 12-23], and 7 [IQR 5-10], respectively. Patients had at least 3 dysfunctions at admission, the most frequent being the cardiovascular one with vasopressors requirement in 82% of cases. The resuscitation bundle was fulfilled in 76% of cases. The least fulfilled step during the first 3 hours was the administration of 30ml/kg of crystalloids (63%). Assessment of potential further response to volume using pulse pressure variation or echocardiography was registered in 71% of cases during the 6 hours. In-hospital mortality was 23% and was higher in cases which did not fulfill the bundle (32% *vs* 15%, p-value= 0.047). Fulfillment of the sepsis bundle was significantly and independently associated with less mortality (OR= 0.25, p-value= 0.026). On the other hand, ICU LOS in survivors who fulfilled the bundle was 11 [IQR 5-16] days, while it was 19 [IQR 10-37] days in those who did not (p-value= 0.004), and it was independent of age, sex, SOFA and lactate levels (Beta= -16.8, p-value= 0.017).
CONCLUSION. Fulfillment of the sepsis bundle is high but still needs improvement. SSC-bundle fulfillment is associated with lower mortality and less ICU LOS independent of age, sex and severity scores.

INTRODUCTION. Levels of MR-proAdrenomedullin (MR-proADM) have been related to the diagnosis and mortality of septic patients associated with organ failure even at low SOFA scores, being more effective than other biomarkers
OBJECTIVES. To evaluate the usefulness of MR-proADM levels in the diagnosis and prognosis of sepsis in patients admitted to the ICU according to its focus of origin, etiology and severity.
METHODS. Prospective observational multicenter study. Patients with suspected sepsis were recruited to the ICU of six spanish hospitals. Epidemiological, clinical, laboratory data and MR-proADM, procalcitonin , and C reactive protein levels were collected at the time of admission, at 48 hours, at the 5th day and on the day of discharge from the ICU. Also the MR pro ADM clerance at 48 hours and at the 5th day were calculated. The results were compared by different foci of infection and germs. The results were compared with groups of patients with non-septic SIRS, critical cardiac patients and healthy volunteers. The levels are expressed in median and interquartile range (IQR)
RESULTS. A total of 606 patients were enrolled: 484 septic patients, 36 patients with SIRS without sepsis, 61 patients with infectious diseases not admitted to the ICU, 9 critical cardiac patients and 10 healthy volunteers. MR-proADM levels were in patients with sepsis 2,567 nmol/l, compared to patients with SIRS (1,373 nmol/l, p= 0.0061), to infectious patients not admitted to the ICU (0,034 p< 0,001), to critical cardiac patients (0.034 nmol/l p<0.001) and healthy volunteers (0.020 nmol/l;p <0.001). Regarding the distribution by source of focus: urological origin had higher levels of MR-proADM (5,147 nmol / l) compared to abdominal sepsis (3,307 nmol / l, p = 0.0195), and pulmonary sepsis (1.266 nmol / l, p <0.0001), even to bacterial pneumonias (2.3475 nmol / l; p <0.0001). According to the degree of SOFA the differences were significant: SOFA> 13 points were of 6.44 nmol / l for SOFA 7-12 points: 3.01 nmol / l and for SOFA < 6 points 1.84 nmol/l (p<0.0001). Depending on the type of germs, we found no significant differences except for viral sepsis (1.05 nmol / l), which were lower than gram + bacteria (2,568;p<0.05) gram- (3.13 nmol/l;p<0.05) fungi (2.95 nmol/l;p<0.05) and polymicrobial (3.01 nmol / l; p <0.05). The ROC-AUC to predict the mortality increase with the time of evolution 0.608 to the income, 0.724 to the 48 hours of income and 0.767 to the 5th day; similar improves for the biomarker clearance.The ROC-AUC comparison for germs are similar to both at admission and at 24 hours and in the 5th day except for influenza A N1H1 viruses (0.756 at admission and 0.782 at 48 hours). The AUC-ROC of the SOFA group <6 point was 0.654 vs 0.579 of the SOFA group>13 point. In multivariable model, MR-proADM levels at 48 hours and on day 5 and clearance on day 5 following admission were statistically significant predictive factors of mortality. The subgroup of severe pneumonias due to influenza A N1H1v since admission was statistically significant predictive mortality factor.
CONCLUSION. In clinical practice, high levels of MR-proADM help to diagnose organic failure secondary to sepsis and, after 48 hours of evolution, the prognosis of the risk of death with some differences depending on the foci of origin, germ and organic dysfunction severity.

INTRODUCTION. There has been adequate evidence based literature to suggest and conclude that high sugars portend a worse prognosis in subsets of sepsis and there have been a gamut of trials effectively backing up on the above statement. This communication deals in diabetic patients with sepsis with variable Glycosylated hemoglobin (Hba1c) levels and a focus on correlating their outcomes with the same.
OBJECTIVES. Objective:
To analyze outcomes of diabetic patients with elevated HBa1C levels with sepsis and to look for an association between the same.
Setting: Multidiscliplinary tertiary care medical surgical ICUs of two hospitals.
METHODS. Study Module:
Consecutive patients with diabetes and sepsis were admitted and analyzed with reference to demographics, Hba1C levels at baseline(< 7 versus>7), SOFA scores (<10 versus>10), Length of stay in days (LOS) and type of infections. Discharges from ICU/mortality were considered as end points. SPSS version 24 was used for statistical analysis.
RESULTS. Results:
Sixty eight patients were included (n=68, M:F- 44:24/Range-32 -80/ Mean-59.1±10.6).HBA1C levels were 8.5±1.24(Range-6.9-12).LOS was 6.78±4 days(Range-2-27).SOFA scores were 13.04±2.64(Range-8-18).In hospital mortality was n=26 (38.24%).Infections demonstrated were urinary tract infections-36.8% (n=25), Cutaneous infections- 26.5%(n= 18) ,Pneumonias 20.6%(n=14), Intrabdominal infections-7.4% (n=5) and Mucormycosis 8.8%(n=6).Chi square test was applied. The subset with a higher HBA1C value (>7) had a higher percentage mortality vis-à-vis the subset with lower HBA1C value (<7) [38% v/s30% respectively] the test did not achieve a statistical significance when subjected to analysis (p -0.85NS).A skewing of data with reference to higher clustering of HBA1C patients in higher cut off group was noted. SOFA scores were tested [>10 versus <10] for association with mortality across the subsets and there was no demonstrable statistical significance for the same (p-0.65NS).ROC curves were drawn and AUC for HBA1C levels and SOFA scores was 0.30 and 0.47 respectively for association with mortality.
CONCLUSION. Conclusion:
Our study demonstrates no significant statistical differences in patient outcomes for sepsis in diabetic cohorts based on poor remote glycemic control. This would probably translate into mortality in diabetic sepsis cohorts independent of remote glycemic control. However, we will require bigger numbers with HBA1C levels <7 for data to be more equitably comparable.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001248

INTRODUCTION. The red blood cell (RBC), an essential actor of the microcirculation, is exposed to various levels of shear stress (SS) in the blood flow and has the capacity to modify its shape to pass through capillaries. Two recent studies (1,2) performed on RBCs from healthy volunteers, showed that after prolonged physiological SS exposure (< 30 Pa during 300s) like in blood flow, RBC deformability was improved.
OBJECTIVES. We investigated the effect of preconditioning on the RBC deformability from septic patients.
METHODS. Blood samples from 20 healthy volunteers and 20 critically ill patients with sepsis were compared. RBC deformability was assessed by the elongation index (EI) via an ektacytometry (Laser-assisted Optical Rotational Red Cell Analyzer – LORRCA) for SS from 0.3 to 50 Pa. EI was defined as (A-B)/(A+B), where A is the length and B is the width of the RBC. A higher EI indicates greater RBC deformation.
To evaluate the effect of preconditioning on RBC deformability, we studied EI just after a constant physiologic SS of 5 Pa during 300 s. Data were reported in mean ± SD or median values with 25-

75thpercentiles and compared by Kruskall-Wallis test. The effect of preconditioning on EI was assessed by Wilcoxon test. Correlations were tested by Spearman test.
RESULTS. Compared to volunteers, septic patients were significantly older and had a high APACHE II score: 22 (15-24). As expected, they were also significantly more anemic and had a higher inflammatory syndrome than volunteers.
RBCs deformability was significantly altered in septic patients compared to healthy volunteers for all SS > 4.89 Pa. After preconditioning, only RBCs from healthy volunteers improved EI for low SS (0.3 to 3.07 Pa) as demonstrated in previous studies (1,2). Despite a large variability in the response, no significant effect of preconditioning was observed on EI for RBCs from septic patients for all SS. Only RBCs from septic patients showed an inverse significant correlation between EI before preconditioning and delta EI (EI after – EI before preconditioning); r = -0.65; p = 0.001 for SS 0.3, 0.48, 1.21 and 1.93 Pa.
CONCLUSION. The RBC deformability is significantly altered during sepsis. In contrast of RBCs from healthy volunteers, preconditioning with low SS, as observed in blood flow, did not improve the deformability. Nevertheless, the response was variable and was inversely correlated with the EI at baseline. Mechanisms of these alterations should be investigated.

INTRODUCTION. Sepsis is the main cause of death due to infection
OBJECTIVES. Aim of the study was to evaluate the impact of sepsis in critically ill patients' outcome in relation to site of sepsis acquisition (ICU vs non-ICU acquired)
METHODS. We retrospectively reviewed ICU admissions during 2018. We analyzed data from patients with sepsis either on admission or during ICU stay. Demographic data, site of infection, pathogen and ICU mortality were recorded. Data of 183 patients (64% men, of mean age 60± 18 years, with APACHE II score 20± 8) were available and were analyzed.
RESULTS. Fifty six patients (31%) had sepsis on admission. Twenty four of them had subsequent septic episode during ICU hospitalization and were excluded from analysis, and 32 patients comprised group A. Seventeen patients (9%) had ICU acquired infection (group B). Mortality of septic-patients was more than 2fold compared to patients never presenting sepsis. Nevertheless, ICU acquired sepsis presented a significant lower mortality compared to non-ICU acquired sepsis (18% vs 63%, p<0.001).
The respiratory system was the most frequent site of infection in group A (30%) while bacteremia was in group B. Sepsis was most frequently attributed to Gam negative microbes in both groups although at different rates (22% and 59%). *Klebsiella sp. and Acinetobacter sp.* were the main causative pathogen (29% and 24%) in group B.
Among the mortality-correlated risk factors examined (sex, comorbidity, medical history, APACHE II score) only age was statistically different between the groups (66±13 vs 56±21, P=0.04). Group's A mortality risk, compared to group-B remained much higher after age-adjustment (OR: 6.7 CI 95% 1.5-30, p:0.014)
Delayed admission of septic patients was recorded to be very frequent (more than 70% of non-ICU acquired sepsis patients were admitted more than 12 hours post sepsis onset). Since immediate treatment of these patients has a significant impact on outcome, the delayed admission could explain the different mortality. Nevertheless, further studies are needed to make concrete conclusions.
CONCLUSION. Forty percent of ICU patients presented at least one septic episode. Non-ICU acquired sepsis had a worse outcome compared to ICU acquired sepsis, possibly due to delayed ICU admission

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001292

INTRODUCTION. Sepsis, a syndrome of physiologic, pathologic, and biochemical abnormalities induced by infection, remains to be a significant health care issue associated with high mortality. Our understanding of the pathogenesis of sepsis is broader, however the function of some cellular elements that are an essential part of the innate immune line is still unknown. Unlike the alterations documented in neutrophils and lymphocytes during sepsis, the role played by monocytes is still unclear, especially if the absolute count is directly or inversely associated with the prognosis of these patients.
OBJECTIVES. To evaluate the association of monocytic counts with the severity and mortality in patients with septic shock at the intensive care unit (ICU) of a tertiary hospital Mexico City.
METHODS. Retrospective analysis during 6 months in 2018, collected patients with septic shock (Sepsis-3). Monocyte counts were categorized into <300 and >1000 cell/UL; 28-day mortality and organ dysfunction were defined as the primary endpoint and compared between the groups. Pearson´s correlation coefficient was used for statiscal test to evaluate the association of initial monocytes counts with severety. To determiny 28-day mortality risk, the odds ratio (OR) was calculated with 95% confidence intervals, and $p < 0.05$ was considered significant. The data are presented as absolute values and percentages. Treatment standardized protocols were followed for each patient.
RESULTS. We collected 48 patients (54.2% female), mean age was 48 ±17.3 years. The causes of septic shock were: medical 54.2%, surgical 43.8% and trauma 2%. Mean APACHE II and SOFA score were 17.8 ± 7.9 and 9.7 ± 4.9 respectively. The length of stay in ICU was 6.4 ± 5.8 days. Eleven patients (22.9%) died during the follow-up. Pearson´s correlation coefficient between initial monocytes counts and organ dysfunction was -0.094 (p=0.52), with determination coefficient of 0.9. Initial monocyte counts < 300 cells/uL showed highest risk of mortality at 28 days with OR 2.375 (95% IC 0.553 – 10.196, p=0.244), whereas patients group > 1000 cells/uL showed lower risk of mortality with OR 0.950 (95% IC 0.086 –10.499, p=0.966).
CONCLUSION. In our study monocyte count <300 cells/uL was associated with highest mortality and severity in patients with septic shock but without statistically significance contrary to international

literature. Additional studies are be needed to elucidate the potentially role of monocytes on prognosis septic shock.

The prognostic value of one hour bundle completion in septic shock patients in KOREA

WI. JEONG, SM. Ryoo, JS. Kim, WY. Kim
[1]Emergency medicine, University of Ulsan College of Medicine, Asan Medical Center, Seoul, Republic of Korea
Correspondence: W.I. JEONG
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001303

INTRODUCTION. Since 2018, Surviving sepsis campaign recommended 1 hour bundle therapy in septic shock patients. However the evidence of bundle therapy has not been established. The object of this study was to determine a prognostic value of 1 hour bundle completion in septic shock patients.
METHODS. This prospective, registry based, observational study was performed between January 2016 and December 2018. 1 hour bundle in septic shock was defined as a serum lactate measurement; obtain blood cultures; administration antibiotics and adequate fluid within 1 hour from emergency department admission. Eligible septic shock patients were included for analysis and we analyzed prognostic ability of all completion of 1 hour bundle and each of them. The primary outcome was 28-day mortality.
RESULTS. The study included 381 patients and overall 28-day mortality was 24.7%. Overall 1 hour bundle completion rate was 12.2% and each completion rate of serum lactate measurement; obtain blood cultures; administration antibiotics and adequate fluid were 85.0%, 72.5%, 18.8%, and 52.3% respectively. However, overall bundle completion as well as each bundle were not associated with 28-day mortality except adequate fluid administration (Odd ratio (OR) 0.67 [95% Confidential interval (CI) 0.30-1.50], OR 1.33 [95% CI 0.66-2.70], OR 1.50 [95% CI 0.85-2.64], OR 1.17 [95% CI 0.66-2.07], and OR 0.54 [95% CI 0.34-0.87], respectively). Multivariate logistic regression analysis shows that adequate fluid administration was an independent predictable factor in 28-day mortality (OR 0.50 [95% CI 0.29–0.84], p=0.009).
CONCLUSION. In this study, we found since septic shock is very complicated, most of 1 hour bundle completion were not associated with mortality. Although adequate fluid administration was associated with 28-day mortality, to generalize this result, we need multicenter interventional study with improving physician's compliance.

INTRODUCTION. Pneumonia due to gram negative multiresistant bacteria (GNMB) is an important problem in the intensive care unit. There are few studies evaluating the efficacy of aerosolized antibiotics.
OBJECTIVES. To compare whether combined intravenous and inhaled colistin administration is better than intravenous colistin alone in the treatment of respiratory infection by multiresistant microorganisms in critically ill patients.
METHODS. This study was observational and retrospective. Patients admitted to the ICU who received intravenous colistin, inhaled colistin or both, as a treatment for a respiratory infection due to multiresistant pathogens were analyzed in the period between January 2014 and January 2019. The primary outcome was the clinical response. Secondary outcomes included microbiological response, ICU and hospital mortality and side effects such as neurologic or renal failure. Chi-square, t-Student, Mann-Whitney and Kaplan-Meyer tests were used for the statistic analysis.
RESULTS. Total 107 patients were studied but only 90 with lung infection were included: 43 pneumonia, 47 tracheobronchitis). 53 patients received endovenous colistin, 24 received both endovenous and aerosolized colistin and 13 received aerosolized colistin and other endovenous antibiotic. Pseudomonas aeruginosa caused lung infection in 93% of patients. No differences between groups in age, sex, gravity, previous colonization, shock development or type of infection were found. Treatment related adverse events were reported in 21 patients. Main results are shown in the table.
CONCLUSION. In conclusion, additional aerosolized colistin did not show better outcomes in critically ill patients with lung infection caused by multiresistant microrganisms.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001758

INTRODUCTION. Dysregulated endothelial activation is the key mechanism in development of septic shock, resulting in an increased permeability and dysfunction of the endothelial barrier. Endoglin as a part of the transmembrane TGF-β receptor complex is located on the surface of endothelial cells. Its extracellular domain can be cleaved, leading to the production of soluble endoglin (sEng). sEng production seems to be forced by hypoxia/oxidative stress, and can be considered to be a marker of endothelial activation/dysfunction (1,2). Endoglin is also expressed on monocytes, where it has regulatory functions during the immune response (3).
OBJECTIVES. The aim of the study was to evaluate a kinetics of sEng plasma concentration in septic shock patients and determine whether sEng could be used as biomarker in prediction of mortality of sepsis and whether it correlates with other biomarkers and severity of septic shock.
METHODS. Patients admitted to the ICU with early septic shock were prospectively enrolled into the study. Plasma samples and clinical data were collected at admission (T1) and in subsequent six days (T2-T7). Soluble endoglin concentration was measured using Human Endoglin/CD105 Quantikine ELISA Kit (R&D systems). Obtained data were compared to 3-months mortality and Pearson coefficient was used for estimation statistical correlation of sEng with patient's age, sex, CRP and procalcitonin.
RESULTS. Recruited patients (n=24) were predominantly male (71.4 %) with median age 68.5 (53.5-73.0) years. All patients were mechanically ventilated and the average SOFA and APACHEII scores at admission were 11.5 (9.5-13.5) and 28.0 (26.5-35.5) respectively. 3-months mortality rate was 43.8 %. There were no statistical differences in the patients' past medical history, chronic medication or sepsis severity at the time of admission between survivors and non-survivors. Median sEng concentration at admission was significantly higher (p=0.004) in deceased patients 5.18 (3.78-10.21) µg/l compared to survivors 3.24 (2.92-3.66) µg/l. There was no statistical correlation between sEng and age, APACHEII, CRP or PCT. Regarding 7-day trend, there were no changes in sEng levels in the group of surviving patients, but sEng levels were consistently elevated in the group of deceased patients with a slight drop observed on the 6-7th day. Data are provided as median (IQR).
CONCLUSION. Our pilot data suggests that soluble endoglin has a good predictive power in prediction of mortality in septic shock patients. Markedly higher levels of sEng in the group of deceased patients over the entire seven-day follow-up period might reflect a high degree of sEng production and therefore a high degree of endothelial dysfunction. Results needs to be verified in the bigger cohort of septic patients. Whether sEng could also differentiate between infectious (sepsis) and non-infectious etiology (SIRS) of shock or what is its specific function in endothelial dysfunction or host-response reaction in sepsis remains to be elucidated.

The Role of the Spirituality of Intensive Care Unit Patient's Relatives and their Satisfaction with ICU Professionals' Communication

P. Stamou[1], M. Gouva[2], M. Christaki[1], V. Koulouras[1], G. Papathanakos[1]
[1]Intensive care unit, University Hospital of Ioannina, Ioannina, Greece; [2]Department of nursing, research laboratory psychology of patients families and health profession, University of Ioannina, Ioannina, Greece
Correspondence: G. Papathanakos
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000072

INTRODUCTION. Spirituality substantially influences coping strategies of family members of patients hospitalized in an Intensive Care Unit (ICU). Spirituality might also influence the communication between family members and ICU physicians and nurses.
OBJECTIVES. To explore the effect of spirituality of critically ill patient's family members on their satisfaction during communication with ICU health professionals.
METHODS. The research was conducted from March 2018 to March 2019. Family members (first degree relatives, close relatives and intimate friends) of patients hospitalized in a University ICU constituted our research material. A questionnaire for sociodemographic data and the Spiritual and Religious Attitudes in Dealing with Illness (SpREUK) Scale was completed by family members during the first week after their beloved one's ICU admission. One way ANOVA and MANCOVA was used for statistical analysis.
RESULTS. One hundred and three family members mean-aged 45.92±11.43 years corresponded to 86 ICU patients responded to the Study. Forty-four of them were men (42.7%) and 59 women (57.3%), Most of them were children (48.5%) and the remaining family members were patients' companions (23.3%), siblings (7.8%), parents (7.7%) or other relatives (12.7%). Spirituality was found to positively increase the satisfaction of family members (F=3.632, p=.009). General linear model analysis found strong association between "Trust in

Higher Guidance/Source" (SpREUK) and feelings of information completeness (p=.034), openness and honesty of information (p=.020), understanding of the information (p=.010) and ease of accessing information (p=.010) among family members during their communication with ICU physicians and nurses. Data analysis did not show any significant difference in spirituality of family members based on sex, marital status and place of residence except for the educational level of relatives with the SpREUK subscale "reflection" (p=.001); the higher the educational level the higher was the score in "reflection" subscale while the most prominent differences were found between 'high school' and 'postgraduate' family members (p=.041).

CONCLUSION. Critically ill patients' relatives are more satisfied with their communication with ICU health professionals when they have higher levels of spirituality and they believe in something "higher" to overcome the difficulties.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000131

INTRODUCTION. Simultaneous pancreas and kidney transplantation (SPK) has been established as the treatment of choice for type 1 diabetic patients with end-stage nephropathy, leading to marked improvement in cardiovascular function and long-term survival. Adequate fluid therapy is essential to maintain intravascular volume and to obtain appropriate graft perfusion. Hypovolemia can result in further organ injury or thrombosis. Furthermore, excessive volume infusion with hemodilution and tissue edema, increases oxygen diffusion distance and impairs graft perfusion.

METHODS. Retrospective study of patients admitted for SPK during 2018 in an Intensive Care Unit (ICU) in a Transplant Reference Center. Fluid management was implemented according to protocol (urine-output per hour plus 200mL for two days). Doppler ultrasound was done on the first post-operative day and when clinically relevant. All patients received 100mg aspirin pre and post-transplant associated with low-molecular weight heparin. Immunosuppression induction and maintenance included thymoglobulin, methylprednisolone, tacrolimus and mycophelonate mofetil. Daily fluid balance, serum urea, creatinine and C peptide were recorded every day during the first 4 days post-SPK. Fluid balance was defined as primary exposition and pancreatic thrombosis as primary outcome.

RESULTS. Nineteen caucasian patients (63% male) were admitted. Fourteen were under pre-transplant dialysis for more than 1 year. One needed plasmapheresis before SPK. Pancreatic graft thrombosis happened in 5 patients (26%) between the 2-6 days of ICU. No positive differences were found in both groups according to donor's age or past history of thrombosis. No relevant differences were found in fluid balance on the first three days pos-SPK transplant in both groups. Fourth day fluid balance was significantly lower in the group of pancreatic thrombosis (-1,20L *vs* +0,03L, $p < 0,05$). The percentage of patients who needed vasopressor support during surgery was higher in the thrombotic group (80% *vs* 35,7%,$p = 0,14$). Time-to-event analysis (Cox regression) with Kaplan-Meyer curves adapted for vasopressor support revealed a 30 day pancreatic graft survival worse for those who needed perioperative vasopressor (56% *vs* 90%, $p = 0,11$). Hospital mortality rate of 10,5%.

CONCLUSION. SPK survival can be influenced by multifactorial variables where fluid balance is one of them. Nevertheless, optimal fluid management remains a challenge for both peri and post-operative periods. The use of minimal invasive hemodynamic devices with patient-centered targets may play an important role in best understanding flow parameters in this specific group of patients with impaired cardiovascular physiology and reduced hemodynamic autoregulation. Avoiding excessive fluid resuscitation and its consequences as well as hypovolemia may be helpful in increasing graft survival and patient outcomes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000187

INTRODUCTION. Elderly patients have a high in hospital mortality1. Physicians may support patients and families in the decision making process by providing information2.

OBJECTIVES. We aimed to characterize the patients admitted via the emergency department to medical and neurologic intensive care units and analyze in hospital mortality and transition to palliative care

METHODS. We conducted a retrospective study of patients ≥80 years who were admitted in 2016 and 2017 via the emergency department to a medical or neurointensive care unit. The electronic medical record of each patient was studied to extract data regarding the therapies, outcomes and the decision making process.

RESULTS. During the two- year period 248 (114 male, 134 female) patients ≥80 years were admitted from the emergency department to our ICUs. Mean age was 85,27 (±3,61; range 80,1-96,78) years, mean length of stay was 11,9 (±18,5; range 0-202) days.

In 66 (26,6%) patients, therapy was transitioned to palliative care, 68 (27,4%) patients died in hospital and 83 (33,5%) patients either died or therapy was changed to palliative care.

Frequent primary diagnosis include stroke/ICB, infection, cardiac disease, trauma, renal disease/electrolyte disorders and GI-Bleed.

113 patients required mechanical ventilation (92 patients invasive ventilation, 21 patients non invasive ventilation), 73 patients received catecholamines.

Patients requiring mechanical ventilation had a higher rate of the combined result of in hospital death or transition to palliative care

(50,4%) than patients without mechanical ventilation (19,3%) (OR 4,27, 95%CI 2,43-7,51; p < 0,0001).
In the subgroup of patients treated with invasive ventilation the rate of in hospital death was 53,3%.
In 51 of the 68 patients (75%) that eventually died therapy was changed to palliative care.
The differences in age between survivors (mean 85,3 ±3,4 years, median 84,5 years) and non survivors (mean 85,2 ±3,2 years, median 84,8 years) were not significant (p=0,7642).
CONCLUSION. Patients ≥ 80 years admitted to the ICU had a high rate of death or transition to palliative care. The high rate of transition to palliative care in the non- survivors underlines the importance of support in the decision making process in order to prevent futile treatments. In this group of patients ≥80 years we did not find a significant age difference between survivors and non survivors.

Critical care in the elderly: A survey of attitudes and knowledge

B. Narayan[1], T. Samuels[2], M. Alice[2]
[1]ICU, Salford Royal NHS Foundation Trust, Manchester, UK; [2]Critical care, East Surrey Hospital, Redhill , UK
Correspondence: B. Narayan
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000370

INTRODUCTION. A 2009 review conducted by the UK Centre for Policy on Ageing found evidence of ageist attitudes among hospital staff and suggested that doctors may be more ageist than other healthcare professionals. The authors emphasised the need to study this in more detail.
The incidence of frailty and chronic illness increase with increasing age yet are not always present so should not be assumed to co-exist. In 2017, 18.2% of the population were aged 65 or older, compared to 10.6 % in 1948, when the NHS was created.
OBJECTIVES. To explore attitudes regarding age within our own multi-disciplinary team.
METHODS. A survey was distributed to healthcare professionals: acute internal medicine (AIM) physicians (n=14); intensive care doctors (n=8), and ICU nurses (n=9). Responses were anonymous and without conferring or using additional information. Of the 8 multiple-choice questions, three tested knowledge and two specifically asked whether the respondent felt doctors (physicians and intensivists) had an ageist attitude when making decisions about critical care referral/admission. Options were "Never", "Occasionally", "Sometimes", "Often" and "Always".
RESULTS. Regarding escalation and/or setting ceilings of treatment in elderly patients, **only half of doctors** (43% of AIM, 50% of intensivists), compared with a **majority of ICU nurses** (89%) **were happy with decision-making** in their workplace. A minority of AIM (36%) and intensivists (38%) but a **majority of nurses** (78%) felt it was **sometimes acceptable to use age as the main factor** in deciding whether or not a patient's treatment should be escalated. Regarding knowledge-based questions, **intensivists gave reasonably accurate answers regarding ICU mortality in the elderly and the average age of patients admitted to ICU**. The **majority of AIM over-estimated both mortality and average age**. All groups significantly **underestimated average life expectancy** in the elderly population. Both physician groups viewed both AIM and intensivists as having an ageist attitude at least some of the time, but using bootstrapping methods (10,000 replications), the difference between the opinions of the ICU and AIM doctors was not statistically significant (p = 0.1969).
CONCLUSION. There is significant dissatisfaction amongst both acute physicians and intensivists regarding escalation of treatment decision-making in elderly patients. ICU nurses are more satisfied, and are much more likely to accept the use of age as the main factor when decisions are made. Both doctor groups viewed both AIM and intensivists as having an ageist attitude at least some of the time, but this difference in opinion was not statistically significant. Intensivists had better awareness about ICU mortality and average patient age, but all groups significantly underestimated life expectancy in the elderly. A larger multicentre study would be useful to further explore these findings, and more training and education is needed to address the issues raised.

INTRODUCTION. For many years there has been a reluctance to admit cancer patients to the ICU. However, whether ICU clinicians tend to discriminate cancer patients is unknown.
OBJECTIVES. The aim of this study was to compare the time until treatment limitation decisions (TLDs) and death, and the one year outcomes in patients with and without concordant perceptions of excessive care (PECs) by two or more ICU clinicians in the following subgroups : uncontrolled and controlled cancer vs. patients without cancer.
METHODS. Subanalysis of the DISPROPRICUS study performed in 68 ICUs in 12 European countries and the USA between 2014 and 2015 [1]. Clinicians (nurses and physicians) completed daily a questionnaire about the appropriateness of care for each of their patients during a 28 day period. We compared the cumulative incidence of patients with concordant PECs, TLDs and death, and the proportion of patients attaining the combined endpoint (death, poor quality of life or not being at home) at one year across subgroups via Cox-regression (accounting for competing risk) and Fisher-exact tests, respectively. To adjust for country, ICU and patients characteristics we used inverse probability weighting based on propensity scores. Results are presented as weighed % and hazard ratios (HR)

with their 95% confidence intervals (CI). The subgroup of patients without cancer was used as reference category.
RESULTS. Of the 1641 patients not admitted for monitoring only during the study period, 117 (7.1%) had uncontrolled cancer and 270 (16.4%) had controlled cancer. Of the 2690 participating clinicians, 2293 (85.2%) provided 25025 perceptions of appropriateness of care, of which 2279 (9.1%) PECs by 728 (27.0%) clinicians in 334 (20.3%) patients. The cumulative incidence of concordant PECs in patients with uncontrolled and controlled cancer vs. patients without cancer was 20.4%, 9.2% and 8.9% (p=0.005 and 0.85, respectively). In patients with concordant PECs, we found no evidence for a difference in time from concordant PECs until death (HR 0.99, 95%CI 0.59-1.65 and 0.90, 95%CI 0.50-1.62) and TLDs (HR 0.93, 95%CI 0.36-2.40 and 0.68, 95%CI 0.24-1.89) across subgroups. In this group, the risk of reaching the combined endpoint at one year was 93.7% and 82.5% vs. 93.4% (p=0.99 and p<0.001). In patients without concordant PECs, we found evidence for a difference in time from admission until death (HR 2.23, 95%CI 1.58-3.15 and 1.66, 95%CI 1.28-2.15) whereas the time from admission until TLDs was statistically non-significant (NA, p=0.3 and 0.7) across subgroups. In this group, the risk of reaching the combined endpoint at one year in patients with uncontrolled and controlled cancer vs. patients without cancer was 70.8% and 63.0% vs. 54.5%,respectively (p=0.003 and p=0.02).
CONCLUSION. The absence of evidence of a higher risk of TLDs and death in patients with concordant PECs makes discrimination of cancer patients by ICU clinicians unlikely. However, relative to patients without cancer, our results suggest prognostic pessimism in ICU clinicians who provided PECs in patients with controlled cancer and prognostic optimism or ignorance in ICU clinicians who did not provide PECs in patients with uncontrolled cancer, respectively. This study highlights the need to improve intra-and interdisciplinary ethical reflection and subsequent decision-making in the ICU [1].

INTRODUCTION. The increasing number of older patients admitted to the ICU with multiple comorbidities and frailty is often at the center of debate in daily practice. However, whether ICU clinicians tend to discriminate elderly patients is unknown.
OBJECTIVES. The aim of this study was to compare the time until treatment limitation decisions (TLDs) and death, and one year outcomes in patients < and ≥75 year with and without concordant perceptions of excessive care (PECs) by two or more ICU clinicians.
METHODS. Subanalysis of the DISPROPRICUS study performed in 68 ICUs in 12 European countries and the USA between 2014 and 2015 [1]. Clinicians (nurses and physicians) completed daily a questionnaire about the appropriateness of care for each of their patients during a 28 day period. We compared the cumulative incidence of patients with concordant PECs, TLDs and death, and the proportion of patients attaining the combined endpoint (death, poor quality of life or not being at home) at one year across subgroups via Cox-regression (accounting for competing risk) and Fisher-exact tests, respectively. To adjust for differences in country, ICU and patient characteristics, we used inverse probability weighting based on propensity scores. Results are presented as weighed % and hazard ratios (HR) with their 95% confidence intervals (CI).
RESULTS. Of 1641 patients not admitted for monitoring only during the study period, 405 (25%) were ≥75 years. Of the 2690 participating clinicians, 2293 (85.2%) provided 25025 perceptions of appropriateness of care, of which 2279 (9.1%) PECs by 728 (27.0%) clinicians in 334 (20.3%) patients. The cumulative incidence of patients with concordant PECs was significantly higher in patients ≥75 years than in patients < 75 years (13.6 % vs. 8.5 %, p-value = 0.01). In patients with concordant PECs, we found no evidence for a difference in time from concordant PECs until death (HR 1.08, 95%CI 0.73-1.61) and TLDs (HR 0.98, 95%CI 0.51-1.91) between older and younger patients. We neither found evidence for a difference in risk of reaching the combined endpoint at one year in this group between older and younger patients (90.4% vs. 93%, p= 0.54). In patients without concordant PECs, we found evidence for a difference in risk of death (HR 1.38, 95%CI 1.11-1.73) and TLDs (HR 2.11, 95%CI 1.37-3.27), though half of the TLDs were installed already before ICU admission. The risk of reaching the combined endpoint was also significantly higher in older compared to younger patients (62.1% vs. 52.8%, p<0.001).
CONCLUSION. The absence of a higher risk of TLDs, death and one year outcomes in patients with concordant PECs makes discrimination of older patients by ICU clinicians unlikely. The poorer one year outcomes in older patients without concordant PECs after weighing for confounders confirms that age need to be taken into account during ethical decision-making.

INTRODUCTION. Objectives: To evaluate among ICU patients that evolved to death those with an indication of performing and applying end-of-life decisions and palliative care (EL-PC); and to

analyse the application of items of PC, either 'unperformed items' or items of 'futile/unnecessary treatment'.
METHODS. Observational prospective cohort in five ICUs. Patients who evolved to death were evaluated searching for indication of EL-PC. The correct application of nine preselected items was studied.
RESULTS. Among 253 admissions, 52 patients died; and among these, 38.5% met criteria for EL-PC. Among PC candidates (n = 20), the PC was started later (after day 3) in 60%, and only 3 patients received adequate palliative care. 'Analgesia' and 'Daily family interviews' were the most correctly applied PC items. 'Terminal extubation/weaning' was not performed in any of the patients. A reduction in the interval from the onset of PC to death was observed in patients who underwent 'correct' interventions—66.6% died on the first day of PC.
CONCLUSION. In a low/medium-income country, one-third of patients who died in the ICU had indications for EL-PC; however, the PC was adequately performed for only 15% of the candidates, with great heterogeneity and delays in regards to its initiation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000578

INTRODUCTION. The decision-making process regarding end of life treatment is complex and challenging. Several authors report a substantial variability in this process among intensivists 1-3.
OBJECTIVES. The primary aim of this qualitative study was to investigate Swedish intensivists' perceptions and attitudes towards withdrawing or withholding life sustaining treatments. The secondary aim was to identify underlying factors that may contribute to inherent biases in the decision-making process.
METHODS. This is a descriptive study with qualitative approach. Semi-structured interviews was chosen as method for the study. The interviews were recorded and transcribed verbatim. All the data was categorized into thematic patterns as the primary basis for organizing findings and data coding was used. A two-step process, beginning with basic coding in order to distinguish overall themes, which was followed by a more in depth, interpretive code in which more specific trends and patterns were interpreted.
RESULTS. Nineteen semi-structured interviews with intensivists with different experience, education, age and gender, from five different hospitals were performed. The main finding of this study is that there is an unchallenged, accepted variability in end of life decision making among Swedish intensivists. The contributory factors to this variability are personality of the intensivist, lack of continuity among senior intensivists, disagreements with physicians from other specialties, lack of competence during on call hours, and concerns of criticisms for making questionable decisions. Few of the respondents had any formal education on how to approach end of life decisions and it was generally not demanded. All of the respondents knew about existing on-line guidelines, but few used them in daily clinical practice.
CONCLUSION. There are significant variabilities in the decision-making on withdrawing or withholding life sustaining treatments on the intensive care units. We propose a more structured approach, formal education and routine adherence to clinical guidelines in order to improve the management of this group of complex patients.

Learning from stakeholders to inform good practice guidance on consent to research in intensive care units: mixed methods study

K. Paddock[1], L. Frith[1], C. Gamble[2], I. Welters[3], K. Woolfall[1], B. Young[1]
[1]Health services research, University of Liverpool, Liverpool, UK; [2]Biostatistics, University of Liverpool, Liverpool, UK; [3]Critical care, Royal Liverpool and Broadgreen University Hospitals NHS Trust, Liverpool, UK
Correspondence: K. Paddock
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000610

INTRODUCTION. Alternatives to prospective consent by patients are necessary for conducting clinical research with critically ill patients. It is important that such consent practices align with the perspectives of key stakeholder groups - patients, relatives and clinical practitioners.
OBJECTIVES. To determine the perspectives of different stakeholder groups towards current consent practices for research with critically ill patients, with the overall objective of informing good practice guidance on consent to intensive care unit (ICU) studies.
METHODS. Mixed methods study comprising surveys and in-depth interviews in 14 English ICUs.
RESULTS. 1409 surveys were included (ICU patients n=333, relatives n=488, practitioners n=588) and 58 stakeholders were interviewed. Survey responses indicated that most stakeholders agreed it was acceptable for relatives to decide about research participation on behalf of incapacitated patients, although the proportion of patients who agreed (68%) was lower than relatives (83%) or practitioners (76%). The practice of doctors consenting to research on behalf of incapacitated patients was supported by most stakeholders in situations where there were no known relatives (patients 60%, relatives, 63% practitioners 63%) or if time was too short to contact relatives (patients 57%, relatives, 51%, practitioners 53%). Most patients (55%) and relatives (52%) also supported consent by doctors when relatives were unavailable, but only 45% of practitioners supported this. Practitioner experience of research influenced their views on

consent by doctors – those who had a research role were more accepting of this practice than practitioners with no research role. In all three stakeholder groups approximately 25% of members disagreed with doctor consent for ICU studies whatever the situation. However, interviews indicated that stakeholders were more flexible towards doctors consenting on behalf of incapacitated patients than their survey responses suggested, with the views of most patients and relatives, and some practitioners shifting markedly depending on particularities of the study and situation.

CONCLUSION. Stakeholder support for current ICU research consent practices that involve relatives in decisions was generally high. In situations where involving relatives was not possible, most stakeholders also supported consent by doctors, although a sizable minority disagreed with this consent practice. When interviewed, stakeholders were rarely fixed in their views, with many willing to countenance a range of consent practices depending on their perceptions of what the research involved and provided safeguards were in place. Findings point to the importance of explaining clearly why alternative consent practices are used in ICU studies and what safeguards are in place.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000619

INTRODUCTION. Stagnation in the number of donors after brain death (BD) requires strategies to increase the pool of donors to meet expanding waiting lists. Intensive care to facilitate organ donation (ICOD) has been defined as the initiation/continuation of intensive care measures in patients with a devastating brain injury (DBI) in whom treatment for curative purposes is deemed futile, and who are considered possible organ donors, with the aim of offering donation after brain death (DBD) inside their end-of-life care plans [1].

OBJECTIVES. We describe the impact on the donation activity in Vall d'Hebron University Hospital, Barcelona, following introduction of a new strategy promoting the referral of possible donors from outside the ICU to consider ICOD over a 4-year period.

METHODS. Retrospective analysis (2015-2018) of all patients located outside the ICU with a DBI referred to the donor coordination (DC) to be considered for ICOD. Once the DC evaluated the medical suitability and likelihood of progression to brain death (BD), families were approached to discuss the option of donation. If favourable, further evaluation and maintanance was performed in the ICU until BD ensued, leading to donation in elegible cases. In those cases where BD did not occur, life-sustaining therapies were withdrawn and the option of controlled donation after circulatory death (cDCD) was offered to the family.

RESULTS. Of the 983 possible donors evaluated during the study period, ICOD was considered in 206 (21%), of whom 115 (55.8%) were medically unsuitable for donation. Family consent was obtained for 69 (76%) of the remaining patients. Refusal rate was twice as high when non-therapeutic ventilation was required for organ donation (34%) compared to those patients previously ventilated (13.6%) (p =0.02). Patients subject to ICOD died in a median of 2 days [1 – 3] and 88.4% became actual donors (AD) (39 after BD/22 after circulatory death). Nine (17.6%) donors were finally not utilized. ICOD contributed to 27% of the 195 utilized donors and 26% of the 603 organs transplanted. Over the 4 years analyzed, ICOD was responsible for a progressively greater percecentage of AD ranging from 27.7% in 2015 to 31.6% in 2018.

CONCLUSION. ICOD has proved to be a procedure well-accepted by families, which facilitated the offer of donation in end-of-life care to an increasing number of patients at our hospital. It also provided, with a short ICU stay, an important and sustained increment of the organ pool for transplantation.

INTRODUCTION. More than 70 % of ICU deaths occur after an End-Of-Life (EOL) decision consisting in withholding or withdrawing of life-sustaining therapy (LST). EOL decision-making varies greatly within Europe. Switzerland is separated into distinct cultural regions defined by languages related to the neighboring countries. The three linguistic regions are the French (FR), the German (GR) and the Italian speaking region.

OBJECTIVES. To determine the differences in EOL decisions between the FR and GR, and their influence on ICU and hospital length-of-stay (LOS) and mortality. As secondary objectives, we evaluated whether the type and timing of EOL decision had an influence on outcome issues.

METHODS. Patients admitted to ICU and who had treatment limitations over a 6 month period were included as part of the ETHICUS 2 study. Seven Swiss ICUs (3 in FR, 4 in GR) allowed us to compare two cultural regions. Patients were followed from admission until discharge from the ICU, death, or 2 months after the decision to limit the therapy.

RESULTS. Results of 1'115 patients are summarized in Table 1. ICU and hospital mortality differed significantly between FR and GR (33 vs 63 %, $p < 0.0001$, 48 vs 75 %, $p < 0.0001$ respectively), whereas mortality after ICU was similar in both groups. ICU LOS was similar in both groups. Post-ICU LOS was longer in FR and EOL decisions were made earlier in FR. Time from decision to death was considerably longer in FR than in GR. FR took decisions in multiple steps

compared to GR (40 vs 24 %, p < 0.013), and GR withdrew LST as a single decision that impacted shortly on survival.
CONCLUSION. Mortality was significantly higher in GR. EOL decisions were made later in GR ICUs but with more withdrawals that were associated with more deaths. ICU LOS was similar in both regions but hospital LOS after ICU and total hospital LOS was significantly shorter in GR. Depending on the way EOL decision is made, the hospital LOS and the outcome may be impacted.

INTRODUCTION. Many ICU patients receive end-of-life care. There is a lack of knowledge about current end-of-life practices in Germany.
OBJECTIVES. This study presents data from the subset of German ICUs which participated in the worldwide Ethicus-2 study on ICU end-of-life care practices (EOLP) in ICUs.
METHODS. Observational study of consecutive ICU patients with end-of-life care, defined as patients who died and/or had end-of-life decisions (EOLD) during a 6-months period.
RESULTS. Eleven German ICUs participated, 9 were mixed medical/surgical, 1 medical and 1 neurosurgical, 9 centers were in academic hospitals. A total of 1092 patients were included, representing 13,7 % of all admitted ICU patients. Median age was 72 (IQR 60-80) years, 647 (59.2%) patients were male. Patients had a median ICU and hospital length of stay of 4 (IQR 1-11) days and 10 (IQR 4-22) days, respectively. Patients with EOLD had longer median ICU and hospital stays (4 days (IQR 1-12) and 11 days (IQR 4-23), respectively) than patients without EOLD 2 (IQR 0-6) days and 5 (IQR 1-11) days respectively, both p≤ .0001). Most frequent admission diagnoses were respiratory disease (37%), surgery (35.6%) and neurological disease (23.6%). Among all patients, 270 (26.9% of all) had an advance directive, 440 (43,7%) had legal patient representatives and 126 (11.7%) of patients were mentally competent at the time of EOLD decision-making.
Among all patients, 967 (89%) had limitations of life-sustaining therapy: 555 (57%) decisions to withdraw (WD), 411 (43%) decisions to withhold (WH) and one patient with active shortening of the dying process (SDP) (0.1%). Among 125 patients without therapy limitations, 33 (26%) experienced brain death (BD) and 92 (73%) received full cardiopulmonary resuscitation (CPR). Overall, 941 (86%) of patients died in the hospital, among these 125 (13%) without and 816 (87%) with therapy limitations. In median, the time interval between ICU admission and first EOLD was 2 (IQR 0-8) days and between the first EOLD and death 1 (IQR 0-3) days.
EOLD were commonly initiated by physicians (80.4%) but rarely by nurses (0.1%). The primary reason for EOLD were unresponsiveness to maximal therapy (35%), neurologic reasons (18%) or patient preference (15%). Old age (0.4%) or poor quality of life (4%) were rarely primary reasons.
CONCLUSION. End-of-life decisions occurred for nine out of ten patients with end-of-life care. The final EOLD was more often to withdraw than to withhold life sustaining therapy. The fact that nurses almost never initiate EOL decisions suggests that nurses lack opportunity or motivation to make meaningful and specific contributions in the EOLD process. In a third of patients with EOLD, the primary reason was unresponsiveness to maximal therapy. Age was almost never the main reason for EOLD.

Unexpected needs for follow-up bereavement care in relatives

S. Wagener[1], C. Den Uil[1], J. Rietjens[2], M. Van Mol[1]
[1]Departement of intensive care, Erasmus University Medical Center, Rotterdam, Netherlands; [2]Department of public health, Erasmus University Medical Center, Rotterdam, Netherlands

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000836

INTRODUCTION. Integration of bereavement care into the management of relatives of intensive care (ICU) patients is endorsed by international ICU societies. When a patient dies at the ICU, the relatives need to make a transition from aiming at recovery of their beloved one, to preparation for an unavoidable death. Relativesmay develop complicated griefas a consequence of this unpredictable situation. Complicated grief is defined as serious and persistent grief with adjustment problems in the long run [1]. To support the relatives during ICU admission, a multidisciplinaryICU team has developed strategies to guide the bereavement process [2], e.g., an evidence-based checklist. However, little is known about needs for follow-up bereavement care.
OBJECTIVES. To explore relatives' needs for follow-up bereavement support.
METHODS. A qualitative study design in a 48-bed ICU in a university hospital with semi-structured conversations by telephone. All reported first and second contact persons of patients who died in the ICU in 2018 (n=305) have been approached by medical students. They invited the bereaved relatives to participate in a large study

exploring complicated grief and gathered contact details to send additional written information and an Informed Consent Form.
RESULTS. In total 180 persons have been called of which 123 agreed to participate, 12 refused further contact, and 45 were unavailable. The pre- scheduled time was 5 minutes per call, although; 55 "call-hours" with an average of 20 minutes were measured.
The respondents spontaneously started to explain the patient's life and their experiences during and after the death of their loved one in the ICU. They felt acknowledged and subsequently shared their grief with the medical students. The widespread and profound need evoking from the conversations, was an unknown and unexpected result showing the need for supportive follow-up bereavement care by ICU professionals.
CONCLUSION. Relatives of a patient who died in the ICU showed needs to support them in their bereavement. ICU professionals should meet those needs by listening, recognizing and providing information in structured follow-up bereavement care.

Inconsistency in assessments of appropriateness of treatment

S. Playfor[1], B. Hunter[2]
[1]PICU, Royal Manchester Children's Hospital, Manchester, UK; [2]Medical school, The University of Manchester, Manchester, UK
Correspondence: S. Playfor
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001011

INTRODUCTION. Over the last 10-15 years Paediatric Critical Care has evolved from a service that provides specialist care to mostly previously-well, acutely ill children to being one part of a multidisciplinary system delivering care to children with complex chronic conditions, many of whom regularly rely on life-sustaining interventions. With this evolution there has been an inevitable increase in the frequency with which judgements are made by clinical staff of the appropriateness of therapeutic interventions being delivered. There is however little data available evaluating the consistency of such assessments made by individual team members.
OBJECTIVES. We undertook a prospective, interview-based project in a tertiary, general Paediatric Intensive Care Unit (PICU), to determine the consistency between assessments of appropriateness of treatment made by multidisciplinary team members for individual patients. The data was analysed according to professional group (medical staff Vs nursing staff) and according to seniority (Consultant medical staff Vs doctors in training/Advanced Practitioners (junior medics), and senior nurses Vs bedside nurses).
METHODS. A convenience sample of individual PICU staff were approached and asked to make an assessment, for any patient whose circumstances they felt they had sufficient understanding of, on whether the overall treatment being delivered, in their opinion, was appropriate, inappropriate or futile according to standard definitions.
RESULTS. In total, 534 assessments were made regarding 25 patients, by 66 PICU staff members (7 Consultants, 12 junior medics, 9 senior nurses and 33 bedside nurses). There was a significant lack of consistency in assessments of appropriateness of treatment. In only 9 patients (36%) was there complete consensus, and these patients were all considered to be receiving appropriate treatment. In 11 cases (44%) treatment for the same patient was assessed as appropriate, inappropriate and futile by different PICU staff members.
Overall, 22.1% of assessments were deemed inappropriate or futile with more senior staff, both medical and nursing staff, much more likely to draw these conclusions. Consultants considered 34.4% of assessments inappropriate or futile, compared to only 9% of junior medic assessments (p=0.00004). Senior nurses considered 26.8% of assessments inappropriate or futile, compared to 20.5% of bedside nurse assessments (p=0.11).
Even amongst the 7 Consultants involved in the project there was a considerable lack of consistency in assessments with the treatment of 4 patients being deemed appropriate, inappropriate and futile by different Consultants.
CONCLUSION. We have demonstrated a significant lack of consistency in assessments of appropriateness of treatment amongst PICU staff members. Junior members of medical and nursing staff are far more likely to consider treatment to be appropriate, and even within distinct professional groups there is a striking lack of consistency. These factors must be taken into account when discussing the appropriateness of treatment with critically ill children and their care-givers.

INTRODUCTION. Despite technological advances death in the intensive care unit (ICU) remains common. When life support is likely to result in an unacceptable outcomes, ICU clinicians must ensure that patients die with dignity. The concept of dignity in death implies that patients remain in the center of care until the very end. Enrollment the family in the process is part of "Dying with Dignity".
OBJECTIVES. To determine the practice of end-of-life care in a general ICU located in South of Portugal, and understand the role of the family in the process of dying.
METHODS. Retrospective analysis of patients who died in the ICU from July 1, 2016, to May 30, 2018.
End-of-life care was defined as the clinical care for patients in whom a decision to withhold or withdraw therapy was made. Data were analyzed using the SPSS statistical program v. 25.0. The significance level used was 0,05.
RESULTS. During the period of study 602 patients were admitted to the ICU, the mean APACHE II and SAPS II for these patients was 19 and 44, respectively. Of these 164 (27%) died, 114 (70%) were males, the median (IQR) age was 72 (61-80) years and ICU length of stay (LOS) was 3 (1-8) days. The mean± SD APACHE II was 29 ± 8, SAPS II 63± 18 and SOFA score on admission 10±4. Type of admission was medical in 130 (79%), urgent surgery in 25 (15%), elective surgery in 7 (4%) and trauma in 2 (1%) patients. Cause of death was refractory septic shock in 99 (60%) patients, cardiogenic shock in 18 (11%), associated with anoxic encephalopathy in 16 (10%), massive stroke in 9 (5%), ARDS in 8(5%), hypovolemic shock in 7 (4%) and 9 (5%) from other causes.
In 150 patients (91%) death was associated with an end-of-life decision either withholding or withdrawing; always after team discussion and the decisions based on predicted outcome of the critical illness. All this patients had comfort therapy. End-of-life decision regarding ventilator support were: weaning from mechanical ventilation in 80 (53%) patients, extubation in 29 (19%) and a Do Not Intubated decision in 41 (27%).
Only in 14 patients (8.5%) dead occurred unexpectedly. These patients were older [74 (61-78) vs. 72 (61-81) years, p=0.994], with similar APACHE II 31±7 vs. 29±8 (p=0.671), SAPS II 70±19 vs. 64±18 (p=0.964) and SOFA score 10±3 vs. 10±4 (p=0.308) but with a shorter LOS [1 (0-7) vs. 3 (1-10), p=0.019] than those in whom an end-of-life decision was taken.

In 152 (93%) of the deaths, the family was informed of the prognosis in the first 24 hours and the medical decisions were reported daily. Excepted in 12 patients (7.3%) who had no any close family, in remain cases the families accompanied the patient along their end of life.
CONCLUSION. End-of-life care is frequent in an ICU in South of Portugal. The different end-of-life categories were withholding and/or withdrawing life support. In 14 patients (8.5%) dead occurred unexpectedly. These patients had similar severity scores them those with decision of end-of-life, but the LOS was shorter (p=0.019). The family were involved in the dying process in 93% of death.

INTRODUCTION. Scarcity of potential dead brain donors and the persistent mismatch between supply and demand of organs for transplantation has led the transplant community to reconsider donation after circulatory death (DCD) as a strategy to increase the donor pool. Normothermic regional perfusion (nRP) by extracorporeal membrane oxygenation (ECMO) may be the most effective method for preserving abdominal organs in DCD, especially in liver transplantation. A pitfall of this method is its complexity and the unavailability of this resource in some hospitals, especially in regional hospitals, where potential DCD donors may exist.
OBJECTIVES. Aim of this study is to report the use of Mobile ECMO team in controlled DCD.
METHODS. From June 2018 to Abril 2019 our group has worked as a mobile ECMO team for cDCD outside our center. The portable equipment included cannulation material and the ECMO device. The transplant team consisted of 1 transplant coordinator (anesthesiologist-intensivist, ECMO operator and organ extraction supervisor), 1 cardiac surgeon (cannulation), 1 interventional radiologist (cannulation) and one cardiovascular perfusionist (ECMO operator).
RESULTS. Sixteen cDCD donations were performed. Characteristics of donors and organs retrieved are summarized in Table 1. From 16 cDCD, 10 livers, 4 lungs, 27 kidneys were obtained. The evolution of grafts and receptors was favorable at day 30 post-transplant.

Table 1 (abstract 001036). WLST, withdrawal of life-sustaining therapy; ICU, intensive care unit; M, Male; F, Female; TBI, traumatic brain injury; L, liver; RL, Right Lung; LL, Left Lung; RK, Right Kidney; LK, Left Kidney

	Age	Sex	Cause of WLST	ICU stay	Donation/Transplantation
Patient 1	71	M	Hemorrhagic stroke	8	L, RK, LK
Patient 2	74	M	Hypoxic–ischemic encephalopathy	9	L, RK
Patient 3	57	F	Hemorrhagic stroke	9	L, RL, LL, RK, LK
Patient 4	59	M	Hypoxic–ischemic encephalopathy	5	RK, LK
Patient 5	65	F	Ischemic stroke	6	LK
Patient 6	62	M	Hypoxic–ischemic encephalopathy	10	RK, LK
Patient 7	66	M	Hemorrhagic stroke	15	L
Patient 8	64	M	TBI	10	L, RK, LK
Patient 9	57	F	Poisoning	10	L, RK, LK
Patient 10	70	F	Hemorrhagic stroke	8	L, RK
Patient 11	52	M	Hypoxic–ischemic encephalopathy	17	RK, LK
Patient 12	76	F	Hemorrhagic stroke	4	RK, LK
Patient 13	68	M	Hemorrhagic stroke	8	L, RK, LK
Patient 14	69	M	Respiratory failure	8	L, RK, LK
Patient 15	52	F	Hemorrhagic stroke	14	L, RL, LL, RK, LK
Patient 16	19	F	Hemorrhagic stroke	16	RK, LK

CONCLUSION. Mobile ECMO teams may enable cDCD in hospitals without these resources, thereby increasing the pool of donors and optimizing graft outcomes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001195

INTRODUCTION. Decision-making about end-of-Life (EoL) care is frequent in Intensive Care Units (ICUs). EoL situations can be traumatic for physicians, nurses and families. Conflicts - often triggered by lack of communication - can arise from EoL situations. Since 2005, the

French law prescribes that EoL decisions should be taken after a "collegial procedure" that involves the whole ICU care team and a physician not involved in patient care. However, guidelines regarding the practical organization of the "collegial procedure" are vague. Nurses often feel that they aren't involved enough in these decisions. This may have a detrimental impact on the clinician well-being and quality of care.
OBJECTIVES. We hypothesized that there is significant variation in the conduct of EoL decisions in French ICUs. We conducted this study to i) describe EoL decision-making processes, ii) explore differences between ICUs in terms of organization of collegial procedures, iii) and define the place and roles granted to nurses in those EoL decision-making processes.
METHODS. We selected a sample of 5 university affiliated ICUs (4 adult / 1 pediatric units) representative in terms of medical case mix and geography. In each ICU, we conducted structured interviews of physicians (residents, junior and senior consultants) and nurses (young and experienced) for a total of 57 interviews in the goal of reaching theoretical saturation. Interviews wer transcribed verbatim and analyzed using the grounded theory methodology (Glaser & Strauss 1967). We also attended ICU team meetings regarding EoL decisions in those ICUs whenever possible.
RESULTS. We interviewed a total of 27 physicians (20 M/7F, age 33 y.o. [IQR 28.7-52]; median ICU experience 6 years [2-22]) and 27 nurses (5M/22F, age 29 y.o. [26.2-32.7]; median ICU experience 5 years [2.3-8]). Data analysis revealed a common 5-steps chronology in EoL decision-making processes. First: informal discussions beginning either inside the medical or the nursing team, or both at the same time. Second, disclosure: open questions related to appropriateness of care raised by a clinician (physician or nurse) during a moment of interprofessional communication (staff meetings, rounds, etc). Third, formalization of the EoL decision in interprofessional meeting. Fourth, information of the patient and his/her relatives when applicable. Fifth, implementation of the EoL decision, if consensus achieved. Step 3 can occur in 2 distinct models. In the vertical model, the goal of the meeting is to advise nurses and allied healthcare professionals (NAHP) of the medical decision. Those meetings aim to improve the NAHP's understanding of the overall project and promote homogeneous communication with patient and family. In the horizontal model, NAHP & physicians share information & opinions & discuss the best possible care for the patient; the meeting ends with a written summary of the decision signed by every caregiver present at the meeting.
CONCLUSION. The "collegial procedure" for EoL decision-making as described in the French law gives way to very different interpretations. Although the decision-making chronology includes 5 steps in all ICUs studied, processes can be very different between ICUs. The role of the ICU nurses varies a lot depending on the model of interprofessional collaboration. Further investigation is needed to understand the reasons of this variability, the factors that drive the approach in each unit, and the outcomes associated with each model of interprofessional decision-making.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000430

INTRODUCTION. Ventilator-associated tracheobronchitis (VAT) has not been tracked for surveillance purpose despite its increasingly recognized impact on antibiotic use and outcomes in critically ill patients. Moreover, there are no data comparing long-term effect of the ventilator care bundle on ventilator-associated pneumonia (VAP) and VAT.
OBJECTIVES. To compare the annual rates of VAP versus VAT among critically ill children before and after the application of a ventilator care bundle over a 9 years period.
METHODS. A cohort study of a prospectively collected quality improvement database from 2010 to 2018 in a 16-bed-medical-surgical Pediatric Intensive Care Unit. Basal data were recorded in 2010. A ventilator-bundle was implemented in 2011. Cases of VAP and VAT were recorded according to the United States Centers for Disease Control and Prevention criteria (1).
RESULTS. 5,414 patients (20,357 ventilatory-days) were analyzed over 9 years. We documented a total of 37 VAP and 115 VAT during the study period. VAP incidence decreased from 4.13 per 1,000 ventilator-days to 1.2 per 1,000 ventilator-days (p= 0.230). The decrease was greatest until 2014, three years after the implementation of the ventilator-care bundle (0.44 per 1,000 ventilator-days; p=0.010) followed by a steady rise over the subsequent years and a new decrease in 2018 after optimizing adhesion to the ventilator-bundle. VAT rates always were higher than VAP rates. As in case of VAP, VAT incidence experienced the lowest rate in 2014, decreasing from 6.88 to 3.96 per 1,000 but this was not statistically significant (p=0.357). In the following years, VAT rates remained stables between 5.81-5.98 per 1,000 ventilator-days without parallelism with the ventilator-bundle effect on VAP. Even more, in the last year there was a spike on VAT incidence (from 5.98 to 10.2 per 1,000 ventilator-days) whereas VAP incidence experienced a fall (from 2.39 to 1.2 per 1,000 ventilator-days).
CONCLUSION. VAT incidence were three times higher than VAP incidence. VAT rates showed a different behavior than VAP rates to the ventilator-bundle. Clinical impact of VAT must be considered

when assessing emerging surveillance definitions, quality indicators and bundles.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000444

INTRODUCTION. Subject recruitment in the critically ill and injured pediatric population is challenging due to the complexities of the consent process, limited population, and vulnerabilities of the child research subject. Recruitment can be further complicated by differing perceptions of risk with respect to patient age. A critically ill or injured child may meet enrollment criteria for a clinical trial, yet parental opinions toward research may hinder research participation. Further, few studies have focused on co-enrollment (participation in multiple research studies) in this population.

OBJECTIVES. To examine the opinions of parents of critically ill or injured pediatric patients toward research based on age.

METHODS. Study participants who required a pediatric intensive care unit (PICU) stay >24 hours were identified at an urban hospital. Parents were approached to complete an anonymous electronic survey between 3-7 days following PICU admission. Surveys consisted of 20 closed-ended questions aimed at assessing parental opinion toward research participation for their ill or injured child. Subject responses were stratified based on their respective child's age and divided into three age groups: infancy (<12 months), childhood (1-9 years), adolescence (10-17 years). Data was analyzed using Chi-squared test for categorical variables and Student's t-test for continuous variables.

RESULTS. A total of 201 parents of critically ill or injured children were surveyed from April 2018 to April 2019. Among them, 41.8% (84) were parents of infants (I), 32.3% (65) were parents of children (C), and 25.9% (52) were parents of adolescents (A). There were no differences in mean age, race, gender or length of hospital stay among the age groups. Most parents would consider research participation for their child. Significantly fewer parents would consider enrollment in multiple studies (62.7% vs. 43.3%, p<.001). Parents of adolescents were significantly more likely to consider research participation than parents of children or infants (A=80.8% vs. C=58.5% vs. I=54.8% respectively, p=0.007). There was no significant difference in attitudes toward participation in multiple research studies across the age groups (A=50.0% vs. C=40.0% vs. I= 41.7%, p=0.514). Parents were significantly more likely to consider participation in research if there was perceived direct benefit to their child as opposed to benefitting other children (81.6% vs 45.3%, p<.001).

CONCLUSION. Parental attitudes toward research participation in the critically ill or injured pediatric population are generally favorable. However, parents of adolescents are more inclined to participate in research compared to those with younger children. Parental enthusiasm toward research participation appears to be greatest when there is a perception of direct benefit toward their child. Many parents appear receptive to co-enrollment and this may be an acceptable recruitment practice.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000506

INTRODUCTION. There is an increasing incidence of type 1 diabetes mellitus (T1D) among children in Croatia. A study published in 2014 showed annual increase of 5.87% and that is higher than the European average, which is 3.9%. Diabetic ketoacidosis (DKA) is the leading cause of morbidity and mortality in children with T1D, with cerebral edema as most severe complication. Development of brain edema is likely a consequence of abnormalities in cerebral perfusion and inflammation that occur during DKA. Since early recognition of cerebral edema leads to better outcome, it is important that patients with moderate or severe DKA are closely monitored and treated in Pediatric Intensive Care Units (PICU).

OBJECTIVES. The aim of this study is to investigate clinical and laboratory parameters of children treated in PICU because of DKA.

METHODS. Patients treated due to DKA in PICU of the University Hospitals of Split and Osijek from 2013 to 2017 were included in this study. Retrospectively collected data included age, gender, clinical signs and symptoms, and various laboratory parameters. After dividing subjects into two groups: newly diagnosed with T1D (NT1D) and previously diagnosed with T1D (PT1D), collected data was compared between the two groups.

RESULTS. Total of 82 patients were enrolled. Those with NT1D were more often treated in PICU. Decreased consciousness level was found in 41.5% of patients, with majority of them being somnolent. No difference was found between the groups. Of the total number of DKA patients, the rate of cerebral edema was 2.4% and both patients with cerebral edema belonged to the NT1D group. Dehydration was the most frequent clinical sign, found in 95% patients at admission. There was no significant difference regarding laboratory data at admission.

CONCLUSION. More children with NT1D required treatment in PICU due to DKA with two of them developing cerebral edema. Since cerebral edema is a life threatening condition, treatment of patients with moderate or severe DKA in PICU will provide necessary monitoring enabling early recognition and treatment of cerebral edema and better treatment outcome. As the dehydration is the leading sign at admission, a good estimation of dehydration severity is important during the initial management as well. To minimize the incidence of DKA among NT1D it is important to continuously carry out public health education programs aimed to early identification of signs and symptoms of T1D. For patients with PT1D it is essential to well educate and support both children and their families aiming for good control of diabetes and prevention of complications.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000509

INTRODUCTION. Acute Kidney Injury (AKI), Fluid Overload (FO) and MODS increase mortality in Pediatric Acute Respiratory Distress Syndrome (PARDS). AKI in PARDS may be multi-factorial due to hypovolemia, SIRS and cytokine storm and exposure to nephrotoxic drugs. It has been shown in critically ill children that FO is associated with AKI and increased mortality. At our center, retrospective analysis has shown a high PARDS mortality and that FO>10% and AKI are not uncommon. Hence the need for this prospective study.
OBJECTIVES. To study the effects of AKI and FO on severity of PARDS and its mortality
METHODS. Prospective observational study from August 2017 to August 2018, in a tertiary care PICU in North India, including 48 children aged 31 days to 12 years, mechanically ventilated for PARDS (PALICC definition)
RESULTS. Thirty-five children (72.9%) had severe, while 9(18.8%) had moderate and 4(8.3%) had mild PARDS. The median (IQR) P/F ratio and oxygenation index(OI) were 164 (122,213) and 7.21(4.7,13.9) respectively. Thirty two (66.6%) children had FO%>10; more so in severe as compared to mild-moderate ARDS (80% vs. 30.8%;P<0.001). Odds of severe ARDS were 9 times higher in children with FO (OR 9;95%CI:6.125-13.224;P<0.0001). Linear mixed modeling regression analysis of peak FO%(PFO) on serial OI showed that PFO was a significant predictor of worst OI (F-value 23.47; P<0.001); for every 1% increase in PFO, worst OI increased by 0.67 (95% CI: 0.40-0.94;P< 0.001). Also, for every 1% increase in daily FO%(DFO), mean OI increased by 0.9 [95% CI:0.82-0.96; P<0.001].
Children with AKI had higher baseline vasoactive-inotrope score (VIS) (mean+SD=38.5±38.0;P-0.038), severe ARDS(n=26/30;P-0.005) and higher mortality (n=24/30;P-0.001), than those without AKI. Logistic regression failed to show a relationship between AKI and PFO (OR 1.02;95%CI: 0.97-1.07, P-0.40). However, on linear mixed modeling, for every 1 mg/dL rise in creatinine, there was a rise in FO by 3%(P< 0.001).
The odds of undergoing RRT increased by 6% for every 1% increase in FO (OR-1.06;95%CI:1.01-1.11,P-0.03). The area under curve (AUC) for PFO, as a predictor of RRT was 0.69 (95%CI:0.54-0.85;P-0.024). Higher proportion of non-survivors (25/30;83.3%) as compared to survivors (7/18;38.8%) had FO(P-0.002). Although higher proportion of children with progressive MODS (23/31;74.2%) had FO, this was not statistically significant.
CONCLUSION. AKI and FO together contribute to worsening lung injury and increased mortality in PARDS. Children with shock are at high risk for developing AKI. Early detection of AKI using non creatinine based markers and initiation of RRT based on FO% could prevent worsening ARDS.

INTRODUCTION. Admission to an intensive care unit (ICU) is an extraordinary experience for the patient's relatives. Critical illness paired with an uncertain future triggers substantial psychological symptoms.
OBJECTIVES. This study analyses the baseline data of the ongoing randomised controlled trial (RCT, ClinicalTrials.gov Identifier: NCT02931851) and examines the degree to which relatives of ICU patients are affected by symptoms of anxiety, depression and stress at the time of a relative's admission to an ICU.
METHODS. This RCT study was performed in Austria and Switzerland. The Hospital Anxiety and Depression Scale (HADS) and the Impact of Event Scale (IES) were assessed for relatives upon admission of the patient to the ICU (0-2 days after admission, T0) using face-to-face interviews. Clinically relevant values on the HADS score are those ≥11, while values over 15 indicate severe symptoms. For the IES, scores ≥27 points are deemed to be clinically relevant, while values ≥35 can support a diagnosis of PTSD in the right context. Data collection took place between 2017 and 2019.
RESULTS. 60 relatives (12 male, 48 female) were included in the study, with an average age of 46.9 13.6 years. Relatives were recruited in Graz (n=11), Vienna (n=8) and Bern (n=41).

At T0, a mean HADS score of 16.7 6.6 (min. 3.0 max. 31.0) points was observed. On average, women scored higher than men at T0 (18.1 6.3 vs. 11.1 4.9).
At T0, a mean IES score of 28.3 12.3 (min. 1.0 max. 60.0) points was observed. On average, women scored higher than men at T0 (30.5 11.3 vs. 19.4 12.5).
There is a positive correlation between HADS and IES (p <.0001, Pearson correlation coefficient 0.64). The need for nursing care of a relative before admission to ICU did not correlate with HADS score or IES score (Spearman correlation coefficients: -0.13, -0.05).
CONCLUSION. The relatives reported clinically relevant symptoms of anxiety, depression and stress at admission. Women reported higher scores than men, and psychological symptoms occurred regardless of whether or not the patient was urgently in need of care before admission.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000587

INTRODUCTION. Monitoring of the sublingual microcirculation (SMC) offers insight into oxygen transport. In contrast to findings in adults, it remains unclear whether children with congenital heart disease (CHD) undergoing cardiac surgery on cardiopulmonary bypass (CPB) also show microcirculatory alterations and thus altered tissue oxygenation.
OBJECTIVES. 1. To assess whether the SMC differs between CHD patients and healthy controls before surgery;
2. To assess whether the SMC is altered during the first 6h after cardiac surgery on CPB.
METHODS. A prospective observational study was performed in a tertiary children's hospital, comparing CHD patients aged 0 – 17 years undergoing cardiac surgery on CPB and healthy controls aged 0 – 17 years undergoing minor non-cardiac surgery. The SMC was monitored with handheld vital microscopy, after induction of anesthesia (baseline) in both groups and intermittently until 6h after cardiac surgery. Parameters of vessel density and perfusion were assessed for all vessels (diameter <100μm) and small vessels (diameter <20μm). Linear mixed models were built to assess differences between groups and change over time.
RESULTS. Thirty-eight CDH patients (median age 0.62 years (IQR: 3.06), 16 females, 20 cyanotic heart defects, frequency RACHS-1 categories 1-6: 6, 21, 9, 1, 0 and 1 respectively) were included. In addition, 35 healthy controls (median age 1.29 years (IQR: 2.99), 15 females) were included. Survival was 100%. CHD patients showed lower median microcirculatory flow index (MFI) (MFIall 2.86 vs. 3.00, p<0.001; MFIsmall 2.83 vs. 3.00, p<0.001) and lower median proportion of perfused vessels (PPV) (PPVall 98.8% vs. 100%, p<0.001; PPVsmall 98.7% vs. 100%, p<0.001) than controls at baseline. After cardiac surgery, MFIall and MFIsmall decreased compared to baseline and did not improve during the first 6h after surgery. Other SMC parameters were unaltered after cardiac surgery and did not change over time. Also, cyanotic heart disease did not affect SMC parameters.
CONCLUSION. Children with CHD presented with altered microcirculatory perfusion, with lower blood flow quality and less perfused vessels than healthy controls. Blood flow quality decreased even further during the first hours after cardiac surgery.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000681

INTRODUCTION. Mechanical ventilation(MV) is the most widely used of life support in Intensive care unit(ICU).But accurately and timely identify the "time window" to weaning successfully from mechanical ventilation is challenging.Both premature and delayed weaning can increase mortality,ICU duration and costs,So an objective and convenient predicting parameter is very important to mechanical ventilated patients.
OBJECTIVES. To assess the diagnostic accuracy of Tidal volume(VT),Rapid shallow breathing index(RSBI),Max inspiratory pressure(MIP) and P0.1 for weaning success by diagnostic meta-analysis
METHODS. PubMed, Web of Science, Embase, Cochrane Library and gray literature were searched from inception to December,2018 to collect retrospective and prospective studies about weaning index of mechanical ventilated patients in Intensive care unit.Two authors independently extracted data and evaluated study quality using the Quality Assessment of Diagnostic Accuracy Studies-2 tool and Standards for Reporting of Diagnostic Accuracy Studies Checklist. Stata 13.0 and Review Manager 5 software were used for data analysis.
RESULTS. A total of fourteen studies,1 720 patients were included.the pooled sensitivity and 95%*CI* of VT,RSBI,MIP and P0.1 respectively was 0.87(0.74,0.94), 0.82(0.68,0.91), 0.84(0.71,0.92) and 0.86(0.78,0.91), the pooled specificity and 95%*CI* was 0.54(0.46,0.63), 0.66(0.56,0.74), 0.41(0.21,0.65) and 0.62(0.43,0.78).the DOR respectively was 8.08, 8.94, 3.68 and 9.76,SROC and sensitivity analysis showed that all no threshold phenomenon and were stability
CONCLUSION. The sensitivity and specificity of the four weaning index were similar,but P0.1 showed a better diagnostic value on the weaning success from mechanical ventilation.then was the RSBI,the VT and MIP

Non-pharmacological interventions to improve sleep quality in ICU patients:a network meta-analysis

LJ. JIANG
College of Nursing, Lanzhou University Lanzhou, Lanzhou, China
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000684

INTRODUCTION. Sleep is one of the most basic physiological needs of human beings. One third of life is spent in sleep. Sufficient sleep can make people relieve fatigue, better restore their mental and physical strength, maintain a good awakening state after sleep, improve work efficiency, and is also a necessary condition for the rehabilitation of patients in intensive care unit. However, a large number of studies have shown that ICU patients suffer from sleep disturbances due to various factors, and more than 80% of ICU patients have sleep disorders. Sleep disorders or sleep cycle disturbances cause great damage to the body, especially for ICU critically ill patients. Therefore, it is very important to find interventions to improve sleep disorders in ICU

patients. At present, the commonly used interventions in clinical practice are divided into drug therapy and non-drug intervention. Drug therapy includes sedative drugs, analgesic drugs and hypnotic drugs. Although the use of sedative analgesic hypnotics is quickly and effective, it is easy to cause different degrees adverse reactions and drug dependence, so non-pharmacological interventions are receiving more and more attention. At present, the study on the effect of non-drug intervention on improving sleep quality in ICU patients has been started in clinical practice, but the results are not the same, and there is no reliable clinical research literature support. Network meta-analysis is a method developed from traditional meta-analysis. Its greatest advantage is that it can summarize the different interventions for treating similar diseases and perform quantitative statistical analysis according to a certain result.

OBJECTIVES. To study the effect of non-drug intervention on improving sleep quality in ICU patients by network meta-analysis.

METHODS. Computer search database The Cochrane Library, PubMed, Embase, Web of Science, China Journal Full-text Database (CNKI), Wanfang Database (WanFang Data), VIP Database (VIP) and China Biomedical Literature Database (CBM), search and construction The library reviewed the RCT literature on non-pharmaceutical interventions to improve the sleep quality of ICU patients in December 2018, using the Stata13.0 software for network meta-analysis.

RESULTS. This study included 18 RCTs with a total of 1720 patients and 11 non-pharmacological interventions. The Pittsburgh Sleep Quality Index (PSQI) network meta-analysis showed that non-drug interventions improved sleep quality in ICU patients, and comprehensive nursing interventions, lavender essential oil aromatherapy, eye masks, eye masks and earplugs were statistically different from conventional care. There was no significant difference between the Richards-Campbell Sleep Scale and the VSH sleep scale. The Pittsburgh Sleep Quality Index (PSQI) ranked as follows: eye mask and earplugs > eye mask > comprehensive nursing intervention > lavender essential oil aromatherapy > routine care.

CONCLUSION. Based on the results of the Pittsburgh Sleep Quality Index (PSQI) network meta-analysis and ranking results, non-drug intervention eye mask and earplugs were the best in improving sleep quality in ICU patients compared with other interventions.

Efficacy of urinary catheter securement in the reduction of urinary tract infection, urinary meatus injuries and discomfort, in the critically ill patient: preliminary results

N. Calpe[1], L. Wennberg[2], M. Llauradó[2]
[1]Intensive Care Unit, Hospital Universitari General de Catalunya, Barcelona, Spain; [2]Nursing department, UIC Barcelona -Universitat Internacional de Catalunya, Barcelona, Spain
Correspondence: N. Calpe

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000689

INTRODUCTION. Urinary catheter securement is recommended as part of care bundles for general Urinary Catheter (UC) care and for Catheter Associated Urinary Tract Infection (CAUTI) prevention (1–4). However, prevalence studies show a low prevalence of catheter securement(5). Moreover, the relationship between this care and CAUTI, discomfort and urinary meatus injuries have not been studied individually.

OBJECTIVES. The purpose of this study was to determinate the impact of securing urinary catheters on the rate of CAUTI, urinary meatus injuries and discomfort in critically ill patients

METHODS. Randomized, non-blinded multicentre clinical trial conducted in two general Intensive Care Units of two tertiary hospitals. *Inclusion criteria*: Age> 18, UC inserted in Intensive Care Unit or in the Operating room, informed consent. *Exclusion criteria*: Securement not possible, urinary tract infection at the admission, UC plan to be used and anticipated ICU stay for 48 hours or more. Participants were randomized into the control group (CG), to which the UC received traditional care, and the experimental group (EG), to which the UC was secured to the upper half thigh. Before securing, a barrier film was applied to protect the thigh skin from adhesive lesions. Protocols from both sites were equivalent. Data were obtained twice a day until study ends, including: properly done securement, sings of CAUTI, UC related injuries and discomfort. Study ends was defined as: If CAUTI was diagnosed, 48 hours after catheter removal, 48 hours after ICU discharge or after 30 days of catheter use. If CAUTI was suspected an urine sample was collected. A descriptive and bivariate analysis performed with SPSS 21 program. IRB approval from both sites was obtained.

RESULTS. Sixty-seven patients have been analysed at the moment (47,8% male, 52,2% female. Mean age 59 ± 14 years). Allocation: 55,2% IG (n=37), 44,8% CG (n=30).[U1] Six CAUTI have been diagnosed, all of them from CG ($p<0,05$). Twenty five percent of communicative patients from CG experimented UC related discomfort, in front of 5% from EG ($p<0,05$). The Incidence of urinary meatus injuries was found to be 10,4%, without statistically differences between two groups

CONCLUSION. UC securement seems to decrease CAUTI and UC-related discomfort, according to the preliminary analysis

End-expiratory volume and lung stress and strain longitudinal changes evoked by PEEP escalation in ARDS and non-ARDS children

S. Ilia, E. Geromarkaki, P. Briassoulis, P. Bourbaki, T. Tavladaki, M. Miliaraki, G. Briassoulis
[1]Picu, university hospital, medical school, University of Crete, Heraklion, Greece
Correspondence: S. Ilia
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000817

INTRODUCTION. End-expiratory lung volume (EELV) is functional residual capacity (FRC) plus lung volume increased by the applied positive end expiratory pressure (PEEP). Monitoring EELV has been proposed as a valuable tool to optimize ventilator settings and improve lung protective ventilation in clinical practice
OBJECTIVES. To detect longitudinal changes of EELV, compliance (Crs), driving pressure (ΔPrs), stress and strain when applying incremental PEEP levels in mechanically ventilated (MV) children with or without acute respiratory disease syndrome (ARDS).
METHODS. Twenty-five critically-ill children were enrolled in this cohort study. Patients with ARDS (oxygenation index ≥4) or non-ARDS (at risk of ARDS or without lung injury) were subjected to PEEP trials of 4-6-8-10cmH2O. At each PEEP level, EELV (nitrogen washin/washout technique), Crs, ΔPrs, strain and stress were calculated at 6-12-24-48-72 hours.
RESULTS. Seven-hundred measurements were carried out. Age, height, ideal-weight, and body mass index (BMI) influenced EELV and Crs in all groups, better in ARDS ($p<0.001$). EELV was related with Crs ($p<0.001$); ΔPrs with EELV/kg and Crs/kg ($p<0.001$). Following PEEP increases, EELV increased at all time-points. EELV remained lower in the ARDS compared to at-risk group only the first 12 hours ($p<0.05$). Stepwise incremental PEEP from 4 to10 cmH2O raised static and global stress and strain earlier in non-ARDS groups compared to ARDS group ($p<0.05$). Changes in strain, stress, EELV, and Crs were evident by 72 hours of MV ($p<0.001$). Longitudinally, at all studied PEEP levels, stress and strain remained within safe limits and did not interfere with hemodynamics.
CONCLUSION. EELV and Crs are weight-height and ΔPrs dependent, differently in ARDS compared to non-ARDS patients. Repeated, non-invasive calculations of EELV and lung strain/stress in children with and without ARDS using the nitrogen washin/washout technique might represent a promising tool for optimizing PEEP in mechanically ventilated children.

Correspondence: R. Lefebvre
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000855

INTRODUCTION. The benefit and necessity for prophylactic physiotherapy post-operatively remains unclear [1]. Combined with an increased demand on resources, scores to identify those patients who would most benefit are being increasingly used [2]. At present no validated tool exists for those following cardiac surgery. The Birmingham cardiac surgery screening tool (BCSST) was developed to identify patients at high risk of developing post-operative pulmonary complications (PPC's).
OBJECTIVES. To evaluate the effectiveness of introducing a post-operative screening tool to identify patients at risk of PPC's following cardiac surgery
METHODS. All patients undergoing cardiac surgery between 25th November and 24th December 2018 were included in the analysis. BCSST scores were calculated on day 1 post-operatively. For patients identified as low risk, post-operative care was led by nursing staff with no physiotherapy involvement. High risk patients received standard physiotherapy input, including respiratory interventions and mobilisation. Primary outcome was development of PPC's, assessed using the Melbourne risk prediction tool.
RESULTS. During the trial period 21/47 (42%) of patients were classified as low risk. None of the patients in the low risk group developed a PPC, although two patients were re-referred to physiotherapy (1 for mobility assessment and 1 for respiratory deterioration). Patients in
the low risk group mobilised 30m earlier and spent less time in hospital than the high risk group.
CONCLUSION. The BCSST was effective at identifying low risk patients, with no patients in this group developing a PPC. For these low risk patients care was safely led by nursing staff with no adverse events or falls reported.References

Table 1 (abstract 000855). See text for description

	High Risk	Low Risk	Re-referral
Screening Outcome	26 patients (53%)	21 patients (42%)	2 patients (4%)
Developed PPC	8 patients (31%)	0 patient	0 patient
Time to Mob > 30 m	5.58d	4.65d	5d
Physio complete	6.65d	0d	10.5d
Length of stay	9.31d	6.60d	11d
Treatment duration	317min	15min	345min

Acute Coronary Syndrome patient perceptions of their illness while hospitalized

F. DeKeyser Ganz[1], O. Raanan[2]
[1]School of nursing, Hadassah Hebrew University, Jerusalem, Israel; [2]School of nursing, Sheba Medical Center, Ramat Gan, Israel
Correspondence: F. DeKeyser Ganz
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000859

INTRODUCTION. Previous studies have shown that patients' perceptions of their illness can influence their health behaviours. While Acute Coronary Syndrome (ACS) is an acute event, it is indicative of a chronic illness. Few studies have described the perceptions of those with ACS in the acute phase of their illness.
OBJECTIVES. To describe illness perceptions of patients with ACS while still hospitalized for the event.
METHODS. Every Israeli patient admitted to a hospital over a 2 month period with ACS (n=1958) was included in a bi-annual, national, two month prevalence study, Acute Coronary Syndrome Israel Study (ACSIS). Clinical medical data were collected for the entire sample. A convenience sub-sample of these patients (n=990) completed the Brief Illness Perception Questionnaire. Patient demographic and clinical data were collected from the patient's medical record.
RESULTS. ACS patients reported mean levels of 4.8/10- 7.7/10 of their perceptions of their illness, with highest scores for medical treatment control and coherence and lower scores for identity and emotional representations. Some respondents reported that their illness would have little or no impact on their life (n=230, 30%) and its effects were for a short time period (n=314, 31%)
CONCLUSION. While most ACS patients perceived that they understood their illness and its impact on their lives, many did not. Increased efforts should therefore be made by nurses in the acute phase to educate patients about the full implications of coronary disease.

Communication tools used with the intubated patient in the Intensive Care Units of Catalonia

N. Grané, R. Gonell, C. Cobo, A. Parera
Intensive care unit, Mútua Terrassa University Hospital, Terrassa, Spain
Correspondence: A.M. Parera
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000884

INTRODUCTION. Over the last years has been stablished sedation guides recommending that the mechanical ventilation (MV) should be applied with low doses of sedation, to avoid complications and prolonged admissions (6,3,2). Therefore, more often we can find ICU patients awake with MV. Not being able to communicate leads to negative emotions and frustrating levels for the health team, the patient and the family (3,5). Some needs within the context of ICU are easy to unsdesrtandand,but there are some other needs, social and emotional, where the use of a communication tool can be useful (5,10,4).

OBJECTIVES.

- Identify which methods and/or communication tools are used in Catalonia ICUs with intubated or tracheostomized patients.
- To know the degree of acceptance perceived by nursing professionals in the use of pictograms/ electronic devices.

METHODS. Multicentre, observacional , descriptive and transversal study carried out from November 2018 to March 2019. Charge nursers and nurses of all adult ICUs of Catalonia with more than 2 years of experience in ICU were included. Those nurses that are not regular staff of ICU were excluded. The nurse manager was informed by phone about the purpose of the study and her collaboration and the collaboration of two nurses per shift was requested. We collected demographic variables, professional category, work shift, years of experience at ICU, hospital name and type of ICU. An ad-hoc questionnaire was developed to know the communication tools used and the degree of acceptance perceived by nursing (Likert scale from 0 to 10) in the use of pictograms and electronic devices by their own group, the patients and the relatives. A pilot test with nursing at the ICU Universitiy Hospital Mutua Terrassa was carried out to assess the suitability of the questionnaire. Intentional non-probabilistic sampling. Descriptive statistics with averages (standard deviation) and percentages.
RESULTS. An 89.2% of UCIs responded (33 out of 37) and a total of 140 questionnaires were received. Low-tech tools (pen/paper, alphabet, blackboard) are used by 91% of ICUs, and 30% of them use pictograms. High-tech tools (tablets) are used by 9% of ICUs. The 73% of respondents value the use of pictograms as a tool that improves communication and 82% have the same opinion about electronic devices. The 61% of respondents did not have pictograms neither electronic devices, but 99% indicate the need to have them.
The degree of acceptance perceived by nursing in their own group, patients and relatives scored an average of 6.2 (DE=1.7) points in the use of pictograms and 6.7 (DE=1.9) in the use of electronic devices.
CONCLUSION. Most ICUs use basic methods and low-tech tools. The use of more technological devices is recent at ICUs and they are well accepted. The degree of acceptance perceived by nursing in the use of these devices is good. It will be necessary to revalue it when its use is more extensive. We propose a new study to know at first hand the acceptance of these tools by relatives and patients. The findings of this study are a motivation to continue working on communication and thus improve an element that will give high quality to our care.

Should time be abandoned as a definition of early mobilisation in critical care?

J. Grant, R. Haylett, E. King, P. Piper, O. Gustafson
[1]Adult intensive care unit, John Radcliffe Hospital, Headington, UK
Correspondence: J. Grant
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000904

INTRODUCTION. Early mobilisation has been demonstrated to be safe and feasible for patients admitted to intensive care units (ICU),$_1$ however there is significant heterogeneity in its definition. Mobilisation has often been defined as early when it occurs within the first 2 to 5 days of admission to ICU or alternatively, within 72 hours of admission$_2$. However the course of patients' critical illness varies greatly with decisions to initiate mobilisation based on a patients' clinical condition as opposed to time. Recent interventions to facilitate earlier rehabilitation have resulted in mobilisation during a more acute phase of illness as measured by the SOFA score, despite not meeting the traditional definitions of early mobilisation$_3$.
OBJECTIVES. To compare time to first mobilisation and SOFA score on first mobilisation for critically ill adults.
METHODS. A retrospective review was undertaken in a general adult ICU of a UK university teaching hospital. Patients admitted to the ICU receiving invasive ventilation for more than 48 hours between August 2017 and March 2019 were included. Patients who active mobilisation was deemed inappropriate were not included e.g. palliative treatment pathway. Mobilisation was defined as sitting on the edge of the bed/dangling or any out of bed activity, and termed early when occurring within 72 hours of admission.
RESULTS. The analysis included 303 patients with a median duration of ventilation of 5 days (IQR 3-9) and time to first mobilisation of 4 days (IQR 3-8). For those receiving early mobilisation (n= 114), median SOFA score was 4 (IQR 2-6) and day of mobilisation was 2 (IQR 2-3). In the group receiving late mobilisation (n= 187) the median SOFA score was also 4 (IQR 2-5), however the day of mobilisation was 6 (IQR 4-9).
CONCLUSION. In this study of patients receiving invasive ventilation for more than 48 hours, time to first mobilisation was comparable to previous published ICU rehabilitation studies. Patients who did not meet traditional definitions of early mobilisation were mobilised with the same level of acute illness as those receiving early rehabilitation. Early mobilisation is better defined through acuity of illness as opposed to time based metrics, which would allow better evaluation of future mobilisation interventions in ICU.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000943

INTRODUCTION. Respiratory failure (RF) in children is one of the most common causes of admission in pediatric intensive care units (PICU). Chest x-ray has an important role in diagnosis and assessment upon presentation and during clinical course.
OBJECTIVES. We aim to propose a radiography-based severity scoring system for the assessment of children with RF in PICU and investigate possible correlations with clinical and laboratory indicators of clinical severity and with predictors of outcome.
METHODS. 104 children under 18 years old hospitalized with acute RF in PICU between 2014-2018 were enrolled. Disease severity (PRISM and PELOD scores), PaO2/FiO2 (PF) ratios, duration of ventilator support, length of PICU stay (LOS), and outcome were recorded. A five-point radiographic severity score was introduced by enhancing Taylor et al1 score, considering all possible radiographic abnormalities. Chest x-rays upon admission and on worst PICU day (defined by maximum respiratory support and worst oxygenation/ventilation parameters) were blindly reviewed and independently scored by four doctors, 2 radiologists and 2 intensivists, following training.
RESULTS. 104 children (68 males) aged 5.44±0.6 years were evaluated. 62 (59.6%) patients were mechanically ventilated for 10.8±2.1 days; PICU LOS was 15.1±2.1 days. 162/283 radiographs (85 upon admission, 77 on worst PICU day) were assessed. PRISM and PELOD scores, duration of mechanical ventilation and PICU LOS were positively related with radiographic scores, and negatively related with PF ratio (all, $p<0.001$). Higher imaging score from previous radiography, indicating deterioration, was associated with lower PF ratio, prolonged mechanical ventilation and PICU LOS (all, $p<0.001$). Mortality (5.8%) was related to increased number of radiographs ($p<0.001$) and higher radiography severity score ($p<0.001$). There was a strong statistical correlation of radiographic scores between radiologists and intensivists (Spearman's $p<0.001$).
CONCLUSION. We introduce a reliable radiography-based severity score for assessing respiratory failure in critical ill children. This valuable bed side tool, associated with outcome, can be reproducibly utilized by both radiologists and clinicians following training.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000948

INTRODUCTION. Coma is considered an emergency and life-threatening condition in children. According to the 2019 edition guidelines for management of pediatric brain Injury, monitoring of intracranial pressure (ICP) and cerebral perfusion pressure (CPP) is recommended. Marshall Computed tomography (CT) scores of the brain correlate with outcome in adult patients with traumatic brain injury. Similar evidence for children with traumatic and non-traumatic coma is lacking.
OBJECTIVES. We sought to determine whether a newly introduced imaging severity scoring system correlates with intracranial monitoring, therapeutic strategies, and outcome in children undergone head CT for coma, regardless of its aetiology.
METHODS. Data of all children under 18 years old with traumatic and non-traumatic coma admitted to pediatric intensive care unit (PICU) between 2014 and 2018 were retrospectively reviewed. Demographics, ICP, CPP, PICU course, and outcome were recorded. A modified Marshall CT score was evaluated for all CT scans upon admission, and on worst clinical PICU-day, when available.
RESULTS. 85 children (47 males) aged 7.5±5.3 years were classified in three groups, traumatic coma (n=21), non-traumatic non-surgical coma (n=62), and non-traumatic coma requiring neurosurgery (n=2). Mortality was 2.3%. 14 children (16.5%) had at least 2 CT scans. CT score was positively associated with increased PRISM ($p<0.001$), prolonged mechanical ventilation ($p<0.01$), and length of PICU stay ($p<0.01$). CT score was higher in patients with ICP monitoring ($p<0.01$) and, particularly, when ICP>15mmHg ($p<0.04$) in all groups. CPP< 50mmHg was related to increased number of CT scans, higher CT score, need for intracranial hypertension treatment, and mortality in all groups (all, $p<0.001$). Repeated CT scan due to clinical deterioration or increased intracranial pressure exhibited higher imaging scores ($p<0.02$) and contributed to new information, change of diagnosis and/or treatment in 63% of re-scanned children ($p<0.001$).
CONCLUSION. The introduced modified Marshall CT score is associated with ICP/CPP measurements and outcome, contributing to therapeutic adjustments in children with coma.

Patients with Acute Coronary Syndrome and high-bleeding risk: analysis of therapeutic management and 5-years outcmomes

AM. González González, AM. García-Bellón, C. Lara-García, M. De Mora-Martin
[1]Cardiology, Regional Hospital of Malaga, Málaga, Spain
Correspondence: A.M. González González
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000531

INTRODUCTION. Improvements in antithrombotic therapy have led to a significant reduction in ischemic events in patients with acute coronary syndrome (ACS), although at the expense of an increase in hemorrhagic complications.
OBJECTIVES. The objective of this study was to evaluate the impact of the high risk of high bleeding risk in the therapeutic treatment of patients diagnosed with ACS and its influence on the very long-term prognosis.
METHODS. An observational, analytical, retrospective study of patients admitted in Cardiology department with the diagnosis of ACS between May 2012 to September 2013. We included 578 patients (p).They were divided in 2 groups:
- Group A: patients with high bleeding risk (n: 126; 21,8%; 43,2% female)
- Group B:patients without high bleeding risk (n: 452; 78,2%; 27,8% female)

High bleeding risk was defined as a CRUSADES Score > 40. They were compared according to clincial and invasive management, mortality and composite primary endpoint (CPE) : reinfarction, stroke and cardiovascular death; at 5 yeras follow-up.
RESULTS. Patients in group A were older (A= 72,3 ± 9,3 vs B= 63,3± 13,9; p = 0,08), had more chronic kidney disease, arterial hypertension, diabetes mellitus, and chronic heart failure. (Table 1)At admission, 63,7% of group A presented with non-ST elevation ACS and Killip> 1 was presented in 54,1% of patients. Patients in group A had less invasive risk stratification (A= 54,8% vs B= 67,0%; p< 0,01). There were no differences regarding dual antiplatelet therapy (DAPT) or anticoagulantion during hospitazation or at discharge.
During hospitalization, group A presented with more bleeding complications. At 5 years follow-up, group A had higher rates of CPE. (Table 1)
CONCLUSION. Patients with a high risk of bleeding were associated with a worse cardiovascular profile. Although there were no statistical differences between the groups with respect to invasive stratification or antithrombotic therapies, in the very long term follow-up, these patients presented a worse prognosis.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001550

INTRODUCTION. Ischemic heart disease (IHD) represents the main cause of mortality worldwide. Among the ischemic heart diseases, ST-segment elevation myocardial infarction (STEMI) is noteworthy, as not only it occurs more frequently with severe complications, such as cardiogenic shock and heart failure, but also the simple presence of the ST-segment elevation is an independent risk factor for mortality prediction. Emergency medical system (EMS) -based STEMI networks allows not only STEMI diagnosis in the pre-hospital phase but also reduces treatment delays; treat your fatal complications and the immediate activation of the catheterization laboratory.
OBJECTIVES. The aim of study was investigate the effect of Pre-hospital versus Hospital treatment in the length stay and survival of patients with STEMI diagnosis.
METHODS. We performed an observational retrospective through single centre registry of consecutive patients (n = 360) admitted with STEMI to the intensive care unit of the Guadalajara Hospital, Spain, between 2015 and 2018. Two groups were established; on the one hand the intervention group or prehospital care by MICU (Group I) and the control group of patients who came to the Hospital by their own means (group II). We compared demographic variables, cardiovascular risk factors, treatment in prehospital phase or in ED, time to firs medical contact to percutaneous coronary intervention (PCI), location of coronary lesions, GRACE score, length in ICU and hospital stay as well as survival to discharge and about 30 days.
RESULTS. 360 were evaluated by STEMI, 219 (60.8%) by MICU and 141 (39,2%) arrived themselves to hospital. 280 (77,8%) male and mean age was 61.0 (RIC: 53.0-71.0) years old.
Patients treated for MICU had a GRACE score greater than the control group 119.85 (112.5 – 127.1) Vs 97.4 (87.2-107.5) (p= 0.002). There were differences in P2Y12 inhibitor administered. Ticagrelor was more frequent in patients admitted directly in hospital 94 (66.7%) Vs 82 (37.4%) (p=0.00) and Prasugrel was more frequent by MICU physicians 13 (9.2%) Vs 112 (51.2%) (p=0.00). Morphyne was more administered in MICU 49 (34.8%) VS 121 (55.3%) patients (p= 0.00).
The initial attention of patients with STEMI by MICU reduced time to PCI, stay length in ICU: 76.8 (37.4-191.0) Vs 44.8 (36.6-53.1) hours (p= 0.02), and was associated with lower mortality at hospital discharge 13 (9.2%)Vs 8 (3.7%) (p=0.02) and at 30 days compared to those who went to the hospital by themselves 15 (10.6%) VS 10 (4.6%) patients (p=0.02).
CONCLUSION. Around of 40% of patients with STEMI still come to hospital by themselves. An EMS based STEMI networks and MICU with presence of physicians on board allow to reduce the time to PCI and decrease the mortality of patients with STEMI in Guadalajara.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001708

INTRODUCTION. Ventriculo-arterial coupling (Ees) optimisation allows to increase stroke work efficiency and is a parameter of growing interest in intensive care unit. Chen method is the most validated non-invasive method to estimate ventriculo-arterial coupling, yet, several simplified methods are often used at bedside. Those method assume that the end systolic volume pressure relationship (ESPVR) passes through the origin and calculate Ees as a derivate from ESP/ESV. However, neither of those simplification have been tested against Chen method in the intensive care unit.
OBJECTIVES. The objective of the present study was to determine whether the simplifications proposed by Tanoue and Robotham might substitute to Chen formula for the measurement of ventriculo-arterial coupling at baseline and to track ventriculo-arterial coupling change with therapeutic intervention.
METHODS. We perfomed a monocentric retrospective study in Dijon teaching hospital. Ventriculo-arterial coupling was calculated as Ea/Ees. The 3 non-invasive Ea/Ees calculation methods were applied on 87 patients, cardiac surgical ICU patients. The reference method for measuring Ees was this of Chen (1). Ees was also calculated according to Tanoue *et al.* (2): 0.9 * SAP/ ESV and Robotham *et al.* (3)*:* Ea/(1/LVEF)-1. All patients received either fluid expansion (n=35), norepinephrine (n=32) or dobutamine (n= 20) (prescribed by the physician in charge). Measurement were performed before and after intervention.
RESULTS. Eighty seven patients were analysed. Median age was 67 [60-75] years, 76% were male. To measure baseline Ea/Ees, the concordance correlation coefficient (CCC) was of 0.13[-0.05;0.30], the bias was of -0.19, limit of agreement ranged from -4.1 to 3.8 and mean absolute percentage error (MAPE) was of 57% for Tanoue. Regarding Robotham, the CCC was of 0.32 [0.14;0.49] bias was of 0.26, limit of agreement ranged from -2.4 to 2.9 and MAPE was of 42%. When used to follow Ea/Ees evolution with interventions, only 65 and 70% of measures evolved in the same direction (four-quadarant plot analysis with a 15% exclusion zone) respectively for Tanoue and Robotham methods when compared to Chen.
CONCLUSION. Our results do not support interchangeability between Tanoue or Robotham and Chen method. These methods neither allowed a precise estimation of ventriculo-arterial coupling nor to follow its change with hemodynamic treatment.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001756

INTRODUCTION. Management after major cardiac surgery is typically done by the integration of data from monitoring, echocardiography, lab values, imaging techniques and patient observation. Monitoring of pressures and flow is often used to titrate vasoactive and inotropic agents postoperatively. Optimal targets for therapy are often driven by institutional habits but are not universally accepted.
OBJECTIVES. We aimed to determine whether an optimal level of common hemodynamic parameters can be identified that are associated with an improved outcome.

METHODS. We included all patients admitted with a pulmonary artery catheter after cardiac surgery to one ICU from 2012-2015. All data were extracted from the patient data management system Critical Care Manager (PICIS) that stored values every 10 minutes. We calculated first median values for a 1 hour period and excluded thereafter extreme values that are most likely artefacts (e.g. pressures below zero, heart rate below 40 and above 200). For each patient a minimum, maximum and median value for the whole stay was determined. These values were coded as categorical variables based on quintiles, the middle category serving as reference for all logistic regression analysis (STATA 15.1). Results are given as odds ratios with 95% confidence intervals from models including all 3 selected values. We analysed heart rate, systolic blood pressure, diastolic blood pressure, central venous pressure, continuous cardiac output and mixed venous saturation in 645 patients that stayed in the ICU for 219 242 hours. 59 patients died during the hospital stay.
RESULTS. We found a U-shaped association in the combination of minimum and maximum values with the exeption of cvp where high minimum and maximum appear detrimental.
CONCLUSION. We found that simple hemodynamic variables can be analysed to identify an optimal zone where both low minima and high maxima are associated with poor outcome whereas for cvp the lowest values for minimum and maximum are associted with better outcome.
A multivariable model including duration of states may allow safe margins of treatment in the future.

Table 1 (abstract 001756). Odds ratio for hospital death after cardiac surgery

Variable	Q1	Q2	Q3	Q4	Q5
heart rate minimum	6.5(2.4-17.3)	2.9 (1.0-7.8)	1	0.4(0.1-1.6)	0.07(0.01-0.72)
heart rate maximum	0.04(0.005-0.36)	0.11(0.03-0.43)	1	0.9(0.4-2.2)	1.4(0.6-2.2)

Accuracy of arterial dP/dtmax for continual monitoring of left ventricular contractility depends on systemic vascular resistance, heart rate and cardiac output

P. Ostadal, D. Vondrakova, A. Krüger, M. Janotka, J. Naar, P. Neužil
[1]Cardiovascular center, Na Homolce Hospital, Prague, Czech Republic

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001350

INTRODUCTION. Continuous reliable evaluating of left ventricular (LV) contractile function in patients with advanced heart failure requiring intensive care remains challenging. Recently, continual monitoring of dP/dtmax from arterial line became available for hemodynamic monitoring. However, factors influencing the accuracy of arterial dP/dtmax for the assessment of LV dP/dtmax remain not fully understood.
OBJECTIVES. The aim of our study was to determine hemodynamic factors that affect the relationship between arterial dP/dtmax and LV dP/dtmax in patients with acute heart failure.
METHODS. Fifty patients with acute heart failure requiring intensive care, inotropes/vasopressors and hemodynamic monitoring were recruited into the study (mean age 70.2 years, 64% were males). Hemodynamic variables including arterial dP/dtmax were continually monitored using arterial line pressure waveform analysis. LV dP/dtmax was assessed using continuous-wave Doppler analysis of mitral regurgitation flow.
RESULTS. The values from continual arterial dP/dtmax monitoring significantly correlated with the LV dP/dtmax assessed by echocardiography (r=0.70, 95% confidence interval [CI] 0.51-0.82, P˂0.0001). Linear regression revealed that (LV dP/dtmax) = 1.25×(arterial dP/dtmax), P˂0.0001. We analyzed the relation between arterial dP/dtmax and LV dP/dtmax in the subgroups above or bellow the mean value of individual hemodynamic variables. We have found markedly stronger correlation in subjects with higher systemic vascular resistance (>900 dyn.s/cm5, N=20, Spearman r= 0.91, 95%CI 0.78 to 0.97, P<0.0001), in the subgroup with cardiac output <6 L/min, (N=26, Spearman r=0.81, 95%CI 0.60 to 0.91, P< 0.0001) and in patients with heart rate ˂92 beats/min (N=26, Spearman r=0.90, 95%CI 0.79 to 0.96, P˂0.0001).
CONCLUSION. Our results indicate that arterial dP/dtmax values correlate with LV dP/dtmax, particularly in patients with higher systemic vascular resistance, lower heart rate and lower cardiac output. Arterial dP/dtmax could be, therefore, used for continual monitoring of LV contractility especially in hemodynamic conditions corresponding to cardiogenic shock.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001362

INTRODUCTION. Treatment with VV-ECMO or VA-ECMO interferes with thermodilution methods for measuring cardiac output (CO) [1]. The thermal pulse generated in a central vein or the right atrium can be considerably disturbed by or even largely diverted into the ECMO system.
OBJECTIVES. Explore the feasibility of using the water heater unit (HU) circuit of the ECMO system itself as a transducer of defined thermal pulses.
METHODS. A pig with a body weight of 49 kg was anesthetized, ventilated and connected to a Cardiohelp (Maquet Cardiopulmonary AG, Rastatt, Germany) VV-ECMO system. Thermistor-tipped catheters were used to measure the temperature as a function of time T(t) at 3 places: at the venous inlet of the ECMO: T-VE(t), at the arterial outlet of the ECMO: T-AE(t), and in the femoral artery: T-FA(t). The membrane oxygenator was connected with a heater unit (HU) (HU-35, Maquet Cardiopulmonary AG, Rastatt, Germany) that provided a continuous water flow temporarily set at a temperature 1 to 1.5 oC above body temperature. The ability of the ECMO-HU to generate thermal pulses was assessed by interrupting the water flow from the

HU to the ECMO for a few seconds and monitoring T-AE(t), T-VE (t) and T-FA(t). The interaction of the ECMO-HU with incoming thermal pulses was assessed by comparing T-AE(t) and T-VE (t) after central venous injection of 20 ml cold boluses. High time-resolution experiments were performed in triplicate.

RESULTS. Interruption of HU water flow generated a rapid decrease of ≥0.5 oC in T-AE, followed after a median time of 7 seconds by a drop T-VE of 0.1 oC and after 14 seconds by a drop of T-FA by 0.3 oC. Systemic cold bolus injections generated distinct thermal spikes in T-VE (t) and T-AE(t). The nadir value for T-VE was followed 11 seconds later by a nadir value for T-AE. This interval is largely explained by the transit time resulting from the blood flow and dead volume. When the area under the curve of the thermal pulse entering the ECMO system was compared with the pulse leaving the ECMO system, we saw a 66% reduction, indicating considerable thermal transfer to the HU- water circuit.

CONCLUSION. Modifying heater unit water flow or temperature can be used to generate thermal signals in the arterial output of the ECMO system, which are propagated to the venous input of the ECMO system and the femoral artery. Thermal signals originating in the patient are also propagated to the ECMO system and may even be transduced to the water circuit.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001367

INTRODUCTION. The setting of peep during operative period is recommended to avoid derecruitement and atelectasis. High peep decrease venous return and cardiac output and can be deleterious in hypovolemic patients. it is widely accepted that the dynamic indices, pulse pressure variation (PPV) , stroke volume variation (SVV) , systolic pressure variation(SPV) accurately predict fluid responsiveness in mechanically ventilated patients passively adapted to the ventilator.

OBJECTIVES. The **objective** of this study was to evaluate the fluid responsiveness using peep challenge in patients undergoing digestive surgery

METHODS. 30 patients, Asa 1, 55 +-10 years old, without cardiac failure or pulmonary pathology were enrolled for programmed digestive surgery. Anesthesia was performed using propofol, sufentanil and cisatracurium and all the patients were intubated. We evaluated the increase of peep on hemodynamics in patients Asa 1 selected for digestive surgery. This group of 30 patients was submitted to a peep challenge 60 minutes after induction, increasing peep progressively from 4cmh2o to 10 cmh2o with a time of 5 minutes to reach 10cmh2o. We monitored arterial pressure with a catheter inserted in radial left artery and central venous pressure with a three lumen catheter inserted in right jugular vein. We recorded continuously, systolic pressure variation, mean arterial pressure and pulse pressure variation from the arterial wave line. Central venous pressure(CVP) , pulse pressure variation(PPV), systolic pressure variation(SPV) and mean arterial pressure (PAM) were observed and recorded before and after the peep challenge which consisted in increasing peep from 4to 10cmh2o. So, recordings of these hemodynamic parameters were performed at peep 4cmh20 (control value) and at peep 10(peep challenge). Fluid responsiveness was defined as a more than 10% decrease of arterial pressure and pulse pressure variation more than 13% after peep challenge

RESULTS. Statistical analysis was performed using student's t test. We observed finally that peep challenge from control values at peep 4, increase PPV, SPV, CVP and decreases PAM. Results were expressed as mean +- std deviation. PAM(mmHg) decreases from 77,258 +- 4,016 to 69,581+-5,714.(p<0.001). PPV(%) increases from 10,097 +-1,904 to 16,677 +-1,641 (p<0.001). SPV(%)increases from 7,839+-1,393 to 14,968 +-1,835 (p<0.001). CVP(cmh20) increases from 8,516+- 2,143 to 10,129 +-2,061 (p<0,007).After fluid challenge , we came back to the control values.

CONCLUSION. During operative period, the setting of peep 10 (from peep 4) can detect fluid responsiveness in patients undergoing digestive surgery.

Context-sensitive indexation of global end-diastolic volume: A validation study

W. Huber, T. Lahmer, A. Herner, U. Mayr, G. Batres-Baires, S. Rasch, R. Schmid, A. Hoyos

[1]Medizinische klinik und poliklinik ii, Klinikum rechts der Isar; Technische Universität München, Munich, Germany

Correspondence: W. Huber

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001703

INTRODUCTION. Global end-diastolic volume is a static marker of preload. Indexation to body surface area BSA results in GEDVI. Several studies demonstrated better prediction of fluid responsiveness by GEDVI compared to CVP. However, the results are inconsistent and at least two studies suggest inappropriate indexation by BSA (1;2). Furthermore, the two commercially available devices measuring GEDVI use different indexations: The PiCCO uses predicted bodyweight (BW_pred) to calculate BSA_pred, while the EV-1000 uses actual BW to calcualte BSA_act.

Recently, the concept of context-sensitive indexation (CSI) has been introduced to optimize indexation. Based on analyses of a large haemodynamic database including about 20,000 haemodynamic measurements, CSI individually adjusts each haemodynamic parameter according to its specific association to biometric data including age and gender in addition to weight, height and BSA. Furthermore, CSI also adjusts for „contexts" such as atrial fibrillation (AF) , mechanical ventilation and catheter position, which might have a stronger impact on the haemodynamic raw value than biometric data.

OBJECTIVES. This study tried to validate CSI of GEDV (GEDVI_CSI) in a group of 33 ICU-patients with shock undergoing a volume challenge (VC) with 7mL/kg saline 0.9% over 30 minutes.

METHODS. Methods: All patients were equipped with PiCCO-monitoring (Pulsion; Germany) and under assisted mechanical ventilation. Transpulmonary thermodilution was performed immediately before and after the VC. GEDVI_CSI was calculated as described previously using a formula adjusting GEDV for age, gender, weight, height, CVC-position (femoral or jugular) and heart rhythm (sinus

rhythm or AF). Statistics: Primary endpoint: increase in Cardiac Index CI ≥10%. Second endpoint: Change in cardiac power index CPI ≥10%. ROC-analysis. SPSS 25.
RESULTS. 12 (36%) female, 21 (64%) male patients. SOFA 13±4. AF in 7 of 33 patients (21%). 31 of 33 patients were under vasopressor therapy (noradrenaline dosage 1476±3277µg/h).
The VC resulted in significant increases in CI (4.8±2.1 vs. 4.6±2.2L/min/m^2, p=0.002), CVP (16.5±4.8 vs. 13.9±6.3mmHg, p=0.002), GEDVI (831±203 vs. 790±175mL/m^2, p=0.020), MAP (82±10 vs. 76±8mmHg, p=0.001), cardiac power index (0.86±0.36 vs. 0.78±0.42W/m^2, p< 0.001) and stroke volume index (±, p<0.001), while heart rate decreased (100±17 vs. 102±18/min, p=0.006). Stroke volume variation SVV (p=0.287) and pulse pressure variation PPV (p=0.596) did not change significantly.
As expected due to the lack of controlled mechanical ventilation, baseline PPV (AUC=0.566; p=0.566) and SVV (AUC=0.664; p=0.145) did not predict an increase in CI ≥10%. While baseline CVP (AUC=0.423; p= 489), unindexed GEDV (AUC=0.510; p=0.933), GEDVI indexed to BSA_pred (AUC=0.433p=0.554) and GEDVI indexed to BSA_act (AUC= 0.400; p=0.375) did not predict the primary endpoint, GEDVI_CSI was the only significant predictor of an increase in CI ≥10% (AUC=0.745; p= 0.028). Similarly, GEDVI_CSI was the only baseline parameter to predict an increase in CPI ≥10% (AUC=0.733; p=0.025).
CONCLUSION. GEDVI_CSI adjusted according to CSI was the only significant predictor of fluid responsiveness, whereas CVP, SVV, PPV and GEDVI according to all other indexations were not predictive. These data support the concept of context-sensitive indexation.

CVP reduction associated with higher CO favors good prognosis on circulatory shock: a single center, retrospective cohort study

L. Su, X. Wang, Y. Long, X. Zhou, D. Liu
ICU, Peking Union Medical College Hospital, Beijing, China
Correspondence: L. Su
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001676

INTRODUCTION. Changes in cardiac output (CO) caused by central venous pressure (CVP) are the most important concerns in the treatment of shock. It is a pathophysiological axiom that the lower the CVP, the better.
OBJECTIVES. This study was performed to explore how to use CVP and what its relevant mechanisms with respect to CO in the critically ill patients.
METHODS. A total of 134 patients with circulatory shock were retrospectively included and analyzed. Hemodynamic data were recorded and analyzed at PICCO initiation and 24 hr after PICCO. Data regarding 28-day mortality and renal function were also collected.
RESULTS. The patients were divided into a CVP↑+ CO↑ group (n=23), a CVP↑+ CO↓ group (n=29), a CVP↓+ CO↑ group (n=44), and a CVP↓+ CO↓ group (n=38) based on PICCO initiation and 24 hr after PICCO. Post hoc tests showed the CVP↓+ CO↑ group had higher 28-day survival than the other groups [log rank (Mantel-Cox)=8.758, *P=0.033*]. In terms of hemodynamic characteristics, the CVP↓+ CO↑ group had a lower cardiac function index (CFI) (4.1±1.4 /min) and higher extravascular lung water index (EVLWI) (11.0±4.7 ml/kg) at PICCO initiation. This group used more cardiotonic drugs (77.3%, *P<0.001*) and had a negative fluid balance (-780.4±1720.6 ml/24 hr, *P=0.018*) 24 hr after PICCO than the other three groups. Cardiotonic drug use and dehydration treatment was associated with increased CFI (from 4.1±1.4 /min to 4.5±1.3/min, *P=0.07*) and reduced ELVWI (from 11.0±4.7 ml/kg to 9.0±3.5 ml/kg, *P=0.029*). Renal function tests showed that SCr and BUN levels in the CVP↓+ CO↑ group were significantly improved (SCr from 197.1±128.9 mmol/L to 154.4±90.8 mmol/L; BUN from 14.3 umol/L±7.3 to 11.6±7.0 umol/L, *P<0.05*).
CONCLUSION. Lower CVP associated with CO increased, which may improve 28-day prognosis in patients with circulatory shock. Higher CO derived from lower CVP may also contribute to renal function improvement.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001657

INTRODUCTION. Acute Coronary Syndrome (ACS) is one of the leading causes of cardiovascular morbidity and mortality. Therefore, stratification of risk is a very important issue for the prevention and management of ACS.The platelet/lymphocyte ratio, a marker of the systemic inflammatory response, was significantly correlated with mortality during ACS according to several studies.
OBJECTIVES. To study the prognostic value of platelet/lymphocyte ratio in patients admitted to emergency departments for acute coronary syndrome .
METHODS. This was a prospective study, conducted over a period of 3 months from January to March 2019 at the emergency department of CHU La Rabta. We included all patients over the age of 18, admitted for ACS and analyzed the correlation of platelet/lymphoctic ratio (DPR) to intrahospital mortality using SPSS 22 software. The significance threshold was set at 0.05.
RESULTS. We included 100 patients. The average age was 65.74 ± 11.91 and the sex ratio was 1.34. The platelet/lymphoctic ratio (RPL) ranged from 10.35 to 3093.3 with an average of 199.7 ±333.99. We found STEMI in 46% of patients. The percentage of complications was 34% and the mortality rate was 15%. RPL was 150 in 48.2% of patients. We found a significant correlation between an RPL 150 and the mortality rate (p=0.000015, OR=2.6, IC=[0.8318674 -9.099468]). The area under the ROC curve was 0.61.
CONCLUSION. High platelet/lymphocyte ratio could be a predictor of mortality in patients with ACS.

INTRODUCTION. Theupstreampressureforvenous return (VR) is considered to be acombinedconceptualblood pressurewithin the systemic vessels - the mean systemic filling pressure (MSFP). The relevance of the bedside estimation of the MSFP during dynamic changes of the circulation is controversial.
OBJECTIVES. To studie the effect of blood volume on the relationship between VR and central venous pressure (CVP) near zero blood flow.
METHODS. In 9 healthy mechanically ventilatedpigs under anaesthesia, MSFP was estimated from the extrapolated CVP versus VR relationships during inspiratory hold maneuvers (IHMs) with different levels of ventilatory pressure (Pvent), see Maas et al. for a detailed description of the used method (1). VR was recorded continuously using an ultrasonic flow probe, placed around the pulmonary artery. MSFP was measured 3 times during different

volumetric states, i.e. euvolemia or hypovolemia. Hypovolemia was induced by bleeding with 10 ml/kg or until CO was halved compared to baseline. The estimated MSFP values were compared to the arterial blood pressure recording after induced ventricle fibrillation.
RESULTS. Our results revealed a strong linear correlation between cardiac output and CVP (R^2 of 0.92 [range: 0.67-0.99]), during IHMs with different levels of Pvent. Volume status significantly alters the resulting MSFP, 20 ± 1 mmHg and 16 ± 2 mmHg for euvolemia and hypovolemia respectively (Figure 1). This estimation of the MSFP was strongly correlated - but not interchangeable- to the venous blood pressure recording after induced ventricle fibrillation (R^2=0.8 and p=0.045).
CONCLUSION. Absolute values of the VR curve - acquired using IHMs at the bedside – are statistically significant but clinically irrelevant and should therefore not be used to guide clinical volume therapy in its current form.

INTRODUCTION. A radial to central pressure gradient (RCG) is a common finding during a cardiopulmonary bypass or during sepsis. This gradient leads the clinician to under evaluate the arterial pressure that can lead to fluid or vasopressor therapy overuse.
OBJECTIVES. We assessed in the present study the prevalence of RCG in patients in intensive care unit and the accuracy of non-invasive assessment of the radial to humeral pressure gradient (RHG) to detect the RCG.
METHODS. Adults patient in an intensive care unit treated with a vasopressor and equipped with a femoral and a radial artery were selected. We recorded arterial pressure at the radial and the femoral artery invasively, and non-invasively at the four limbs: on the arm at the humeral level and on the thigh and calf at the femoral and at the tibial level. This was repeated each hour for 2 hours. A significant RCG was assessed with the invasive radial and femoral arterial line, defined by either a mean arterial pressure difference of more than 10 mmHg or a systolic pressure difference of more than 25 mmHg. We assessed the prevalence of a RCG, and evaluate the correlation between RCG and RHG. We assessed the diagnostic accuracy of the RHG to detect a significant RCG.
RESULTS. Eighty-one patients were included. A significant gradient occurred in 15 patients with a prevalence of 18.5 % [95% CI: 10.8 - 28.7 %]. Considering the 229 measurements, 41 have shown a significant RCG 17.9% [95% CI: 13.2 - 23.5]. No demographic data were significantly associated with a significant gradient. Systolic RCG correlated with systolic RHG (r^2=0.36; p<0.001) and mean RCG also correlated with mean RHG (r^2=0.34; p<0.001).
The area under the curve of the receiving operative curve (ROC AUC) of the mean RHG to predict the RCG was 0.84 [95% CI: 0.68- 0.97]. The best threshold was 14 mmHg with a specificity of 89% [95% CI: 81- 95] and a sensitivity of 80% [95% CI: 60- 100].
CONCLUSION. A significant RCG occurs in almost one in every five patients Non-invasive RHG assessment can be used to detect a significant HRG.

Fluid Management: Still a cause for concern but possible 'greenshoots' of improvement

R. Leach[1], N. Morton[2], M. Leach[3], M. Ostermann[1]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001414

INTRODUCTION. Daily fluid assessment, prescription and administration are essential daily tasks on intensive care, medical and surgical units. Published data suggests that intravenous (IV) fluid management is poor and patient outcomes are adversely impacted by both under and over hydration. Surgical audit data suggests that fluid related complications occurs in 17-54% of post-operative patients contributing to mortality and increased length of hospital stay.
OBJECTIVES. As clinician knowledge has been identified as a major factor in previous reviews of poor fluid management we examined current knowledge in 348 junior and middle-grade medical doctors in Greater London and compared this to that in consultant intensivists to determine if progress had been made to address this issue in recent years.
METHODS. Pre-registration (PRD; n=146) and junior medical doctors (JMD; n=70), specialty medical trainees (SpR; n=133) from 'acute' (e.g. ICU) and non-acute (e.g. rheumatology) medical specialties and consultant intensivists (CIs; n=18) were asked to complete a structured questionnaire which included: 1. Assessment of their previous training in fluid management; 2. How often they had managed fluid related complications (and whether these were reported as significant incidents); 3. Twenty 'best of 5' multiple choice knowledge questions (10 of these questions were similar to those used in previous fluid knowledge assessments (2001-2018) to enable change over time to be assessed) 4. Self-reported confidence in relation to fluid prescription. For comparison 18 CIs completed the questionnaire. Aspects of knowledge addressed included electrolyte composition of commonly administered IV fluids, normal daily fluid and electrolyte requirements and excretory mechanisms, fluid distribution, fluid and electrolyte physiology in health and disease and 4 clinical scenarios relating to the UK NICE guideline (CG 174) 'IV fluid therapy in adults in hospital'.
RESULTS. As in previous reports, PRD and JMD responsible for most IV fluid prescriptions, reported limited training (<10hrs) during medical school and early clinical training. Fluid related complication

were common and had been managed by 25% PRD (mainly <5 episodes) and 90% of JMD and SpR (<5 to >20 episodes). The majority of these were 'never' or 'rarely' reported. On the multichoice questions CIs correctly answered 15.1±2.1 (mean±SD) questions. PRD achieved 6.66±2.4; JMD 8.37±2.6 and SpR 8.14±2.84 correct answers (with 'acute' specialty SpRs performing significantly better than non-acute specialities). Compared to previous knowledge assessments there were improvements in knowledge related to several areas including sodium content of commonly prescribed fluids, daily water and electrolyte requirements and NICE guidelines. Self reported confidence in fluid management was higher than might be expected based on multiple choice question results in all groups except CIs.
CONCLUSION. This study suggests that although fluid management remains a cause for concern in junior clinicians, with evidence of relatively poor training, failure to report complications, poor overall knowledge scores and over-confidence, there is evidence of improvement in a number of key areas previously highlighted in the UK NICE guideline CG174.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001415

INTRODUCTION. Ventriculoarterial coupling (VAC) is often impaired in septic shock patients. Fluid administration is one of the most used treatments in these patients, but its effects on VAC have been scarcely described until now. We made the hypothesis that VAC improves with a preload increase only in case of preload responsiveness because, in this condition, the fluid-induced increase in stroke volume may decrease the arterial elastance (Ea) with lesser effects on the ventricular end-systolic elastance (Ees).
METHODS. We included septic shock patients in whom fluid administration was mimicked by a passive leg raising (PLR) test. Hemodynamic variables and transthoracic echocardiography data before and during the PLR test were compared. Preload responsiveness was defined by a PLR-induced increase in cardiac output ≥10%. VAC was calculated as the ratio of Ea over Ees. Ea was calculated as 0.9 x systolic arterial pressure/stroke volume. Ees was calculated according to the method validated by Chen et al [1].
RESULTS. We performed 31 measurements among 20 patients (SAPSII on admission = 50±13, SOFA = 10±3, 28-day mortality = 30%, pneumonia in 55% of cases, norepinephrine administered in all cases). The PLR test revealed 8 preload responder cases (R) and 23 non-responder cases (NR). The left ventricular end-diastolic volume increased to a similar extent in R and NR (from 67 [57-85] to 75 [67-92] mL in R, from 75 [58-92] to 83 [68-101] mL in NR). Stroke volume increased by 19 [14-23]% in R and by 4 [0-4]% in NR. In R, Ea significantly decreased from 2.46 [1.59-2.65] to 2.01 [1.49-2.61] mmHg/mL and Ees did not change significatively (from 2.05 [1.6-2.78] to 2.09 [1.56-2.64] mmHg/mL). As a result, VAC significantly decreased from 1.14 [0.83-1.44] to 1.02 [0.74-1.3] in R cases. Among NR cases, neither Ea nor Ees showed a significant change during PLR (p=0.80 and p=0.20, respectively). Similarly, VAC did not change in these cases (p=0.18).
CONCLUSION. These results suggest that, in septic shock patients, increasing cardiac preload improves VAC only in cases of preload responsiveness. This suggests an improvement in cardiac efficiency with fluid under this condition. The inclusions are ongoing.

Can dynamic changes of pulse pressure variation during passive leg raising or a tidal volume challenge help predicting preload responsiveness in mechanically ventilated patients with spontaneous breathing activity

O. Hamzaoui[1], R. Shi[2], S. Carelli[2], C. Gouëzel[1], B. Sztrymf[1], D. Prat[1], F. Jacobs[1], JL. Teboul[2]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001424

INTRODUCTION. Predicting preload responsiveness by using dynamic indicators before administering fluids to critically ill patients is nowadays routinely performed at the bedside (1). Unlike other dynamic indicators of preload responsiveness that require cardiac output monitoring, pulse pressure variation (PPV) can be simply obtained via an arterial catheter (2). However, PPV is not reliable in mechanically ventilated patients with spontaneous breathing activity (2). We hypothesized that an increase in PPV after a tidal volume (TV) challenge (TVC) or a decrease in PPV during passive leg raising (PLR) will predict preload responsiveness in such cases.
OBJECTIVES. to examine if the change in PPV during PLR and after a TVC can predict preload responsiveness in patients with mechanical ventilation and persistent spontaneous breathing
METHODS. Prospective non interventional study conducted in two intensive care units. Patients under mechanical ventilation with spontaneous cycles, for whom the physician in charge decided to test preload responsiveness were included. Firstly, transthoracic echocardiography was performed to measure the velocity time integral (VTI) of the left ventricular outflow tract and to calculate delta VTI before and during PLR. Patients were considered as preload responsive when delta VTI was ≥10% (3). Secondly, a TVC was performed by increasing the TV by 2mL/kg predicted body weight from its baseline value. PPV was recorded before and after the TVC.
RESULTS. Thirty patients were included, their mean age was 61 ± 16 and their SAPSII was 57 ± 17. At baseline the TV was of 6.2±0.7 mL/kg predicted body weight, their PEEP was of 11±4 cmH2O and their plateau pressure was of 20±5 cmH2O. Norepinephrine was administered in 29 patients, its mean dose was of 0.37±0.44 µg/kg/min. The blood lactate was of 1.3 [1.1-1.9] and the MAP was 83 ± 12 mmHg. According to the PLR test, 14 were preload-responders and 16 non responders. PPV at baseline predicted preload responsiveness with an area under the receiver operating characteristic curve (AUROC) (with 95% CI) of 0.53 (0.33-0.71). During PLR, the absolute decrease in PPV predicted preload responsiveness with a sensitivity of 86%, a specificity of 63%, an AUROC (95% CI) of 0.72 (0.53–0.87) and a cutoff value of -1%. The increase in PPV during the TVC predicted preload responsiveness with a sensitivity of 71%, a specificity of 88%, an AUROC of 0.74 (0.55–0.89) with a cutoff value of 2. The

AUROC values for decrease in PPV during PLR and for increase in PPV during TVC were similar but were significantly different from 0.5 and from that for baseline PPV.
CONCLUSION. In mechanically ventilated patient with spontaneous breathing activity, PPV does not predict fluid responsiveness, however either the decrease in PPV during PLR or the increase in PPV during a TVC may help physicians to distinguish preload responders from non-responders with an acceptable accuracy.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001429

INTRODUCTION. Surgical procedures cause pain – neuroendocrine (1), inflammatory and immune response that can be modified by anaesthesia (2, 3).
There are several opioids that are used for perioperative and postoperative analgesia: sufentanil (S), alfentanil (AL), remifentanil (R) and fentanyl (F).
OBJECTIVES. Objectiveof this study wasto compare the effects of these opioid analgesic regimens on cardiovascular and hormonal reaction of patientsundergoing elective aortal aneurism surgery under general endotracheal anaesthesia.
METHODS. A total of 60 elderly patients, ASA 3, scheduled for elective surgery of aneurysms of abdominal aorta were randomized in four equal groups to receive either *F*(0.1 μg/kg *iv*bolus +0.1 mg maintenance dose) or a equivalent doses of *AL*, *R*and *S*.
Haemodynamic parameters and concentrations of prolactine (PRO), cortisol (COR) and growth hormone (GH) were determined at critical points: baseline (BL), intubation (INT), first incision (FI), surgical manipulation (SM), extubation EXT and 24 h postop (24hPO). Analgesics were repeated hourly or if cardiovascular parameters changed by more than 20% of their BL values.
A blood sample of 10 ml was taken 10 min after insertion of *iv*catheter (BL) and sampling and was repeated at critical points of operations and 24 h postoperatively.
RESULTS. In the *F* group there was a significant increase in systolic and diastolic BP after INT and SM as well as pulse pressure after SM. Diastolic BP was significantly increased after EXT.
A decrease in systolic pressure was found after INT in the *R, S* and*AL*group (by 32±5%, 25±4% and 18±2%, respectively). Pulse pressure was significantly increased at SM and 24 h postop in the *R*group.
Emergence from anaesthesia was best after use of R (4.9±5 vs. 9.5±2, 12 .9±8 ;12.6±2min in F, Al and S group, respectively). Postoperative analgesia was significantly shorter after use of R (27±6 min) than of *F, S*and AL (50±6, 55±8and 42±7 min, respectively).
Only COR positively correlated with mean arterial pressure (MAP) in all opioid groups, while there were no correlations between PRO or GH and cardiovascular parameters.
During the maintenance of anaesthesia, prolactin values were significantly increased in all groups in Iphases of NT, M and EXT.
CONCLUSION. Cortisol plasma concentration correlates positivelywith cardiovascular parameters in patients undergoing elective surgery of abdominal aorta aneurysm during the operation and thereafter under all used opioid regimens. Its suppression is better marker of analgesia than the changes of prolactin and GH levels.

Ectracorporal heart and lung support (ECLS/ECMO) for patients with refractory cardiogenic shock - boon or bane?

JKM. Fichte[1], HB. Hopf[2]
[1]Asklepios Klinik Langen, Langen (Hessen), Germany; [2]Anestesia and perioperative medicine, Asklepios Klinik Langen, Langen (Hessen), Germany
Correspondence: J.K.M. Fichte
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001651

INTRODUCTION. Patients with cardiogenic shock refractory to treatment still have a very poor prognosis with a hospital mortality above 50%(Thiele, EurHeartJ 2015).
Therefore in patients with refractory cardiogenic shock extracorporal support (ECLS) is increasingly used to treat such patients in order to decrease mortality. However only limited data about the results are availaible. Accordingly we evaluated all patients with refractory cardiogenic shock treated with an ECLS between 2015 and 2018 in our department.
OBJECTIVES. Comparing the predicted mortality (SAVE score) with the actual hospital mortality in patients with refractory cardiogenic shock and treatment with an extracorporal support (ECLS).
METHODS. We compared the predicted hospital mortality with the actual hospital mortality of all patients with refractory cardiogenic shock treated with extracorporal support in the Asklepios Klinik in Langen, Germany (Department of Anestesia and perioperative medicine) between January 2015 and December 2018. To predict mortality we used the SAVE-score, which has been developed by Schmidt. et al. (2).
We devided all patients treated in a palliative care group (patients with unfavorable prognosis and short survival times due to poor neurological outcome/ strict living will) and a non palliative care group.
RESULTS.
CONCLUSION. The actual in hospital mortality of our non palliative care patients was less than half oft that predicted by the SAVE-score. In addition in the non palliative care patients with refractory cardiogenic shock treated with ECLS the hospital mortality was about one third lower than the mortality published in current literature.
Thus, the use of an extracorporal support system like ECLS might improve mortality in patients with refractory cardiogenic shock.
A randomized prospective evaluation of ECLS/ECMO application in patients with refractory cardiogenic shock (ECLS-SHOCK) is under way to answer this question.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**3000698

INTRODUCTION. Intestinal fatty acid binding protein (I-FABP) is a cytosolic protein in the (mainly) small intestine that is released into circulation upon enterocyte necrosis and rapidly cleared renally (Treskes 2017). As such it parallels the onset and cessation of enterocyte damage, e.g. due to ischaemia. Little is known about I-FABP dynamics in a general ICU population.
OBJECTIVES. To describe I-FABP in ICU patients during their first week of stay.
METHODS. Consecutive adult patients in 5 ICUs were studied. Plasma was collected immediately after ICU admission and thereafter daily. Following storage at -80 °C, samples were analyzed for I-FABP using ELISA (R&D Systems Inc., US). I-FABP values between groups were compared using the SPSS Median Test for each day separately.
RESULTS. I-FABP was measured in 224 patients (median age 66.5, range 29-94 years; median APACHE II 18, IQR 11-23; 28 day mortality 10.3%). Median I-FABP level of all measurements was 903 (425-1862), being higher in 28 d survivors [963 (IQR 461-1882)] *vs* nonsurvivors [502 (IQR 284-1197) pg/mL]. Median of individual highest I-FABP values was 2596 (IQR 1286-4691) pg/mL and occurred on admission day in 69% of patients. I-FABP levels were lower in patients after GI surgery (days 3-4) and in patients with sepsis (days 1-3) compared to patients without these conditions respectively. Figures present I-FABP dynamics in all patients, 28 d survivors *vs* nonsurvivors, sepsis *vs* no sepsis and GI surgery *vs* no GI surgery.
CONCLUSION. I-FABP levels were elevated at admission, but rapidly decreased to the reference range by day 2. Interestingly, and different from previous observations, rather lower I-FABP levels were observed in nonsurvivors *vs* survivors and in sepsis *vs* no sepsis.

Factors associated with blood transfusions and early extubation in liver transplantation recipients. Prospective observational preliminary data

C. Spina[1], G. Burgio[2], G. Martucci[2], M. Barbara[3], D. Pagano[3], M. Farbo[2], F. Lullo[2], G. Chiaramonte[2], R. Fumagalli[4], S. Gruttadauria[3], A. Arcadipane[2]

INTRODUCTION. Fluid restriction and early extubation in operating room are recent procedures introduced in the perioperative management of

liver transplantation (LT) recipients in order to avoid hemodilution, blood transfusion and to minimize ICU stay and complications.
METHODS. This prospective cohort study included 18 consecutive patients who underwent a deceased-donor LT at ISMETT from September 2018 to March 2019. Packed red blood cells (PRBC) transfused and early extubation were analyzed in relation to pre and intraoperative variables. LT were performed with the standard technique with or without veno-venous bypass.
RESULTS. Patient characteristics, intra and postoperative variables are described in table 1.
Major indications for liver transplantation were cirrhosis caused by viral diseases n= 7 (38.9%) followed by NASH syndrome n=6 (33.3%).
The overall intraoperative PRBC transfusion was 1.7 ± 2.5 units on average. Patients who received blood transfusions (n=8, 44%) needed in median 3.5 PRBC (2.5-5.5).
Patients were divided between those no required blood transfusion versus those received more than one unit. The factors associated with PRBC transfusions are listed in table 2.
Patients extubated in operating room (n=13, 72%) had a significant lower dose of norepinephrine used during transplantation [0.1 vs 0.3, p 0.019] and were all treated with neuromuscular blockade reversion by Sugammadex (p<0.001).
CONCLUSION. These preliminary results show that low preoperative Hb, high INR value, MELD score, CP, high dose of norepinephrine and long time of surgery and anaesthesia were associated to the need of intraoperative blood transfusions during LT. These data provide also an external validation of the Mc Cluskey index as predictor of intraoperative blood loos. Hemodynamic stability and Sugammadex use were associated with extubation in OR during LT. Further increase of the sample size should confirm these preliminary results.

Comparison of Two Different Nasogastric Feeding Strategies in terms of Gastrointestinal System Complications

E. Ounde, O. Ekinci, A. Ozgultekin
[1]Anaesthesiology and intensive care, University of Health Sciences, Haydarpasa Numune Training and Research Hospital, Istanbul, Turkey
Correspondence: E. Ounde

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000788

INTRODUCTION. Gastrointestinal system(GIS) complications are frequent within first 7 days in patients started to feed by enteric route in Intensive Care Unit(ICU).Researches have been published reporting that these complications are due to the product, the patient or the feding method.(1)In this study, we aimed to investigate and compare the rates of complicaitions related to feeding method. Which today frequently used methods are continuous feeding(CF) and intermitent feeding(IF) via nasogastric tube.
METHODS. After obtaining approval of Institutional Ethics Committee, the patients, who admitted to ICU for different reasons within 4 months, aged 18-95, who had no GIS pathology, no contraindication for enteral nutrition, were included the study and randomly assigned to CF and IF group.Informed consets of subjects were obtained.After reaching the aimed calories within 72 h, diarrhea, constipation, aspiraiton, distantion, residue, nausea and reflux recorded for 7 days.Significance was defined as p<0.005.
RESULTS. The study was performed with a total of 62 cases (31(50%) male and 31(50%) female).The mean age was 74.45 ± 13.43 years. 37(59.7%) patients were followed-up with CF and 25 patients(40.3%) with IF. Results showed that there was no statistically significant difference between these two groups. Complications rates are summerized at Table 1.
CONCLUSION. In the studies comparing CF and IF, stool frequency is higher and access to aimed calories is delayed in the IF compared to CF.(2) However, some other studies declared that there was no significant difference in the effects of both methods related to GIS functions. (3) In our study, although there was no statistically significant difference between the two groups, the rates of two complicitons showed clinically significance. The rate of distension was higher in patients IF (CF-3(%8,1),IF-6(%24)),while the rate of diarrhea was higher in patients CF(CF-10(%27),IF-5(%20)).As a result,CF did not show any superiorty to IF in terms of GIS complications. We suggest that IF can be considered as an option in selected critically ill patients.

Effects of Omega-3 Fatty Acids on Proinflammatory Cytokines in an Experimental Model of Sepsis

M. Arslan, A. Kuntman, K. Demirag, M. Uyar
Anesthesiology and intensive care, Ege University Hospital, Izmir, Turkey
Correspondence: M. Arslan
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000794

INTRODUCTION. Cytokines play a role in the pathogenesis of sepsis by mediating the dysregulation of immune response. Omega-3 fatty acids may exert anti-inflammatory effects, affecting various elements of inflammation together with proinflammatory cytokines.
OBJECTIVES. The aim of the present study was to investigate the effects of omega-3 fatty acids on the level of proinflammatory cytokines and survival in a sepsis rat model.
METHODS. In the study, 40 adult Wistar albino rats weighing 300-350 g were divided randomly into three groups: the Sham Group (n= 10): Tactile stimulation of the intestine and cecum after laparotomy, the Control Group (n=15): Saline solution (1 mL/kg/day) administered intraperitoneally for one week before the induction of an abdominal sepsis model through cecal perforation, and the Omega-3 Group (n= 15): Omega-3 fatty acid lipid emulsion (1 mL/kg/day) administered intraperitoneally for one week prior to the induction of an abdominal sepsis model through cecal perforation. After one week period, serum interleukin (IL)-1, IL-6 and tumor necrosis factor-alpha (TNF-α) levels were measured prior to surgery (basal value) and 3 hours after surgery in all groups.
RESULTS. The 24-hour survival rates were 60% in the omega-3 group and 13.3% in the control group (p=0.008). Serum IL-1, IL-6, and TNF-α levels were significantly lower in the omega-3 group than in the control group at hour 3 (p<0.001).
CONCLUSION. We determined the positive effects of omega-3 fatty acids on proinflammatory cytokine levels, immune response development, and survival in experimental sepsis rat model that is considered to be related to the anti-inflammatory and immunomodulator properties of omega-3 fatty acids.

Metabolomic alterations in ICU patients with worsening of multiorgan failure

J. Helleberg[1], J. Wernerman[2], O. Rooyackers[2]
[1]Perioperative Medicine and Intensive Care, Karolinska University Hospital, Stockholm, Sweden; [2]Department of clinical science, intervention and technology, Karolinska Institute, Stockholm, Sweden
Correspondence: J. Helleberg
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000801

INTRODUCTION. Multiorgan failure is the leading cause of death in the ICU. The severity of multiorgan failure, as defined by the Sequential Organ Failure Score (SOFA), as well as increases in SOFA score are known predictors of death during and after intensive care.
OBJECTIVES. To identify the metabolomic profile at ICU admission that is related to worsening of multiorgan failure versus improving of multiorgan failure during early ICU stay.
METHODS. Consecutive patients over 18 years old admitted to the ICU at the Karolinska University Hospital between September and December 2017 were included if they gave written consent and had no prior decision of withholding treatment. Plasma was sampled on ICU admission and analyzed for metabolomics. Liquid-Chromatography Mass Spectrometry (LCMS) and Gas-Chromatography Mass Spectrometry (GCMS) were used for targeted metabolomics analysis. SOFA scores were calculated automatically using data from the electronic medical record. DeltaSOFA was calculated as the difference between the highest SOFA score on ICU day 2 or 3, and the initial SOFA score. Fisher's exact test was used for non-parametric data. T-tests with False Discovery Rate adjusted P-values and Fold Change Analysis were used to identify compounds that varied significantly between the two groups. R version 3.5.3 and MetaboAnalyst 4.0 were used for all statistical analyses.
RESULTS. From 100 patients, data to calculate DeltaSOFA were available in 89 patients. Metabolomics data were available for 87 patients, out of which 19 patients had DeltaSOFA≥2. Mortality at 30 days was 5/19 in patients with DeltaSOFA≥2, compared to 2/68 in patients with DeltaSOFA<2 (p = 0.0049).
A total of 369 metabolites were identified. 17 metabolites were significantly different at admission between patients with DeltaSOFA<2 and patients with DeltaSOFA≥2, using a P-value cutoff of 0.1 and a fold change threshold of 2.
The 17 significant metabolites were classified according to the Human Metabolome Database (HMDB) (Table 1).
CONCLUSION. Early increase in SOFA score is associated with 30-day mortality. In this pilot study changes in levels of metabolites of different classes at admission are seen in patients with increase of SOFA score during their early ICU stay, suggesting alterations in multiple metabolic pathways in parallel. These findings need to be validated in cohorts with different case-mix and ethnicity.

Usefulness of modified Nutrition Risk in Criticallly ill score to determine the risk of malnutrition in ICU patients

S. Canelles[1], MC. Gilavert[1], M. Cartanyà[1], J. Gómez[1], F. Esteban[1], M. Bodí[1]
[1]Intensive care unit, Hospital Universitari de Tarragona Joan XXIII, Tarragona, Spain
Correspondence: S. Canelles
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000961

INTRODUCTION. The identification of reliable parameters which can help ICU professionals to identify patients at high risk of malnutrition could be important in terms of reducing length of stay, mechanical ventilator days or mortality in ICU. According to the different societies (European Society for Clinical Nutrition and Metabolism, American Society for Enteral and Parenteral Nutrition, Society of Crtical Care Medicine, Canadian Critical Care Nutrition), there is no consensus in which might be the best values to be included in this evaluation.
OBJECTIVES. Determine whether there are differences between ICU patients at low against high risk of malnutrition according to modified Nutrition Risk in Critically ill (NUTRIC) score values.
METHODS. Retrospective study of cohorts carried out in a 30-bed polyvalent ICU. Inclusion criteria: patients admitted to ICU (May 2018 - March 2019) with nutritional risk calculated. Nutritional risk was categorized by the modified NUTRIC score (0-4 Low risk; 5-9 High risk). All data were acquired from our Clinical Information System (Centricity Critical Care from General Electric) database through Extract, Transform and Load processes using Qlik Sense scripts. Statistical analysis was performed using R (https://cran.r-project.org/), applying chi^2 test for categorical variables and the Mann-Whitney U test for continuous variables. P values < 0,05 were considered significant.
RESULTS. 506 patients out of 865 incomes were included. Median age 63 (50-73), 64% male, median APACHE II 20 (15-26), median SOFA 4 (2-6), median length of stay 4,8 (2,6-10,75) days, median days

of mechanical ventilation 5 (2-13), median days with vasopressors 4 (2-7) and 13.24% of mortality.
High risk of malnutrition was determined in 124 patients. Comparing the variables obtained between both groups, there were significant differences in terms of gender, age, days of mechanical ventilation and days with vasopressors, administered KcaL, length of stay in ICU and mortality. No differences in days of renal replacement therapy or administered proteins were found.
CONCLUSION. Modified NUTRIC score could be a good parameter to identify patients at high risk of malnutrition in the ICU. The detection of these patients has changed the professionals' attitude towards the administered KcaL according to the required needs.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000970

INTRODUCTION. Vitamin C deficiency is common in critically ill patients. Vitamin C, the most important antioxidant, is likely consumed during oxidative stress and deficiency is associated with organ dysfunction and mortality [1-4]. Assessment of vitamin C status may be important to identify patients who might benefit from vitamin C administration. Up to now, vitamin C concentrations are not available in daily clinical practice. Recently, a point-of-care device has been developed that measures the static oxidation-reduction potential (sORP), reflecting oxidative stress, and antioxidant capacity (AOC).
OBJECTIVES. Aim of this study was to determine whether plasma vitamin C concentrations were associated with plasma sORP and AOC.
METHODS. Plasma vitamin C concentration, sORP and AOC were measured in three groups: healthy volunteers, critically ill patients, and critically ill patients receiving 2- or 10-grams vitamin C infusion. Its association was analysed using regression models and by assessment of concordance.
RESULTS. We measured 211 samples obtained from 103 subjects. Vitamin C concentrations were negatively associated with sORP (R2= 0.816) and positively associated with AOC (R2=0.842). A high concordance of 94-100% was found between vitamin C concentration and sORP/AOC.
CONCLUSION. Thus, plasma vitamin C concentrations are strongly associated with plasma sORP and AOC, as measured with a novel point-of-care device. Therefore, measuring sORP and AOC at the bedside has the potential to identify and monitor patients with oxidative stress and vitamin C deficiency.

Correspondence: R.A. Posma

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000986

INTRODUCTION. Lactate is a strong prognostic marker for outcome of critically ill patients.[1] Metformin-associated lactic acidosis is a rare but severe complication of metformin therapy. It is unknown whether the prognostic value of lactate is different among critically ill metformin users, because metformin may cause elevated lactate levels in itself.[2]
OBJECTIVES. To determine whether the association between early lactate level and mortality during critical illness is different in metformin users compared to metformin nonusers, we conducted a registry-based cohort study of patients admitted to an intensive care unit (ICU) with available arterial or venous lactate levels and extensive data on preadmission drug prescriptions.
METHODS. The cohort study included patients admitted to ICUs in northern Denmark between 2010 and 2017 with any lactate measured during the period from 12 hours before until 6 hours after ICU admission. The association between mean lactate in this period and 30-day mortality was determined for metformin users and nonusers by estimating hazard ratios (HR) with 95% confidence interval (95%CI) using Cox regression analysis. The magnitude of effect measure modification was assessed by calculating the relative excess risk due to interaction (RERI).[3]
RESULTS. Of 37,293 included patients, 3831 (9%) used metformin at the time of ICU admission. Median (interquartile range) lactate level was 1.6 (1.0-2.7) mmol/L in metformin nonusers and 1.8 (1.2-3.2) mmol/L in metformin users, respectively. Compared to metformin nonusers with a lactate level of <1.3 mmol/L, metformin users within the same lactate category had no increased risk to die (HR 0.94, 95%CI 0.78-1.14). Compared to nonusers with a lactate level of <1.3 mmol/L, metformin nonusers with lactate level between 1.3 and 2.0 mmol/L had increased mortality (HR 1.46, 95%CI 1.36-1.57), while this association was less pronounced in metformin users (HR 1.16, 95%CI 0.97-1.39, RERI -0.24, 95%CI -0.52 to 0.03). Higher lactate categories were strongly associated with mortality, and the magnitude of effect measure modification by metformin use increased accordingly.
CONCLUSION. In this large observational cohort of critically ill patients, increasing lactate levels were strongly associated with mortality. However, this association was only present at higher lactate levels for

metformin users compared to nonusers, indicating that the prognostic value of lactate was modified by metformin use. Therefore, elevated lactate levels should be interpreted differently in these patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001038

INTRODUCTION. Acid-base status is related to the changes in hydrogen ion concentration ([H+]), and it is affected by three independent variables: carbon dioxide, strong ion difference and weak acids (1,2). Recently, unmeasured anions (UAs), which are determined by calculating strong ion gap (SIG), have also been added as the 4th independent variable (3). Additionally, they have been mathematically linked to the total pH (pHtot) (4). However, the effects of independent variables on pHtot changes have not been made a current issue until now.

OBJECTIVES. We hypothesize that there are nine independent variables which directly effect pHtot and the sum of the effects of each of them on [H+] is equal to the pHtot's deviation from 7.40.

METHODS. The pHtot formula was revised by using 8 independent variables instead of HCO3;

$$\mathrm{pHtot} \;=\; 6.1 + \frac{(\mathrm{Na\text{-}Cl}) + \mathrm{KCa} + \mathrm{Mg\text{-}Lactate\text{-}[Alb]\text{-}[Pi]\text{-}UA}}{0.03 \times \mathrm{CO2}}$$

Delta-pHtot (ΔpHtot) was defined as the pHtot's deviation from 7.40. The normal values for Na-Cl difference and albumin were accepted as 32mmol/L and 42g/L (5). The midpoints of current normal limits were accepted as normal for K, Ca, Mg, lactate and inorganic phosphorus (Pi) (4, 1.22, 0.86, 1.1, 1.2 mmol/L respectively) whereas UAs' normal value was accepted as zero. According to the pHtot formula, the deviations from 7.40 caused by every unit change in an independent variable were named as its ΔpH while other independent variables were normal. Every ΔpH formula was obtained from correlation graphs between independent variables' deviations and ΔpHs by using Pearson correlation test. This newly created mathematical model was named as 'The Partitioned pH Model' and used in this prospective observational study.

$$\begin{aligned}\Delta\mathrm{pHtot} = {} & \Delta\mathrm{pHCO2} + \Delta\mathrm{pH(Na\text{-}Cl)} + \Delta\mathrm{pHK} + \Delta\mathrm{pHCa} \\ & + \Delta\mathrm{pHMg} + \Delta\mathrm{pHLactate} + \Delta\mathrm{pH[Alb]} + \Delta\mathrm{pH[Pi]} \\ & + \Delta\mathrm{pHUA}\end{aligned}$$

All patients over 18 years old who were admitted to ICU were included. Demographic data, blood gas parameters, and calculated ΔpHs were recorded. The multivariate linear regression model was used to detect pHtotal's independent variables. UAs values of patients were calculated with two different ways: SIG and ΔpHUA. To calculate ΔpHUA, the sum of all independent variables' ΔpHs was subtracted from ΔpHtot. Pearson correlation test was used for the correlation between ΔpHUA and SIG.

RESULTS. One hundred and twenty blood gas samples of thirty-one patients were evaluated. In the multivariate linear regression model, 1mmol/L increase in Na-Cl difference, K, Ca and Mg caused 0.015, 0.018, 0.023, 0.025 increase in pHtot, whereas 1mmHg increase in carbon dioxide and 1g/L increase in albumin and 1mmol/L increase in lactate, Pi and SIG caused 0.01, 0.004, 0.017, 0.032, 0.015 decrease in pHtot respectively ($p<0.05$ for all). ΔpHUA was significantly correlated with SIG ($p<0.001$ $R2=0.95$).

CONCLUSION. The partitioned pH model allows us to discuss the acid-base status through [H+] changes by separately determining effects of nine independent variables on ΔpHtot. Hence, the usage of this model leads us to clearly identify all metabolic components together with carbon dioxide in critically ill patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001046

INTRODUCTION. Severe liver failure is often accompanied by low plasma albumin (P-alb). This might in part be caused by poor synthesis capacity of the liver, but the relation to other indices of compromised liver function is sparsely investigated in literature.1,2

OBJECTIVES. To study the absolute synthesis rates of albumin and fibrinogen in patients with advanced liver cirrhosis, Child-Pugh scores B and C. To correlate these synthesis rates to Child-Pugh and MELD scores, and to describe albumin pharmacokinetic parameters of distribution.

METHODS. Patients (n=28) were studied while under evaluation for liver transplantation. Synthesis rates of albumin and fibrinogen, were estimated by the flooding technique using deuterium labeled phenylalanine. Plasma volume and transcapillary escape rate of albumin was assessed by radio iodinated (125I) human serum albumin.

RESULTS. Albumin absolute synthesis rate was 65 (30-203) mg/kg/day and was negatively correlated to Child-Pugh ($rs = -0.60$, $p = 0.0008$) and MELD scores ($rs = -0.62$, $p = 0.0005$). Fibrinogen absolute synthesis rate was 12.8 (2.4-52.9) mg/kg/day and correlated negatively to both Child-Pugh score ($rs = -0.47$, $p = 0.013$) and MELD ($rs = -0.48$, $p = 0.010$). Spearman rank correlation (rs) between these rates was 0.717 ($p<0.0001$). Transcapillary escape rate was 6.2 ± 2.1 % per hour, and plasma volume was 4.3 ± 0.7 L. With a P-alb of 26.5 ± 4.5 g/L, the corresponding intravascular albumin mass amounted to 113 ± 29 g.

CONCLUSION. Worsened liver function was related to lower synthesis of both albumin and fibrinogen. P-alb was low, but, because plasma volumes were increased compared to anthropometric values i.e. an increased volume of distribution, the total intravascular albumin mass was only slightly lower than normal values.

Factors associated with discrepancy between prescribed and administered enteral nutrition in general ICU

J. Nurkkala
University of Oulu, Oulu, Finland
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001104

INTRODUCTION. Enteral nutrition (EN) is reported to have several advantages over parenteral nutrition (PN) in critically ill patients[1,2]. Benefits of EN compared to PN include shorter length of stay (LOS), improved bowel function and lower incidence of infectious complications[1,2]. However, the results of previous studies suggest that there is a gap between prescribed and administered EN [3-5].
OBJECTIVES. The aim of this study was to find out the success rate and factors associated with inadequacy of EN delivery in mixed general intensive care unit (ICU).
METHODS. A retrospective single center study of 892 patients with ICU LOS ≥4 days. The factors associated with adequacy of enteral nutrition on day 4 were analyzed. These included disease specific factors, patient related factors, severity of illness and procedural factors.
RESULTS. Of the 892 patients, 349 (39.1%) had EN success rate of ≥70%, which was associated with lower amount of prescribed enteral energy (500 kcal [500-800] vs 800 kcal [500-1200], P<0.001), bolus administration of enteral nutrition (41 of 349 vs 27 of 543, P<0.001), GI (gastro intestinal) diagnosis OR (1.83 (1.15-2.91), P=0.01), severe inflammation (CRP≥100) OR (1.42 (1.08-1.88), P=0.01) and surgery on d4 OR (2.31 (1.12-4.78), P=0.02).
CONCLUSION. In this study we found that in fourth day during ICU stay discrepancy between prescribed and administered enteral nutrition was associated to severe inflammation, GI-related diagnosis, surgical procedures on day 4 and prescription policy. In our study the patients receiving bolus EN had higher caloric intake and it was closer to prescribed amount of administered enteral calories compared to those receiving continuous EN infusion.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001164

INTRODUCTION. Malnutrition is frequent in intensive care unit (ICU) patients and it is related with higher morbidity and mortality rates, more risk of infectious diseases and higher costs of illness. In this study, we aimed to evaluate the effect of frequently used malnutrition scoring systems on ICU outcome in patients who were consulted to nutritional support unit (NSU) in tertiary ICU's of a university hospital.
METHODS. In this study, ICU patients who were consulted to NSU between 2014-2018 in Gazi University Hospital were enrolled. Relationship between rates of reaching nutrition targets and clinical outcomes were evaluated. Nutritional Risk Screening-2002 (NRS-2002) score, Subjective Global Assesment (SGA) score and Mini Nutritional Assessment (MNA) score were used to evaluate the nutritional status. Patients with NRS-2002 score ≥ 3, SGA score < 6, MNA score <11 were accepted as risky for malnutrition. Data about reaching nutrition targets and ICU outcome were evaluated by using univariate and multivariate analysis.

RESULTS. 757 ICU patients were evaluated for the study. Median age was 68 [56-80] and 53% of the study patients were male. Detailed baseline characteristics of the patients were shown in Table-1. The most common causes of hospitalization were central nervous system diseases (25%), respiratory system diseases (20%) and malignancies (17%). Frequency of malnutrition risk in study patients was 90% according to NRS-2002 score, 89% according to SGA and 87% according to MNA score. Targeted calorie levels were reached only in 54% of the patients and targeted protein levels were reached only in 27% of the patients. Target calorie level was 1700 kcal/day [1500-1851], maximum delivered calorie was 1470 kcal/day [1240-1729], median delivered calorie was 1002 kcal/day [800-1100] in study patients. Target protein level was 98 gram/day [90-109], maximum delivered protein was 70 gram/day [59-90] median delivered protein was 55 gram/day [32-66]. ICU mortality was 38% in the study group. There was no significant difference in mortality between patients who reached to targeted calorie or protein levels and who did not ($p<0.05$). When we evaluated the independent risk factors for mortality with the aspect of nutritional parameters, the strongest independent risk factor was being under malnutrition risk according to SGA (OR (95% CI): 3.12 (1.34-7.29), $p<0.01$) score and others were being enterally fed with a feeding tube (OR (95% CI): 2.57 (1.87-3.51), $p<0.01$), being under malnutrition risk according to NRS-2002 (OR (95% CI): 1.97 (1.02-3.79), p=0,042), lover admission albumin level (OR (95% CI): 1.88 (1.42-2.48),$p<0.05$), being followed in medical ICU (OR (95% CI): 1.40 (1.01-1.94), p=0.042), higher admission creatinine level (OR (95% CI): 1.31 (1.16-1.48), $p<0.01$) and advanced age (OR (95% CI): 1.01 (1.00-1.02), $p<0.01$).

CONCLUSION. Malnutrition risk according to SGA score was the strongest independent risk factor for mortality. However, depending on complexity of ICU patients, there are many factors effecting their outcome. Thus, there may be different results about the effect of reaching nutritional targets alone on outcome and it should be evaluated along with additional parameters like ICU prognostic scoring systems.

Postoperative euglycemic diabetic ketoacidosis in patients who take sodium-glucose co-uptake receptor2 inhibitors: case series

Y. Iwasaki, J. Shiotsuka, T. Masuyama, Y. Kondo, S. Masamitsu
Intensive care unit, Jichi University Saitama Medical Center, Saitama, Japan
Correspondence: Y. Iwasaki
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001194

INTRODUCTION. Euglycemic diabetic ketoacidosis (euglycemic DKA) is among side effects of sodium-glucose co-uptake receptor 2 inhibitors (SGLT2 inhibitor). While the incidence of euglycemic DKA associated with SGLT2 inhibitors is reported as approximately 0.1%,[1] the exact incidence of euglycemic DKA is unknown during perioperative periods.
OBJECTIVES. The objective of this study is to describe the incidence of diabetic ketoacidosis caused by SGLT2 inhibitors during perioperative periods.
METHODS. Patients who received SGLT2 inhibitors within two days prior to elective surgeries between April, 2014 and March, 2019 were included. Patients who underwent cardiovascular surgeries using cardiopulmonary bypass, emergency operations, and those who were on hemodialysis were excluded. All arterial blood gas samples during the postoperative ICU stay were analyzed. Blood ketone bodies were not measured for any of the patients. The primary outcome was the incidence of euglycemic DKA, which was defined with high anion gap metabolic acidosis (arterial blood pH< 7.3, anion gap> 12 mmol/L, and $PaCO_2$< 45 mmHg), without significant hyperglycemia or hyperlactemia (lactate levels < 2.0mmol/L and glucose <14mmol/L).[2]
RESULTS. Two hundred and forty arterial blood gas samples from thirty-two patients who received preoperative SGLT2 inhibitors were analyzed. Six patients (18.5%) had at least one blood gas sample suggesting euglycemic DKA. Off-pump coronary artery bypass grafting (n=3), lung resection (n=2), and nephrectomy (n=1) were performed for those six patients, respectively. The minimum arterial blood pH was 7.252 and the maximum anion gap was 24.0 mmol/L.
CONCLUSION. Postoperative euglycemic ketoacidosis may be common in patients who take SGLT2 inhibitors preoperatively. Larger studies are needed to investigate the exact incidence of perioperative euglycemic ketoacidosis associated with SGLT2 inhibitors.

The evaluation of nutritional status in critically ill patients by Bioimpedance vector analysis (BIVA)

Y. Apichatbutr, R. Ratanarat, T. Viarasilpa
[1]Dept of medicine, siriraj hospital, mahidol university, Division of Critical Care, Bangkok, Thailand
Correspondence: R. Ratanarat
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001204

INTRODUCTION. Nutritional risk and malnutrition are highly prevalent among critically ill patients. Screening and assessment tools used to evaluate nutrition status, composed of subjective data. Low phase angle (PhA) derived by BIVA associated with higher severity of malnutrition defined by SGA and NRS2002 in difference populations, but there was no data in the critical ills.
OBJECTIVES. To assess the relationship between nutritional risk tools and PhA derived by BIVA in ICU patients, and the association of clinical outcomes and PhA compared to conventional nutritional risk tools.
METHODS. Nutritional risk screenings and PhA (determined by BIVA) were performed in 64 medical ICU patients (44 male, and 22 female) within the first 24-hrs of admission. Sensitivity and specificity were calculated for PhA compared to degrees of malnutrition stratified by SGA, NRS2002, and NAF. The cut-off values for severe malnutrition risk were assessed by receiver operator characteristics area under the curve (AUC).
RESULTS. PhA was lower in more severe malnutrition risk classified by SGA, NAF, and NRS 2002 ($p<0.001$). PhA of less than 5.8 correlated with severe malnutrition risk defined by SGA [AUC 0.90, sensitivity 92% (95%CI:77-98) and specificity 78% (95%CI: 58-92)]; NAF [AUC 0.90, sensitivity 78% (95%CI:87-100) and specificity 92% (95%CI: 79-97)]; NRS2002 [AUC 0.93, sensitivity 100% (95%CI:16-100) and specificity 66% (95%CI: 53-78)]. The patients with PhA of less than 5.8 have higher mortality, prolonged ICU and hospital length of stay but not statistical significance.
CONCLUSION. PhA has excellent correlation with SGA, NAF, and NRS2002. It is a useful measure for assessment the patients at risk for impaired nutritional status in critically ill patients. PhA below 5.8 is cut - off point for severe malnutrition in our ICU patients.

001262

Time-course of Glucose and Insuline Resistance in 382 patients after Minor, Intermediate and Major Liver Resection

Y. van de Riet[1], R. Steenstra[2], M. Nijsten[1], M. Zeillemaker-Hoekstra[3]
[1]Department of critical care, University Medical Center Groningen, Groningen, Netherlands; [2]Department of anesthesiology, Medisch Centrum Leeuwarden , Leeuwarden, Netherlands; [3]Department of anesthesiology, University Medical Center Groningen, Groningen, Netherlands
Correspondence: Y. van de Riet
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001262

INTRODUCTION. Post-operative liver failure (PLF) remains a feared complication after liver resection. Related to its central role in glucose metabolism, changes in glucose metabolism can be an early sign of liver failure. The effect of the size of the functional liver remnant on the early time courses of glucose and insulin requirements are unknown.
OBJECTIVES. To determine the early changes in glucose levels (Glu(t)), and insulin requirements (Ins(t)) after minor, intermediate and major liver resection. A secondary objective was to compare those early changes between patients with and without PLF.
METHODS. This is a single centre retrospective cohort (2008-2014) of all consecutive patients admitted to the intensive care unit (ICU) after liver resections. In total 382 patients were included. Patients were classified as "minor" (n=72), "intermediate" (n=183) or "major" (n=127) liver resection based on a functional liver remnant (FLR) of >60%, 35 - 60% and <35% respectively. Patients with initial portal vein embolization were excluded. Glucose was targeted at 4 to 8 mmol/L by a computerized nurse-centered algorithm. Insulin was delivered by continuous infusion. Insulin resistance, IR(t) was estimated by Glu(t)·(Ins(t)+1) mmol·IU·L-1·h-1. PLF was defined by the '50/50 criteria' [1].
RESULTS. Glucose levels were significantly higher in the patient group with minor liver resections ($P<0.05$) from ICU admission up to 5h later. After 15h the opposite occurred when the patients with the largest resection had the highest glucose levels ($P<0.05$). Insuline resistance (IR) was initially lowest in patients with the largest resection ($P<0.05$) but 18h after ICU admission IR became lowest in patients with the smallest resection ($P<0.05$). Post-operative liver failure was present in N=27 (7%). For the first 12h the glucose values ($P<0.0001$) and IR ($P<0.0001$) both correlated with PLF.
CONCLUSION. Glycometabolic changes as measured by glucose levels and insulin requirements are significantly different depending on the size of liver resection and the post-operative time. Persistent normal-low glucose levels and low insulin requirements during the

first day after major liver resection could be an early indication of PLF. With regard to these findings there might be a role for protective strategies to support the liver in its early postoperative state of energy crisis and thereby improving its capacity to regenerate and restore its functions.

Variable Rate Insulin therapy in Critically Ill Patients. Too Much or Too Little?

MK. Lim[1], L. Malanjum[2]
[1]Northampton General Hospital, Northampton, UK; [2]Itu, Northampton General Hospital, Northampton, UK
Correspondence: M.K. Lim
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001266

INTRODUCTION. Hyperglycaemia in the critically unwell is oftentimes due to a stress response and can be compounded by their existing insulin resistance. Hyperglycaemia is associated with poorer clinical outcomes but not necessarily causes it. Furthermore strict control may be more detrimental and put patients at risk of hypoglycaemia causing seizures, arrhythmias or death. For example, the COITTSS trial showed no difference between intensive and liberal insulin therapy. In addition, the NICE SUGAR trial showed a higher mortality rate and evidence of hypoglycaemia with intensive insulin therapy. A specific variable rate insulin infusion (VRII) guideline for our ITU is needed as the patients differ from the other ward patients.
OBJECTIVES. The primary objective was to compare our current clinical practice against the local unit guidance. Secondly we will use the results as a baseline for comparison after implementing a new critical care specific VRII guideline to determine if a quality improvement has been made.
METHODS. This was an observational study with a retrospective review of ITU charts.We studied adult patients >16 years old who had VRII started whilst being an ITU inpatient from Nov 2018-Jan 2019. We excluded patients on the DKA/HHS protocol, peri-op patients on 'sliding scales' or those with overly complicated glucose control eg necrotising pancreatitis.
RESULTS. 20 patients were included with a median age of 68 (38-78yo) and average of 4 days of VRII (1-10days). These patients had VRII when their CBG was >10mmol/L although there was a wide inconsistency of number of insulin units started; with only 7 patients (35%) having the correct units/hr as per guidelines. Only 15% of patients had their hourly CBG check for 4 hours after VRII was commenced. 60% of patients did not have the recommended CBG check an hour after a rate change. There was a 15% incidence rate (3 patients) of hypoglycaemia. Overall, we made a rough estimate of to check patients CBGs were in range of 6-10mmol/L by dividing the number of times their CBGs were 6-10 over total number of CBG taken whilst on VRII. The result was a mean of 68.6% and median of 72.1%. In addition, there was a T1DM who did not receive their regular long acting insulin and another T2DM who received it after 3 days of VRII.
CONCLUSION. The lack of CBG checks and absence of a clear guideline could be a strong contributing factor to poor control. We also expressed strong interest in wanting to know the events leading to their hypoglycaemia. How low were their CBGs? Were they eating, on NG feed or TPN? If so were they stopped at any point? Were they having intravenous fluids or glucose? How was the hypoglycaemia managed and how quickly did it resolve? These points will be more closely looked at during the subsequent audit after a few months. We also recommended HbA1C and ketone testing as well as diabetic team referral when appropriate. New hyperglycaemia guidelines will be disseminated to medical and nursing staff via various methods and reaudited soon. Similar VRII audits of other ITUs can also shed more light on how we treat hyperglycaemia around the country.

Early Hyperbilirubinemia in Critically-Ill Patients

J. Juschten[1], PR. Tuinman[1], LDJ. Bos[2], NP. Juffermans[3], A. Girbes, MJM. Bonten[4], OL. Cremer[5], T. Van Der Poll[6], MJ. Schultz[7]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001338

INTRODUCTION. Hyperbilirubinemia, defined as bilirubin levels ≥ 33 mmol/L, is present in 11–33% of all critically-ill patients and associated with increased mortality and a greater length of stay in the Intensive Care Unit (ICU). (1-3) However, studies investigating hyperbilirubinemia as an independent predictor of outcome have yielded conflicting results. (2-4)
OBJECTIVES. This study aims to investigate the association between early hyperbilirubinemia and 30-day-mortality in a large prospectively collected cohort in two tertiary ICU's in the Netherlands.
METHODS. This is an unplanned secondary analysis of the 'Molecular Diagnosis and Risk Stratification for Sepsis' (MARS) biorepository. Patients with measured bilirubin levels within two days after admission were included, except for patients with liver cirrhosis. Multivariable logistic regression modeling was used to determine important characteristics associated with 30-day-mortality and to estimate the impact of early hyperbilirubinemia.
RESULTS. Early hyperbilirubinemia was present in 559 (11.9%) of 4836 patients. These patients demonstrated higher rates of organ failure and mortality compared to patients without hyperbilirubinemia ($p < 0.001$). Multivariable logistic regression modelling revealed thrombocytopenia to be an effect modifier for the association between early hyperbilirubinemia and 30-day-mortality ($p = 0.005$). An independent association between early hyperbilirubinemia and 30-day-mortality was found in patients with a low platelet count ($p < 0.001$; Table 1), but not in patients with a normal platelet count ($p = 0.655$; Table 2).
CONCLUSION. In this large prospective cohort study, 11.9% of all ICU patients presented with early hyperbilirubinemia. We found an independent association between early hyperbilirubinemia and 30-day-mortality in patients with thrombocytopenia suggesting that this may possibly be feature of intravascular hemolysis, dyserythropoiesis or thrombosis in critically ill patients.

INTRODUCTION. Gastro-intestinal bleeding is a common event which may be so severe to require hospitalization within an intensive care unit (ICU). Management of patients with an active bleeding depends on clinical examination and laboratory tests to predict the likelihood of self resolution, persisting or new episodes of bleeding. Identification of high risk patients is often challenging because changes in clinical signs and tests are delayed. Often the attending physician's own experience and practice within the institute contribute more to the final decision than evidence based data.
OBJECTIVES. We sought to develop an artificial intelligence algorithm aimed at predicting high risk patients for active GI bleeding or successive re-bleeding. Because the outcome we try to predict (GI bleeding) was not recorded, blood transfusion was used as a surrogate. We propose a clinically translatable model trained on a fixed time window containing the data gathered during the first hours of a patient's ICU stay able to predict the likelihood of persisting or progressing GI bleeding within the subsequent 24 hours.
METHODS. We exploited the publicly available MIMICIII database to extract parameters and laboratory values of interest for the first ICU stay per hospital admission of adult non-pregnant patients with diagnosed GI bleeding. Extracted parameters were filtered first by clinically driven hypothesis of relevance and subsequently by data availability. We attempted to include in our analysis the maximum number of observations (patients) available with the lowest missing features, resulting in 48 clinical, anamnestic and laboratory parameters across 2925 patient ICU stays. Patient observations gathered within the first 3 to 6 hours of ICU admission were fed into two machine learning models (Bagged logistic regression and Random Forest) in order to predict if the patient would subsequently receive a blood transfusion. The insights of the two models are then combined together through a weighted average of the predicted probabilities. All the hyperpameters of our pipeline are fixed through a model based bayesian optimization procedure and cross-validation.
RESULTS. Results obtained were evaluated based on model accuracy (number of correct assessments over number of all assessments), AUC ROC, recall (sensitivity) and precision (true positive rate) across different time windows of data gathering and prediction time interval as detailed in table 2. Our best performing model could successfully forecast 76.09% of patients who would then receive or not a blood transfusion within 24 hours from data gathered within the first 3 hours of ICU stay.
CONCLUSION. While our model could be refined and optimized to incorporate also temporal patterns within the dataset, we demonstrate a comprehensive application of machine learning models to address clinically relevant open questions from a publicly available database.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000204

INTRODUCTION. Hypertension has long been considered an important risk factor for aneurysm rupture. Some studies had assessed the impact

of premorbid hypertension treatment on clinical course, but the data in the literature assessing the effect of blood pressure on admission is scarce.
OBJECTIVES. Investigate the impact of the blood pressure on the first medical contact on clinical course and outcome of patients with aneurysmal subarachnoid haemorrhage (aSAH).
METHODS. We retrospectively reviewed clinical data of patients with aSAH admitted to our institution from January 2014 to July 2018. Based on the blood pressure, all patients were divided into hypertensive group (BP ≥ 140/90mmHg) and non-hypertensive group (BP <140/90mmHg). Patient characteristics, imaging features, clinical complication, and outcome were analysed between the two groups using STATA 14.0.
RESULTS. A total of 79 patients were included in this study. 67% were women with a mean age 56.84 (SD 1.58), 53.6% were premorbid hypertension. 64.6% of aSAH patients were on the hypertensive group. There was no difference between age, sex or premorbid hypertension between both groups. Fisher grade 4 was 64.29% vs 46.43%, p 0.25 and Hunt Hess 4 or 5 was 46.43% vs 37.25%, p 0.43, for non-hypertensive vs hypertensive group. Neurological complications were vasospasm (21.34% vs 23.53%, p 0.83), hydrocephalus (21.34% vs 23.53%, p 0.83) and rebleeding (7.14% vs 9.8%, p 0.69). Medical complications as cardiac abnormalities (14.29% vs 15.69%, p 0.87) or electrolyte abnormalities (10.73% vs 11.76%, p 0.88). In-hospital mortality was 32.14 vs 31.37% (p 0.94).
Outcome evaluated at 3 month using the Glasgow Outcome Scale (GOS) is described in table 1. Difference was not significant, p 0.30.
Ordinal regression analyses for GOS at 3 months, adjusted by age and Hunt Hess grade 4 or 5, found no association with the exception of Hunt Hess grade 4 or 5 itself (OR 0.06, 0.01- 0.28, p 0.00).
CONCLUSION. Non-hypertensive patients had worse grade in the prognostic scales and higher mortality, but no diferences in outcome at 3 months. There was no difference on neurological and medical complications.

Table 1 (abstract 000204). See text for description

	GOS at 3 months	
	Non hypertensive group	Hypertensive group
1	32.14%	31.37%
2	-	7.84%
3	7.14%	7.84%
4	32.14%	15.69%
5	28.57%	37.25%

Mechanical ventilation and risk factors associated with neurocognitive disorders in critical care patients

S. Victor[1], J. Gomez[2], G. Paola[2], G. Ernesto[2], R. Tania[3]
[1]Intern medicine faculty, Dr. Jose Matias Delgado University Campus 1, Santa Tecla, El Salvador; [2]General medicine, Dr. Jose Matias Delgado University Campus 1, Antiguo Cuscatlan, El Salvador; [3]Health science faculty, Dr. Jose Matias Delgado University Campus 1, Antiguo Cuscatlan, El Salvador
Correspondence: J. Gomez
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000267

INTRODUCTION. In patients that need of Mechanical Ventilation (MV) have shown in multiple studies until 80% of neurocognitive disorders as part of the Post Intensive Care Syndrome (PICS).
OBJECTIVES. Evaluate the association between the changes of PEEP during MV, cerebral hemodynamic variables and PICS.
METHODS. This is a descriptive observational study, conducted in patients with MV, evaluated by TCD and TTE, who are assessed for PICS one month after the discharged from ICU between August 2018 to January 2019. The inclusion criteria involve all patients who underwent MV support and complete PICS battery evaluation. Exclusion criteria were met by any patient who had been previously diagnosed by neurocognitive disorders or was in treatment with psychoactive drugs. Head trauma, evidence of neuroinfectious disease, cardiac arrest, drug dependence or abuse and history of chronic alcoholism were excluded.
RESULTS. During the study period, 4 patients met the inclusion criteria of 89 patients admitted to the ICU. They received mechanical ventilation for 7 days on average. All the patients had an increase in the CaO2. However, the DO2 Index remained below normal parameters. In the cerebral hemodynamic variables, it was observed that the ICP calculated was higher than 14.3 mm Hg, while CPP was between 52.5 ml and 60.49 mm Hg respectively. The average SV at the beginning of MV support was 52.5 ml, that later with PEEP change improved. It was also observed that, with the change of PEEP, the patients presented an increase above the normal ranges in the average speeds both MCA (101.3 mm/sec) and the OA (45.23 mm/sec) which could be due to the increase in MAP and CPP. The mean PI of the MCA at the start of ventilator support was high (1.40 mm Hg), which correlates with the transient elevated PIC. All the 4 patients presented at least one neuropsychological disorder. Only one patient presented CAM-ICU. The MoCa test was positive in 3 out of 4 patients. In respect to sleep disorders, 3 of the 4 patients presented alterations in the subscales of insomnia and hyper insomnia.
CONCLUSION. These patients had prolonged mechanical ventilation with an average of 7 days, in which they maintained a PEEP under 10. They had low levels of DO2 Index and CaO2. In the 30 days after the ICU discharge, all had at least one neuropsychological disorder. Even though there are few cases studied on this research, the context of low O2 contribution to tissues regardless of the MV support with an increased ACM and AO velocities, it is possible to infer as a possible cause of brain damage, causing PICS because of the increase in the PEEP.

Diagnostic and prognostic importance of purine metabolic disoders in acute brain ischemia

E. Oreshnikov, S. Oreshnikova, A. Oreshnikov
[1]Internal medicine, Chuvash State University named I.N.Ulyanova, Cheboksary, Russia
Correspondence: E. Oreshnikov
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000414

INTRODUCTION. It has been established that hypoxanthine, xanthine and uric acid (UA) are present in the brain, their content changes after ischemia, UA is the final product of degradation of purines in the brain, xanthine oxidase (XO) is also present in the brain, catalyzes the oxidation of hypoxanthine to xanthine, and then to UA, and can be a source of free radicals, inhibition of XO and exogenous administration of UA are accompanied by explicit anti-ischemicand neuroprotective effects in the experiment, whereas endogenous increased production, with "by-product" synthesis of XO free radicals oxygen reflects the severity of ischemic and reperfusion injury.
OBJECTIVES. Our attention was drawn to the comparative evaluation of the prognostic value ofimpairments of purine metabolism.
METHODS. We examined 402 patients in the acutest period (1st 7-10 days) of cerebral ischemic stroke at the age of 30-87 years. Patients, in addition to conventional laboratory parameters, determined the blood levels of guanine, hypoxanthine, adenine, xanthine and uricacid by direct spectrophotometry. Evaluated the effects of the conservation of coma and death following the onset of which drugs are widely used in intensive neurology.
RESULTS. The most adverse prognostic factors associated with prolongation sopor or coma are: laboratory - hyperuricemia and hyperHYPOXANTHINemia. The most favorable prognostic factor, "countering" the preservation of a coma and the coming of death in cerebral ischemic stroke is the use of antiplatelet agents. Hyperuricemia most researchers viewed as an unfavorable prognostic factor, although intravenous injection of uric acid in acute cerebral ischemia can improve the results of thrombolytic therapy. Prognostic value of supranormal blood hypoxanthine level in contrast to the hyperuricemia has been insufficiently studied.
CONCLUSION. Launched from the development of acute cerebral ischemia, dynamic control of the blood levels of uric acid and hypoxanthine to predict its course and outcome.

Importance of purine metabolites in preeclampsia and acute brain stroke

E. Oreshnikov[1], S. Oreshnikova[1], A. Oreshnikov[1], E. Vasiljeva[2], T. Denisova[2]
[1]Internal medicine, Chuvash State University named I.N.Ulyanova, Cheboksary, Russia; [2]Obstetrics and gynecology, Chuvash State University named I.N.Ulyanova, Cheboksary, Russia
Correspondence: E. Oreshnikov
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000417

INTRODUCTION. Along with the classic triad: edema, proteinuria, hypertension, many clinicians as an indicator of preeclampsia using the high content of uric acid in blood serum hyperuricemia. It was also found that the hypoxanthine, xanthine and uric acid (UA) are present in the brain, and their content is changed after ischemia, UA is the endproduct of purine degradation in the brain,xanthine oxidase is also present in the brain, it catalyzes the oxidation of hypoxanthine to xanthine, and then in UA and can be a source of free radicals, inhibition of xanthine oxidase and exogenous administration of UA accompanied by explicit antiischemic and neuroprotective effects in the experiment and clinic, while the endogenous increased its production, with the"side" synthesis of xanthine oxidase oxygen free radicals, reflects the severity of ischemic andreperfusion injury. We also know that most fatal path of pathogenesis (and tanatogenesis) in preeclampsia is the development of brain stroke.
OBJECTIVES. Our attention was attracted by a comparative assessment of the features of purine metabolism in women with preeclampsia and acute brain stroke
METHODS. The study involved 33 women with preeclampsia and 350 women in acute period of cerebral stroke, in which, in addition to conventional laboratory parameters were determined in the blood and cerebrospinal fluid - guanine, hypoxanthine, adenine, xanthine and uric acid by direct spectrophotometry.
RESULTS. It was established that between preeclampsia and cerebral stroke there are clinical and pathobiochemical parallels, including according to the characteristics of purine metabolism. Hyperuricemia the most famous and at the same time the most pronounced adverse metabolic factor (marker or predictor) for preeclampsia, and for cerebral stroke. High value level of oxypurines (hypoxanthine, xanthine and uric acid) in the cerebrospinal fluid is good sign for a stroke, and low value level of oxypurines is good sign for preeclampsia.
CONCLUSION. Cerebrospinal liquor can be seen not only as a medium of administration of drugs for spinal anesthesia, but also and a source of valuable diagnostic (and predictive) information.

Analysis of refractory hyponatremia in patients with neurologic critical disease

J. Zhang, C. Qi
[1]Neurology, The Chinese Peoples' Liberation Army General Hospital, Beijing, China
Correspondence: J. Zhang
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000566

INTRODUCTION. Refractory hyponatremia is intimately related to condition changes of patients in NICU.
OBJECTIVES. This study was conducted to explore the causes of refractory hyponatremia in patients with neurologic critical disease. In order to further improve the level of diagnosis and treatment of hyponatremia.
METHODS. A retrospective analysis was including 22 patients with refractory hyponatremia in the Chinese Peoples' Liberation Army General Hospital from June 2010 to June 2018. Hyponatremia was divided into mild, moderate and severe types according to serum sodium level (mild hyponatremia: 130mmol/L≤ Na+<135mmol/L; moderate hyponatremia: 125mmol/L≤ Na+<130mmol/L; and severe hyponatremia: Na+<125mmol/L).
RESULTS. From June 2010 to June 2018, 22 patients in the Chinese Peoples' Liberation Army General Hospital were eligible for inclusion in accordance with the diagnostic criteria of refractory hyponatremia, including 15 males (68.2%) and 7 females (31.8%). The age ranged from 20 to 88 years old, with an average age of 55.0±22.0 years old. The prevalence of young, middle-aged and elderly patients was 40.9%, 18.2% and 40.9%, respectively. Among the enrolled 22 patients with refractory hyponatremia, 5 were cerebrovascular diseases (22.7%), 8 were infectious and immunological diseases (36.4%), 3 were peripheral neuropathy (13.6%), 2 were metabolic encephalopathy (9.1%), 1 was meningeal cancer (4.5%), 1 was leukoencephalopathy (4.5%) and 1 was neurodegenerative disease (4.5%). Furthermore, mild hyponatremia occurred in 1 case (4.5%) with cerebral infarction, moderate hyponatremia in 11 cases (50%) with most of which are cerebrovascular disease, and severe hyponatremia in 10 cases (45.5%) with most of which were tuberculous meningitis, meningeal carcinomatosis or central pontine myelinolysis. The primary causes of refractory hyponatremia were infection and neuroimmune diseases (53.8%) in young and middle-aged patients, while cerebrovascular diseases (44.4%) were the main causes of refractory hyponatremia in elderly patients. Meanwhile, 0 (0%), 6 cases (46.2%) and 7 cases (53.8%) were found to have mild, moderate and severe hyponatremia in young and middle-aged patients, and 1 case (11.1%), 5 cases (55.6%) and 3 cases (33.3%) in elderly patients, respectively. The average hospitalization time of patients with moderate

hyponatremia in the NICU was 40.33±46.38 days, and that was 67.75±111.57 days in patients with severe hyponatremia.
CONCLUSION. The prevalence rate of refractory hyponatremia is higher in patients of NICU. Cerebrovascular disease is the first cause of hyponatremia in elderly patients, while intracranial infection, especially tuberculous meningitis, is the most common pathogenic factors in young and middle-aged patients. Furthermore, in patients with high intracranial pressure, high doses of dehydrating drugs for sodium excretion may aggravate the degree of refractory hyponatremia and prolong the treatment duration of hyponatremia. In clinical practice, early detection of hyponatremia and active formulation of reasonable sodium supplementation therapy can reduce the length of stay in hospital for patients.

Neurocritical patients – can neuromonitoring improve outcome?

R. Ferreira de Almeida[1], N. Mourão[2], I. Martins,[1], S. Vicente[1], P. Perez[1], J. Moreno[1], C. Granja[1]
[1]Intensive care department, Centro Hospitalar e Universitário do Algarve, Faro, Portugal; [2]Internal medicine, Centro Hospitalar e Universitário do Algarve, Faro, Portugal
Correspondence: R. Ferreira de Almeida
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000590

INTRODUCTION. Neurocritical care is a subspecialty of critical care medicine that focusses on the evaluation, diagnosis, and management of patients with acute life-threatening central nervous system diseases.(1,2) Because of their complexity, neurocritical patients needs specific continuous monitorization, to allow their recovery.
OBJECTIVES. To evaluate the influence of neuromonitoring in the outcome of neurocritical patients
METHODS. An observational retrospective study included 90 neurocritical patients in our intensive care unit (ICU) during the year of 2018. Collected variables included age, gender, diagnoses, severity scores (APACHE, SAPS, initial SOFA), in local Glasgow coma score (GCS), hospital admission GCS, Marshall, Hunt & Hess scale, Fisher scale, National institute of Health stroke scale (NIHSS), intracranial pressure (ICP) at ICU admission, time with ICP>24 in the first 72h after ICU admission, mean ICP during ICU stay, doppler variables in the first 24h of ICU stay (middle cerebral artery (MCA) blood velocity and pulsatility index) and Glasgow Outcome Scale (GOS) at ICU discharge and after 1 year from discharge.
RESULTS. Ninety neurocritical patients were included: traumatic brain injury (TBI) (49), aneurism (28) of which 27 had subarachnoid haemorrhage, stroke (10) and arteriovenous malformation (3).45,5% of the TBI population present Marshall scores of 4 and above. We found no statistical significant association between in local and hospital GCS, Marshal scale, mean ICP at ICU admission, time with ICP>24 in the first 72h after ICU admission, mean ICP during ICU stay and GOS at the moment of ICU discharge and GOS 1 year after discharge. In patients with aneurism, in local and hospital GCS, Hunt Hess scale, Fisher scale, time with ICP>24 in the first 72h after ICU admission, mean ICP during ICU stay and doppler variables in the first 24h of ICU stay were not statistically significantly associated with GOS at ICU discharge and GOS 1 year after discharged.
CONCLUSION. Neuromonitoring was not statistical significantly associated with outcome in the group of patients included in the present study. Several limitations must be acknowledged: the retrospective character of the study which implies that important data may have not be included, namely doppler records. Our sample needs to improve in order to make more robust conclusions.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000699

INTRODUCTION. To evaluate patients admitted to ICU diagnosed with spontaneus supratentorial intracerebral hemorraghe and intraventricular hemorraghe,in terms of functional situation and it's relation to surgical intervention.
METHODS. Patients with spontaneus supratentorial intracerebral hemorraghe who were admitted to ICU during 2009-2012 in three different spanish hospitals with Neurosurgery Services, had been studied. Effect of surgical intervention in patients with intraventricular hemorraghe had been studied. Using a propensity index, 26 patients who had undergone surgery were paired with 26 who had not.
RESULTS. 163 patients were admitted with spontaneus supratentorial intracerebral hemorraghe and intraventricular hemorraghe. This patients presented at admisssion a 8+4 in Glasgow, 21.42+7.55 points in APACHE-II, and 2.75+0.9 score in ICH with a 65% predicting mortality(30 days) and a 59.5% mortality(30 days). 13.5% presented non-reactive bilateral midriasis. 23.3% of patients (N=38) were surgically intervened. Mortality of patients intervened was 34.2% and 67.2% (p<0.001) for patients who were not intervened. In the multifactorial analysis OR for surgical intervention was 0.14(0.05-0.41).Afterwards a pairment of 26 surgically intervened patients with other 26 non-intervened in relation to a propensisty index had been done. This index was calculated in relation to age, presence of pupilar abnormalities, hemorraghe size and location, and Glasgow at admission. Patients intervened and not intervened presented similar carachteristics (age, Glasgow, ICH score, APACHE II, hemorraghe volumen and location) and non of them presented non reactive bilateral midriasis at admission. Hospital mortality of patients surgically intervened was 30.8% and 65.4% for patients not intervened (p=0.001) and OR 0.23; CI:95%: 0.07–0.75.After 5 years of admission from the 52 paired patients, 20 of them were still alive, 29 no survived and 3 were missing (1 was surgically intervened and 2 of them were not). From the 25 who were intervened, 14 were still alive (56%) and from the 24 not intervened 6 were still alive (25%) (p=0.027) OR =0.26 (0.08-0.89).For the 14 patients intervened who were still alive, the functional situation evaluated with Barthel index was 38+38 points; and for the 6 patients who were not intervened presented a 54+39 puntos, (p=0.403) in the Barthel index. For he 25 patients surgically intervened, 5 (20%) were still alive and presented a slight dependence (Barthel >60) and for the 24 non intervned, only 2 (8.3%) were still alive and presented a slight disfunction (p=0.245)
CONCLUSION. Patients admitted into ICU with spontaneus intracerebral hemorraghe with ventricular involucration who were surgically intervened presented less mortality after five years in comparision to the ones who were not intervned. In the other hand, survivors presented a poor functional situación with a high dependence degree.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001095

INTRODUCTION. Whereas diabetes mellitus is a clearly risk factor for the occurrence of stroke and for its poor prognosis, hyperglycemia without pre-existing diabetes mellitus is also linked to increased mortality and morbidity in stroke patients.
OBJECTIVES. To assess the role of glyemic control in influencing stroke outcome regarding duration of hospital stay, motor deficit, hemorrhagic transformation and mortality.
METHODS. This retrospective study was conducted in Elzaiton Specialized Hospital from June 2016 to June 2017. A sample size of 80 subjects achieves nearly 90% power to detect this difference.
Inclusion criteria

- Age: 40-70years
- Sex: Any sex
- Patients with acute ischemic stroke without other major comorbidities within 24 hours of onset of symptoms.++

On ICU admission the random blood sugar was recorded and categorized to less than 150mg/dl (accepted) and more than 150mg/dl (not controlled). Also serial Random blood sugar daily was recorded and categorized to good control if less than 150mg/dl and poor control if more than 150mg/dl.
Patients were divided into 2 groups (40 patients each group)
(A) Patients with accepted random blood sugar on admission and controlled blood sugar during hospital stay
(B) Patients with increased random blood sugar on admission and poor blood sugar control during hospital stay
RESULTS. A total of 80 patients were enrolled in the study. There were no significant differences regarding gender, HbA1C%, body mass index (p=0.654), (p=0.114),(p=0.381) respectively between both groups, but poor control group showed significantly higher age, random blood sugar on ICU admission and during hospital stay and longer duration of hospital stay (p <0.001), (p<0.001), (p< 0.001), (p=0.022) respectively. Comorbidities (p =0.007), hemorrhagic transformation (p = 0.048) and 30 days mortality (p < 0.001) were significantly higher in poor control group. Glascow coma score on ICU admission and on discharge, motor power on ICU admission and on discharge (p < 0.001), (p= 0.044), (p < 0.001), (p=0.015) respectively showed significantly higher values in good control group.
CONCLUSION. Hyperglycemia is common among acute stroke patients and is associated with less favorable outcomes regarding mortality, hospital stay and functional outcome, euglycemic control is recommended for those patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001029

INTRODUCTION. Determining and setting the optimal and safest PEEP levels in overweight and obese patients (body mass index>25) can be challenging for the ICU physicians. Real time transpulmonary pressure (Ptp) measurement by an esophageal balloon catheter and titrating PEEP levels according to the end expiratory Ptp shows promising results in these patients (1,2,3).
OBJECTIVES. To assess the feasibility and effect of Ptp guided PEEP titration in overweight and obese patients.
METHODS. An esophageal balloon catheter (Cooper Surgical Inc, Trumbull, CT, USA) was inserted to monitor the esophageal pressure in overweight and obese patients under invasive mechanical ventilation. Patients were connected to a ventilator capable of monitoring airway, esophageal and transpulmonary pressure waveforms real time breath-by-breath (Hamilton G5, Hamilton Medical AG, Bonaduz, Switzerland). PEEP levels were adjusted to achieve a Ptp 0 to 10 cmH2O at end expiration.
RESULTS. Eleven patients were enrolled. Data are expressed as mean±SD and comparisons were done using paired sample t-test. Mean age was 49± 21 years and body mass index was 29±4 . PEEP was increased to 20 ± 5 from 10±4 cmH2O after titrating PEEP according to the Ptp at end expiration (p= 0.001). This also led to a significant improvement in PaO2/FiO2 ratio (from 86±25 to 220±86 , p= 0.001) and allowed a significant decrease in FiO2 levels (from 0.9±18 to 0.67±25, p=0.008). Arterial pH increased from 7.33±0.16 to 7.40±0.10 (p =0.042) and PaCO2 decreased from 54±18 to 44±9 mmHg (p= 0.08).
CONCLUSION. Ptp guided PEEP titration can be effective and safe especially in overweight and obese patients who are in need of high PEEP levels.

INTRODUCTION. Frailty is an independent predictor of short and long term mortality in patients admitted in intensive care unit (ICU).
OBJECTIVES. Describe the impact of frailty at 30 days (30-d) mortality from ICU admission in patients who underwent tracheostomy.
METHODS. Observational retrospective study from May 2014 to October 2018; patients who underwent tracheostomy in ICU were included. Exclusion criteria: patients with tracheostomy before ICU admission and re-admission patients. Demographic (age, gender) clinical (co-morbidity), IMV, tracheostomy, ICU and hospital length data, were collected. To assess de frailty we used Clinical Frailty Scale (CFS) (fragile: CFS $\geq$ 5). We describe qualitative variables as frequency and percentage; and continuous variables as mean $\pm$ SD or median, and interquartile range. We compared percentages using chi-square or Fisher test, and continuous variables with t-Student or U Mann-Whitney tests. Survival was described with the Kaplan-Meier technique (long-rank) and with multivariate Cox proportional-hazard models, adjusted by age, gender, co-morbidities, APACHE II (without age), re-intubation, % of time in IMV, day of tracheostomy, disconnection from the IMV and discharge from ICU without tracheostomy.
RESULTS. Of the 2630 patients admitted to ICU, 105 were analyzed; 16.2% were fragile (Figure 1). Median age 69.9 years (IR: 62.0-77.3) and 71.4% males; median APACHE II 23.0 (17.0-28.0). There were no significant differences in age, gender, co-morbidities, severity scores, variables related to IMV or tracheostomy. Frailty patients had significantly shorter time in IMV (p=0.038). Survival analysis showed a higher probability of 30-d mortality in frailty patients (long-rank=0.018) (Figure 2). Multivariate analysis showed fragility as independent predictor factor of 30-d mortality (OR 3.80; IC 95% 1.59 – 9.12; p= 0.003)
CONCLUSION. There were no differences in characteristics and management between frailty and non-frailty patients whom tracheotomy were made during ICU stay. Time of IMV in frailty patients, was probably shorter because they died earlier. Frailty is an independent predictive factor of 30-d mortality in patients who need tracheostomy during ICU admission.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001054

INTRODUCTION. Acute respiratory distress syndrome (ARDS) is characterized by pulmonary edema due to alveolar epithelial-interstitial-

endothelial injury, associated with profound inflammation and respiratory dysfunction. The IL-33/ST2 axis has a key role in the development of immune-inflammatory responses in the lung.
OBJECTIVES. To assess the anti-inflammatory and restorative capabilities of using Anti-IL33 antibody to alleviate the pathological events occurring in a murine lipopolysaccharide (LPS)-induced lung injury model.
METHODS. Eight to tenweeks-old male BALB/c mice (Harlan, Horst, The Netherlands) were used for the experiments (IRB: JME-16-0025). All mice were anesthetized with 2% isoflurane and challenged with a single intranasal instillation of 8 mg/kg of LPS (E. coli 055:B5:Sigma-Aldrich) dissolved in 50 µl of PBS (ARDS group), or administered 50 µl of PBS alone (control group) on day 0. Day 1, 2 and 3, mice received 3,6µg/day intraperitoneally Anti-IL-33 (treatment group), orintraperitoneally saline (placebo group). The following groups of mice were studied: 1) Control group (n=12) with non-ARDS controls+placebo (n=6) and non-ARDS controls + Anti-IL33 (n=6), 2) ARDS + placebo (n=12) and 3) ARDS + Anti-IL33 (n=12).Body weight gain was registered and bronchoalveolar lavage and blood samples were recollected. Cell count, total protein levels, IL-33 (Abnova, Walnut, CA, USA) and IL-6 (Cloud-Clone Corp, Katy, TX, USA)levels were measured in BAL fluid.IL-33 levels were also measured in blood samples. Histological evidence of lung injury was assessedthrough previous methodology (histological parameter scoring)1 and wet-to-dry lung weight ratio was also evaluated in some animals.The data was expressed as mean (standard deviation) or as median (interquartile range). Significance was set to $p < 0.05$. Statistical analyses were performed using Portable SPSS, PASW Statistics v18.0; SPSS Inc, Chicago, IL.
RESULTS. There were no differences in any studied variables between non-ARDS controls + placebo and non-ARDS controls + Anti-IL33 and therefore they were analysed together as a control group. Both ARDS groups presented a decrease in the body weight gain and an increase in the wet-to-dry lung weight, neutrophil percentage in BALF, protein levels in BALFand alveolar space polymorphonuclear cells (PMN) in the histologic evaluation compared with control group. ARDS + placebo group presented higher levels of IL-33 and IL-6 in BALF, and histologic interstitial space PMN and proteinaceous debris compared with control group. ARDS + Anti-IL-33 mice presented a decrease in the wet-to-dry lung weight [0.13(0.02) vs 0.16(0.02);p=0.024], in the BALF neutrophil percentage [63.1(52.6-68.1) vs 69.4(67.4-71.1);p=0.038], interstitial space PMN [0.4(0.5) vs 1.1(0.4);p=0.015] and proteinaceous debris [0.3(0.4) vs 1.1(0.7);p=0.022] in the histologic evaluation compared to ARDS + placebo group.
CONCLUSION. Anti-IL-33 treatment could partially restore the acute histopathological and biochemical changes occurring after endotoxin challenge. Anti-IL-33 antibody could have a therapeutic potential for ARDS but further studies will be necessaries in the advance toward clinical applications

Prone position enhances regional homogeneity at high and low PEEP assessed by direct pleural pressure measurement

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001055

INTRODUCTION. Prone position (PP) is a cornerstone in the treatment of acute respiratory distress syndrome (ARDS) increasing oxygenation and protecting the lung against ventilator induced lung injury (VILI). Its precise mechanism of lung protection, interaction with PEEP and the regional mechanical response of the respiratory system care still lacking.
OBJECTIVES. To assess the changes in pleural pressure gradient, ventilation homogeneity and regional respiratory mechanics at different PEEP levels, during supine and prone positioning.
METHODS. Twelve pigs (weight 36.1 ± 1.9 Kg) were anesthetized and mechanical ventilated. Catheters were inserted into dorsal and ventral pleural space to obtain a direct measurement of regional pleural pressure (Ppl), PA catheter, an esophageal balloon and an EIT belt were added. Lung injury was established with saline lavages to obtain a PaO2 < 100mmHg followed by high-stress ventilation until a decrease in respiratory system compliance (Crs) by 20%. After a recruitment manoeuvre (RM) each animal underwent a decremental PEEP protocol (PEEP from 20 to 3 cmH2O, steps of 1cmH2O every 5-6 breaths, volume control, 6 ml/kg) in both SP and PP. At every level of PEEP, Plateau pressure, Pes, regional Ppl (dorsal & ventral), and EIT were measured. Vertical gradient of Ppl, distribution of ventilation, compliance (respiratory system, lung and chest wall; total & regional) were calculated.
RESULTS. PP induces a uniform vertical Ppl gradient (Ppl ventral – Ppl dorsal) during expiration and inspiration (i.e. maintains lung homogeneity) and is PEEP independent. Whereas, in SP vertical gradient of Ppl is PEEP dependent (*Fig.1*). Lower PEEP distributes VT toward non-dependent regions; in SP more than PP. At lower PEEP levels, vertical gradient of ventilation (VT dependent – VT non-dependent) is lower in PP. Levels of PEEP required to achieve the best regional lung compliance (CL) in dependent and non-dependent lung was congruent in PP (13 and 12cmH2O respectively) compared to SP (15 and 10 cmH2O respectively).
CONCLUSION. The vertical Ppl gradient across the lung is stable during PP i.e. not affected by both high (overdistension) or low (collapse) PEEP. Thus, lung homogeneity is maintained as reflected by homogenous regional ventilation, stable gradient of ventilation and more uniform best PEEP for regionals CL.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001058

INTRODUCTION. Reverse triggering (RT) is a type of patient-ventilator interaction where respiratory muscle contractions are triggered by the ventilator under different patterns of entrainment. Because it occurs during expiration, RT may potentially cause eccentric myotrauma while on the other hand it could protect the diaphragm from atrophy. The impact of RT on diaphragm function remains uncertain.
OBJECTIVES. To establish the effect of RT in comparison to passive ventilation on diaphragm function in an experimental model of acute lung injury.
METHODS. Sixteen pigs (35±5kg) were anesthetized, mechanically ventilated, and monitored. Lung injury was induced by surfactant depletion and high-stress ventilation to reach PaO2 <150 mmHg and 10% decrease in respiratory system compliance. After lung injury, recruiting maneuver and baseline measurements, pigs were randomized to receive either passive ventilation (n=8; VCV; RR: 35 bpm; VT: 10ml/kg), or ventilation adjusted to induce RT (n=8; VCV; variable RR and VT), for 3 hours. Based on preliminary experiments, we induced RT by stepwise changes in the following settings: (1) decreasing VT and increasing RR; (2) decreasing dose of sedatives; (3) increasing PEEP. Diaphragm function was assessed by measuring transdiaphragmatic pressure (Pdi) during phrenic nerve stimulation by single electrical twitches (PdiTw) and at different stimulation frequencies (10, 20, 30, 40 and 60 Hz) to construct force/frequency curves. PdiTw and Pdi,max after 1, 2, and 3 hours of ventilation was compared to baseline PdiTw and Pdi,max, respectively. Finally, we conducted a post-hoc analysis in the RT group based on the level of respiratory effort [average Pes swing > 10 cmH2O and 1:1 entrainment (n=4) vs. Pes swing <10 cmH2O and 1:2 entrainment (n=4)].
RESULTS. The RT group had lower VT, higher RR, and higher PEEP level as compared with the passive group. There was no difference in PaCO2 but a higher PaO2 with RT. PdiTw ratio and Pdi ratio were not different between groups but a post- hoc analysis showed that in the RT animals with high respiratory effort (n=4), PdiTw and Pdi,max was reduced by 25%. Decrease in diaphragm force was significantly different than both passive and RT with low respiratory effort (Figure 1)
CONCLUSION. Reverse triggering might acutely impair diaphragm strength, and this effect seems to be modulated by the level of respiratory effort.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001060

INTRODUCTION. Esophageal pressure (Pes) measurements are increasingly used as state-of-the-art monitoring technique in ventilated ICU patients. To validate the position and filling volume of the esophageal balloon, the Baydur maneuver is performed. An expiratory hold is applied for at least one breath, during which the ratio of airway pressure (Paw) and Pes is measured. Pes measurements are considered reliable when the Paw/Pes ratio has a value between 0.8-1.2.[1] However, it is unknown if a shorter expiratory hold could be sufficient for validation of the Pes measurements. This would be beneficial as it is less uncomfortable for patients and might allow near continuous calculation of this ratio by the ventilator in the future.
OBJECTIVES. To determine the minimal duration of an expiratory hold in patients on partially-supported modes of ventilation in order to obtain a reliable Paw/Pes ratio.
METHODS. Expiratory hold maneuvers were performed in ICU patients with an esophageal balloon catheter (Nutrivent®, Sidam Italy), ventilated in a partially supported mode. A continuous ratio between Paw and Pes was calculated offline. Subsequently, it was determined how many milliseconds (ms) after the start of patient effort the Paw/Pes ratio reached the reliable range of 0.8-1.2 and stayed stable for 40ms thereafter (Fig. 1).
RESULTS. We analyzed 86 Baydur maneuvers obtained from 10 different patients. The Paw/Pes ratio reached the reliable range of 0.8-1.2 after a median time of 200ms [IQR 94-384ms] after the onset of patient effort.
CONCLUSION. In 75% of the maneuvers, a reliable and stable Paw/Pes ratio can be obtained 384ms after onset of patient effort. Therefore, we advise that an expiratory hold should have a minimal duration of 430ms after onset of patient effort. Implementation of automatic expiratory occlusions within the ventilator software enables a continuous verification of esophageal balloon measurements, increasing its clinical value.

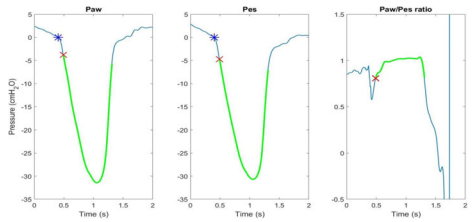

Fig. 1 (abstract 001060). Airway pressure (Paw), esophageal pressure (Pes) and the Paw/Pes ratio during one expiratory hold. The blue asterisks show the onset of patient effort. The green lines show the period of time that the Paw/Pes ratio is in the reliable range of 0.8-1.2. The red cross indicates the first moment when the ratio was stable in the reliable range for at least 40ms. Per expiratory hold maneuver the time between the blue asterisk and red cross is calculated.

Bleeding in lung transplantation with intraoperative support by ECMO

M. López Sánchez, MI. Rubio Lopez
[1]Critical care department, University Hospital Marqués de Valdecilla, Santander, Spain
Correspondence: M. López Sánchez
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001084

INTRODUCTION. Intraoperative support by extracorporeal membrane oxygenation (ECMO) is widely used during lung trasplantation (LT) for cardiac, respiratory or both type of failure. Compared to cardiopulmonary bypass (CPB) ECMO is simplest, lower priming volumen, lesser anticoagulation requirement, lower coagulopathy and systemic inflammatory response. At our institution, CPB has been replaced by ECMO in this setting. Nevertheless, bleeding is an important complication in these patients.
OBJECTIVES. To describe demographic characteristics, ECMO indications, technical aspects, type of membrane oxygenation, ECMO weaning and mortality in LT patients with intraoperative support by ECMO and perioperative bleeding.
METHODS. Descriptive study between Juin 2009 to March 2019 in 12 beds ICU. Inclusion criteria for ECMO entry were cardiac failure (left, righ or both), severe pulmonay hypertension and/or respiratory failure before or during LT proceeding. ECMO systems have centrifugal pumps and polimethilpentene or polypropylene membrane oxygenation. Demographic data, APACHE II, type of ECMO support, thoracic bleeding, anticoagulation practice, ECMO weaning and ICU survival were collected.
RESULTS. ECMO support was used in 49 patients (p). In 35p (71.4%) ECMO was used for intraoperative support. In this group, APACHE II was 21.3 (12-29); 51.4% (18p) were woman with a median age of 49.7 years (rank 16-63). Pulmonary fibrosis was the most common disease for LT in this entity in 13 p (37.1%), COPD/emphysema in 5 p (14.2%), primary pulmonary hypertension in 4 p (11.4%), QF in 3 p (8.5%). Type of ECMO support was VA in 28 p (central 9p, peripheral 19p) and VV in 7p. Cardiac support was needed in 22p, respiratory in 7p and both in 7p. ECMO was weaned at the operating room (OR) in 51.4% (18p). Massive bleeding was present in 17p (48.5%), needing toracotomy in 10p (58.8%). Polypropylene membrane was used in 12 of them (70.5%). Only 6p (35.29%) in this group was weaned at the OR. Anticoagulation during lung transplanation was used in all patients during LT, but 5p (29.41%) didn´t receive anticoagulation at the ICU. Thrombotic complications were not seen. ICU mortality in patients with massive bleeding was 35.2% (6 p).
CONCLUSION. In patients with ECMO as intraoperative support, massive bleeding was present in 48.5% of patients with a ICU mortality of 35.2%. Anticoagulation regimen and type of oxygenator must be reconsidered.

INTRODUCTION. Spontaneous breathing has been suggested in ARDS patients on ECMO to prevent diaphragm dysfunction. However, the use of spontaneous breathing is controversial in severe ARDS as it may promote further lung injury.
OBJECTIVES. To compare the effects of spontaneous breathing versus controlled near-apneic ventilation, on lung injury and diaphragm structure, in a porcine severe ARDS model assisted by ECMO.
METHODS. Twelve pigs (30±5kg) were anesthetized, mechanically ventilated and monitored. Lung Injury was induced by repeated lavages (30 ml/kg of warm saline) until PaO2/FiO2 dropped below 200, followed by 2-h injurious ventilation (PEEP 0 cmH2O, PInsp 40 cmH2O, RR 10/min). After completing lung injury (T0) animals were connected to ECMO. During the first 3 hours, animals were ventilated with near-apneic ventilation (PEEP 10, driving pressure 10, RR 5/min) and NMB. After T3, animals were randomized into 2 groups: i) Near- apneic ventilation, which continued with the same settings, and ii) SB: in this group, NMB was stopped and sweep gas flow decreased until regaining respiratory efforts. Thereafter, ventilation was switched to PS mode (PS 10 cmH2O, PEEP 10 cmH2O) and sweep gas flow adjusted preserving SB at a respiratory rate of 30 to 70 bpm. ECMO weaning started in both groups at T18, sweep gas flow was stopped and animals ventilated in PS mode (adjusted to Vt=6 ml/kg) until T24. Respiratory and hemodynamic variables, as well as regional lung impedance, were collected. After 24 hours, animals were euthanized and tissues extracted (lung and diaphragm). Lung edema was estimated by the wet-dry weight ratio. Lung injury and muscle morphometrics were assessed by histological analysis.
RESULTS. Although the SB group developed higher respiratory rates and minute ventilation, at T18 both groups exhibited similar oxygenation and systemic hemodynamics. At T18, all animals regained spontaneous efforts and could be weaned from ECMO without hemodynamic or respiratory deterioration, and with no differences in the breathing pattern (Table 1). No differences were observed in lung wet/dry weight ratio, cytokines concentration in lung tissues or in the histological lung injury score (Fig 1). Quantification of cross-sectional area showed that slow- and fast-

twitch diaphragm muscle fibers in SB group were smaller (near-apneic ventilation vs SB, fast: 662.9 ± 9.2 vs 460.7 ± 7.4 μm2; slow: 583.1 ± 10.7 vs 356.7 ± 5.6 μm2) (Fig 2). The fraction of each type of fibers did not differ between groups.

CONCLUSION. We found no differences between SB and Near-apneic ventilation in lung injury and lung function, but the SB group exhibited smaller slow- and fast- twitch diaphragmatic fibers.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001086

INTRODUCTION. The intravenous agents used for induction of general anesthesia prior to intubation in ICU are either propofol, ketamine or etomidate. Their choice depends on indications, risks, benefits and preferences without clear superiority among them.

OBJECTIVES. To evaluate the association between agents used for endotracheal intubation and ICU and hospital outcomes in critically ill patients.

METHODS. Retrospective single-center cohort study of consecutive adult critically ill patients who were given a single anesthetic agent (propofol, ketamine or etomidate) for endotracheal intubation in all ICUs of a tertiary center between January 01, 2012 and December 31, 2017. Cardiac arrests and lack of research authorization were excluded. Primary outcomes were ICU and hospital mortality. Second outcomes were ICU- and hospital-free days through 28 days. An inverse probability of treatment weighed approach was used to compare treatments; multiple imputations were used for missing data. The propensity score was estimated using a generalized logit model as a function of patient characteristics: age, sex, BMI, admission source, ICU location, readmission status, length of ICU stay prior to intubation, and acute physiology score. Mortality outcomes were assessed with weighted logistic regression and –free days assessed by weighted linear regression.

RESULTS. The analysis included 2,673 patients, 962 (36%) received propofol, 792 (30%) received ketamine and 919 (34%) received etomidate. Overall ICU and hospital mortality were 19% and 29% respectively and lower with propofol than with ketamine or etomidate, 13, 22, 23% and 23, 32, 32% for each drug respectively. Compared with propofol, patients inducted with ketamine had higher odds of ICU mortality (Odds Ratio; 95% CI; p-value) (1.45; 1.07, 1.94; p=0.015) and higher odds of hospital mortality (1.34; 0.98, 1.84; p=0.07), and those with etomidate had higher odds of both ICU mortality (1.87; 1.40, 2.49; p<0.001) and hospital mortality (1.43; 1.09, 1.86; p=0.009). Ketamine had fewer ICU-free days (-1.24; -2.41, -0.06; p=0.039) and fewer hospital-free days (-1.21; -2.37, -0.05; p=0.041) compared to propofol. Etomidate was also associated with fewer ICU-free days (-2.10; -3.21, -1.00; p<0.001) but not hospital-free days (-0.92; -1.97, 0.13; p=0.087). When compared between them, etomidate and ketamine groups had similar outcomes except for ICU mortality which was slightly higher in the etomidate than in the ketamine group (OR, 1.29; 0.99, 1.68; p=0.057).

CONCLUSION. Compared to ketamine and etomidate, propofol is associated with better outcome in critically ill patients undergoing anesthesia for intubation. The hemodynamic effects of propofol might be more predictable than those with ketamine and the metabolic effects of etomidate might exert their own influence on outcome.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001091

INTRODUCTION. Even though it's widespread implementation, the benefits of bronchoscopy-guided percutaneous dilatational tracheostomy (BG-PDT) have not been consistently demonstrated. One possible cause is the heterogeneity of techniques described(1).
OBJECTIVES. To develop a model for BG-PDT that includes a step by step design for successful execution, based on the literature review of published descriptions and posterior experts' consensus.
METHODS. Major medical databases were searched with the terms: tracheostomy, percutaneous, cricothyroidotomy, cognitive task analysis, toolkit, and evaluation. Relevant descriptions and checklists of BG-PDT and similar procedures were retrieved. Activities were extracted from each report and the adherence to McKinley's dimensions of procedural competence were analyzed: preparation, infection control, communication and work with the patient, teamwork, safety, procedural competence, and post-procedure care(2).- With this information, we developed a model represented in Business Process Model Notation (BPMN). To further validate the model, we used the Delphi method by conducting an online survey in which experts from Latin America were asked to score with a five-point Likert scale the suitability of the proposed activities. Also, experts were allowed to propose changes to the order of activities or propose new ones. Predefined criteria were used to define the "expert" group, to finalize the Delphi panel: more than 80% correlation with Pearson's R test or 3 rounds, and more than 80% of median consensus for inclusion activity in the model. Non-parametric descriptive statistics were used, dates present as median and range.
RESULTS. Twelve descriptions found in the literature and the local protocol were included for analysis. The descriptions presented 19 [6-33] steps and had 3 [1-5] of McKinley's dimensions. No description had all the dimensions. The most frequently represented (85%) were "preparation" and "procedural competence", while no description included "patient communication". The first model used for the Delphi panel includes all McKinley's dimensions, with two operators (bronchoscopy and tracheostomy), with a total of 51 steps divided into 6 stages. The Delphi panel was answered by 25 experts from 9 countries and was ended in the second round with a correlation of 0.83. The final model (Figure 1)included 45 activities proposed in the initial model and 6 new activities proposed by the experts; 6 activities from the initial model were excluded.
CONCLUSION. We have presented a BG-PDT model that includes necessary competence dimensions to be considered complete. The model has been validated by an experts' consensus, allowing to capture the inter-center variability. This model can be used to define local standards or for the training of physicians.

Driving pressure is a predictor of postoperative mechanical ventilation in patients undergoing emergency surgery for peritonitis: Interim analysis from a prospective observational study

R. Thakuria, A. Roy Chowdhury, CA. Kayina, N. Pangasa, S. Maitra, DK. Baidya, G. Prasad
[1]Anaesthesia,pain medicine and critical care, All India Institute Of Medical Sciences, New Delhi, NEW DELHI, India

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001093

INTRODUCTION. Patients who are undergoing emergency laparotomy are at risk of both intraoperative hypoxemia and postoperative pulmonary complications (POPC). POPCs are frequent complications following open abdominal surgery and may be associated with hospital mortality. The most important postoperative pulmonary complications are atelectasis, pneumonia, respiratory failure, and exacerbation of underlying chronic lung disease requiring postoperative mechanical ventilation.Driving pressure, a simple surrogate marker of lung strain has been found to be strongly correlated with mortality in acute respiratory distress syndrome patients and also correlated with POPC in patients undergoing surgery under general anaesthesia.
OBJECTIVES. We hypothesize that Driving pressure is a prognostic marker in patients undergoing emergency laparotomy and may be useful in detecting patients who might require postoperative ventilatory support.
METHODS. The parent study is a prospective observational single centric study, where adult patients of American Society of Anesthesiologists physical status I or II either sex aged between 18- and 65-years undergoing emergency laparotomy for clinically proven

or suspected peritonitis are being recruited.The study was aimed to identify correlation between oxygen index (OI= mean airway pressure x FiO2/PaO2) and oxygen saturation index (OSI)and whether OSI is a predictor of postoperative mechanical ventilation. All patients were followed till hospital discharge.
RESULTS. Data of n=38 patients were analyzed in this interim analysis. Median [IQR] age of the patients was 32.5 [23- 45]y and 12 of them were female. Fifteen patients (41.7%) required postoperative mechanical ventilation and 16.7% patients died during hospital stay. Patients who required postoperative mechanical ventilation, had lower PaO2 (p=0.01), lower oxygenation index (p=0.0004) and higher driving pressure (p=0.0001) after induction of general anaesthesia. However, pCO2, pH and arterial lactate were statistically similar. In a multivariable logistic regression model which included age, baseline INR, baseline arterial lactate, OI and DP, only DP was found to be a significant predictor of postoperative mechanical ventilation [adjusted odds ratio (95% CI) 1.75 (1.14, 2.68), p=0.01; goodness-of-fit p=0.95].
CONCLUSION. We conclude that in patients who are undergoing surgery and having risk of POPC, intraoperative DP is a predictor postoperative mechanical ventilation irrespective of oxygenation status.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001099

INTRODUCTION. Pulmonary perfusion block might be associated with a combination of deleterious mechanisms, including alveolar hypocapnia and heterogeneous distribution of ventilation, which, in turn, could induce lung injury.
OBJECTIVES. To describe the effects of unilateral complete pulmonary perfusion block in healthy pigs undergoing protective controlled mechanical ventilation for 48 hours.
METHODS. Ten anesthetized pigs were randomly allocated to surgical left pulmonary artery ligation (Ligation group, n = 7) or no intervention (Control group, n = 3). All animals were ventilated on volume controlled mode with 10 ml/kg tidal volume, respiratory rate 25 bpm, FiO2 0.5 and PEEP 5 cmH2O for 48 hours or until PaO2/FiO2 fell below 100 mmHg (Tend). Gas exchange, hemodynamic parameters, and respiratory mechanics data were collected at Tend before sacrifice. Quantitative CT scan was performed to assess lung weight variation at Tend compared to initial. At autopsy, portions of left and right lung were fixed in formalin for histologic examination. Plasma samples were stored every 12 hours to measure cytokine levels (IL-6).
RESULTS. Two animals from the Ligation group were sacrificed at 24 and 36 hours, while all animals from the Control group safely arrived at 48 hours. Total histologic score was significantly higher in the Ligation group compared to the Control group, both for the left and the right lung (p<0,001, Figure 1). Most represented histologic alterations were alveolar neutrophils infiltration, alveolar macrophages proliferation and interstitial lymphocytes proliferation and affected both lungs of the Ligation group. In parallel, IL-6 level in the Ligation group reached a higher peak value than Controls during the study period (35.75±25.61 pg/mL vs 8.90±5.63 pg/mL, p= 0.03). At Tend, Ligation group showed lower respiratory system compliance, higher driving pressure, lower oxygenation and higher increase of the lung weight (Table 1).
CONCLUSION. Unilateral ligation of pulmonary artery induces bilateral lung injury in animals undergoing otherwise protective mechanical ventilation.

INTRODUCTION. Cellular profiles in bronchial secretions of mechanically ventilated patients are largely unknown. Different sampling procedures might result in different cellular profiles in material aspirated from the airways.[1]
OBJECTIVES. We aimed to evaluate bronchial secretions in terms of differential cell count and percentages obtained by mechanical ventilated critical care patients using different methods of sampling.
METHODS. This prospective study took place in the Intensive Care Unit of a tertiary Greek hospital during a six-month period. Patients were included if they were under MV for less than 24 hours and required bronchoscopy. Furthermore, non-mechanically ventilated subjects who underwent a single bronchoscopy, were assessed as controls. In all patients, aspiration of bronchial lining fluid (BLF) was performed, Bonchoalveolar lavage (BAL)and two types of Bronchial Washings (BW40 and BW5) were performed with the instillation of normal saline (ml) 150, 40, 5, while visible bronchial secretions were obtained via bronchoscopy (VBS) and blinded, via a common catheter for tracheobronchial aspiration (AC). Samples were homogenized in a Heidolph Silent Crusher S and total cell counting was performed after Trypan Blue staining, while cell types were assessed after May Gruenwald-Giemsa staining.
RESULTS. Twenty-five patients and six controls were evaluated. Mean (SE) age was 65.9(3.0) and APACHE II 18.5(1.5). Ten patients were admitted due to surgical problems. The mean total cell number (TCn) in BLF, BAL, BW40, BW5, VBS and AC were 54.2x104 (82.1x103), 11.6x105(28.8x104), 11.3x105(3.0x105), 80.7x104(13.3x104), 15.2x105(29.9x104), 10.2x105 (12.7x104) in patients and 11.2x104(17.01x104), 10.9x104(15.5x103), 12.2x104(16.8x103), 6.6x104(9.9x103), 10.9x104 (21.5x103) in controls respectively. The percentage of neutrophils (%Net) were 37.31(2.1), 22.4(2.1), 19.5(2.0), 25.8(2.1), 21.9(2.6), 24.5(1.9) vs 21.2(4.5), 23.7(5.0), 20.1(3.9), 16.2(3.9), 22.8(5.3), 11.7(5.0), in patients and controls, respectively. There were significant associations between BAL and BW40 in terms of TCn and %Net (p=0.006, p=0.03) and between VBS and AC in terms of TCn and %Net (p=0.001 and p=0.05).
CONCLUSION. BAL and BW40 may present similar TCn and %Net in mechanical ventilated critical care patients. Samples obtained by blind catheter tracheobronchial aspiration, as in common clinical practice, may present similar TCn and %Net with visible secretions obtained by bronchoscopy.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001111

INTRODUCTION. Intubation in Intensive Care Unit (ICU) is high risk (1,2) with serious airway complications 55 more likely to occur in ICU than in operating theatres (3). Airway training for ICU nurses is challenging: ICU nurses often lack anaesthetic airway experience (1,2); there are limited low risk cases for training (2);nurses receive infrequent exposure to airway management especially advanced and rescue techniques; and skill decay is an issue which affects senior and junior staff alike (4).
OBJECTIVES. Our aim was to design and deliver an airway training programme using the "Bath Tea Trolley" method , (5) teaching ICU staff to use a bougie and apply cricoid pressure during a rapid sequence induction.
METHODS. We ran a month of concentrated airway training named "Janu-Airway" using a trolley with airway training equipment on the top and pot of tea on the bottom. A trainer and the trolley travelled around the ICU providing 10-15 minutes teaching sessions for ICU staff at the bedisede during their normal working shifts. Cricoid pressure application was practiced and its effec on the view at laryngoscopy was demonstrated using a manikin and C-MAC videolaryngoscope (Karl Storz GmbH) and assisting intubation using a bougie was practised. Posters were distributed via email/closed social media groups, and handouts were given to participants to facilitate reflective learning. Feedback was collected with staff self-rating confidence before/after training using a five point Likert scale, followed by a cup of tea.
RESULTS. 81 members of staff received training; 18 senior nurses, 43 staff nurses, 11 junior doctors, 3 physiotherapists, 3 medical students, 1 outreach sister, 2 advanced critical care practitioners (ACCP). This included 100% of ICU nurses and junior doctors. Feedback forms were completed after 57/81 (72%) of training sessions. Resulsts as follows: increase in confidence by one point or more on the Likert scale reported for both cricoid pressure (45/58, 83%) and the use of a bougie (49/58, 84%); improvement in the abilityto assist with intubation reported by all participants - 56/58 (97%) strongly agreed, 2/58 (3%) agreed; similar training in the future was requested by all participants - 47/58 (81% strongly agreed, 11/58 (19%) agreed.
CONCLUSION. Our "Bath tea trolley" training programme provided effective, practical and non-threatening multidisciplinary airway training in the workplace. Training was provided to 100% of our ICU staff -during their usual shifts and for minimal cost. It was quick and easy to set up, flexible and fun. This training method could be transferable and reproducible in other ICUs

INTRODUCTION. Lung ultrasound (LUS) is gaining recognition as a useful tool for assessing lung pathophysiology.Lung Ultrasound Scores (LUSS) have been proposed for the assessment of pulmonary edema without having been validated with a reference gold standard, i.e. invasively determined EVLW
OBJECTIVES. This study has two main goals. First, to test the feasibility of a modified automatic and quantitative scoring system based on the percentage of pleura involved by B-lines in an attempt to provide an objective, operator-independent and quantitative classification of the severity of pulmonary edema in comparison with the previously described semi-quantitative scores. Second, to compare the ability of this new scoring system and those previously proposed

in the assessment of extra vascular lung water (EVLW) as determined by standard thermo-dilution method.

METHODS. Prospective observational study. Single-center, mixed medical-surgical ICU in Europe. Patients over 18 years old admitted to the Intensive Care Unit with acute respiratory distress syndrome (ARDS). Images were collected by a system (Esaote MyLab alpha or Myndray DC-N3) with high-frequency (10 MHz), linear-array probe, with the patients in a supine position. Transverse scanning was used to visualize the pleural line avoiding acoustic interference from the ribs. Six standard areas of each hemi-thorax were identified relative to sternum and axillary lines: anterior, lateral, and posterior, each ones divided into upper and lower halves. On each scan the following data were recorded: presence of A lines, maximum number of B-lines, visual percentage of lung area occupied by confluent B-lines, visual pleural involvement >50% or ≤50% and tissue-like patterns (consolidations). Five scores were defined as follows 1) maximum number of B-lines detected (nLUSS), 2) visual percentage of lung area occupied by B-lines (%LUSS)[5], 3) B-line coalescence (cLUSS)[6], 4) modified B-line coalescence score (qLUSS)[7], 5) computer-aided score (QLUSS).

RESULTS. 144 thoracic areas in 12 ICU patients were examined. Five scores were defined as follows 1) maximum number of B-lines detected (nLUSS), 2) visual percentage of lung area occupied by B-lines (%LUSS), 3) B-line coalescence (cLUSS), 4) modified B-line coalescence score (qLUSS), 5) computer-aided score (QLUSS). EVLW index was significantly correlated with QLUSS mean value (r=0.898; p<0.0001), qLUSS (r=0.822; p=0.001), %LUSS (r=0.743; p=0.006) and cLUSS (r=0.619; p=0.032), but not nLUSS (r=0.055; p=0.865). Absolute agreement between raters was strong for cLUSS [ICC: 0.703 (95 % CI 0.303 to 0.858)], %LUSS [ICC: 0.745 (95 % CI 0.631 to 0.822)], qLUSS [ICC: 0.825 (95 % CI 0.705 to 0.896)] and nLUSS [ICC: 0.895 (95 % CI 0.835 to 0.931)], with the best correlation for QLUSS [ICC: 0.998 (95 % CI 0.996 to 0.999)].

CONCLUSION. This pilot study shows that only computer-aided methods measuring the percentage of pleural line affected by B-lines can give a reliable assessment of extra vascular lung water and performs better than scores. This approach to B-lines quantification can turn images into numbers, thus providing an operator-independent analysis of large amounts of data and improving inter-observer agreement.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001141

INTRODUCTION. Nasal High Flow (NHF) is a non-invasive respiratory support for patients with hypoxic respiratory failure. Currently, intermediate physiologic outcomes that accurately predict mortality lack, but could be useful to test new treatments and to stratify severity.

OBJECTIVES. We aimed to identify physiological parameters that independently predict mortality at 48 hours in hypoxic patients initially supported by NHF.

METHODS. We enrolled eighty-three hypoxic patients with pneumonia and initially supported by NHF. We recorded baseline demographics, disease severity (SOFA, APACHE II, PSI scores) and quadrants involved at chest radiograph. Then, intubation rate and physiological parameters were collected at 48 hours and, finally, in-hospital mortality was recorded. By use of relevant parameters at 48 hours, we calculated a new Saturation Index as (FiO2 × Mean Airway Pressure (MAP))/SpO2; where MAP was 0 for non-intubated and not on NHF patients, flow/10 cmH2O for patients on NHF and the one measured by the ventilator in intubated patients. Finally, we conducted univariate and multivariate analysis for parameters at 48 hours to disclose independent predictors of mortality.

RESULTS. 66% patients were female and mean age was 59 ± 14.7 years old. APACHE II and PSI scores were 17 ± 7 and 104 ± 40. NHF was initially started with flow 42 ± 7 L/min and FiO2 0.68 ± 0.23. At 48 hours, sixteen patients were intubated (19.3%), while thirteen (15.7%) were weaned from NHF support. In-hospital mortality was 30.2% (25 patients). Univariate analysis showed that, at 48 hours, FiO2, SpO2/FiO2, Saturation Index and number of intubations were significantly different between survivors and non-survivors (Table 1). At logistic multivariate analysis performed with these four parameters, only SpO2/FiO2 ratio emerged as independent predictor of hospital mortality (OR 0.97, 95% CI 0.95 to 0.99, p=0.011). ROC curve analysis confirmed this result with AUC-ROC of 0.807 (95% CI 0.69 to 0.92, p<0.001) and cut-off of 138 (sensitivity 65% and specificity 87%).

CONCLUSION. In hypoxic patients initially supported by NHF, lower SpO2/FiO2 ratio measured at 48 hours independently predicts hospital mortality.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001151

INTRODUCTION. Overweight and obesity are increasingly prevalent worldwide and account for about 30-40% of patients with acute respiratory distress syndrome (ARDS). How body mass index (BMI) influences respiratory mechanics in ARDS is unclear.
OBJECTIVES. To compare the respiratory mechanics of obese and non-obese ARDS and assess the influence of BMI on respiratory mechanics and lung volumes.
METHODS. This study is a secondary analysis of 2 cohorts of ARDS according to the Berlin definition: a bicenter Canadian study of 45 ARDS of any BMI enrolled in a prospective study (NCT02457741), and a French monocenter cohort of selected ARDS with a BMI > 40 kg/m2. Airway pressure, flow and esophageal pressure were collected in all patients and we report data at a set positive end-expiratory pressure (PEEP) of 5 cmH2O. Presence of complete airway closure (1) and airway opening pressure were assessed using a low-flow inflation pressure-volume curve. End expiratory lung volume (EELV) was measured using the nitrogen washout/washin technique. The ratio EELV to predicted functional residual capacity (2) was calculated.Patients were sorted in 3 groups according to the World Health Organization overweight classification (BMI < 30, from 30 to < 40, and ≥40 kg/m2).
RESULTS. Among the 54 patients included, 18 patients (34%) had BMI < 30 kg/m2, 16 (30%) between 30 and 40 kg/m2, and 19 (36%) ≥40 kg/m2. The median PaO2/FiO2 was 138 mmHg with a PEEP of 15 cmH2O, and mortality was 32% without difference across groups. Airway closure occurrence increased with BMI (22%, 38% and 58%, p= 0.04). When present, airway opening pressure was 9.6 cmH2O (8.5-13.2) and similar between the 3 groups. With increasing BMI, total PEEP increased from 6.0 to 9.0 cmH2O between groups (p= 0.02). All values of esophageal pressure increased with BMI. End-expiratory esophageal pressure was strongly correlated with BMI (rho= 0.71, p<0.001), as illustrated in Figure 1. Consequently end-expiratory transpulmonary pressure decreased from -2.7 to -9.3 cm H2O with increasing BMI (p= 0.008). The ratio of EELV to predicted functional residual capacity was negatively correlated with end-expiratory pressure (Rho= -0.39, p= 0.01), but not with BMI. Driving pressure and elastance of the respiratory system, chest wall and lung were similar across all ranges of BMI. Likewise, EELV was similar between groups.
CONCLUSION. In ARDS, increasing BMI is associated with increased occurrence of airway closure and increased values of esophageal pressure. Conversely, chest wall elastance is not influenced by BMI, as well as lung elastance. Including BMI in interpreting respiratory mechanics in ARDS patients can provide additional information for the clinical management.

INTRODUCTION. Mottling is a patchy discolouration of the skin, thought to be secondary to a reduction of blood flow within the superficial skin vasculature [1]. Although it may occur in the absence of acute illness, in intensive care patients it is associated with haemodynamic collapse and failing circulation. Mottling was first described as a sign of poor perfusion as early as 1894 [2], but in the last decade there has been a renewed interest in assessing mottling in critical care [3-7]. Previous studies, where attempts have been made to quantify the extent of mottling, have shown that increased mottling of the lower limb is associated with higher mortality rates [3]. The reported incidence of mottling varies considerably. Estimates range from 2.5% [8] to 70% [3], which may be due to relatively small cohorts in these studies (ranging from 14 [4] to 791 [5] patients). It has been suggested that persistent mottling of the skin is an independent risk factor for ICU mortality, after adjusting for the use of vasopressors, mechanical ventilation and hyperlactaemia [5]. However, these factors might not adequately adjust for illness severity, leading to a lack of clarity on whether mottling is truly an independent risk factor of poor prognosis.
OBJECTIVES. The aim of this retrospective cohort study was to assess the incidence of mottling in the intensive care unit (ICU) and its relationship with mortality and length of stay.
METHODS. We used data collected as part of the Post-Intensive-Care Risk-adjusted Alerting and Monitoring (PICRAM) study of patients admitted to ICU at a large UK hospital between June 2008 and December 2015. The presence of mottling was extracted from nursing lower limb skin assessment which were documented from a pre-defined list of terms including 'mottled'. Admissions were classified as either 'mottled for any duration during ICU stay' or 'never mottled'. For each admission, we also calculated the Oxford Acute Severity of Illness Score (OASIS), and outcome data comprising ICU mortality, ICU length of stay and hospital mortality were extracted. Logistic regression analysis was used to assess the effect of mottling status on outcomes.
RESULTS. 8,556 unique admissions to ICU were identified, of which 1,136 (13.3%) had documented mottling of the lower limb at some point during their ICU admission. Unadjusted mortality rate in the mottled group was 33.9% compared to 7.1% in the never-mottled group. Unadjusted within-ICU mortality was significantly higher in the mottled group (OR 6.71 (95% CI 5.76-7.80)). When adjusted for severity of illness using OASIS, ICU mortality risk in mottled patients remained significantly elevated at OR 3.07 (95% CI 2.59-3.64). ICU length of stay was increased by a factor of 1.54 or 4.2 days.
CONCLUSION. This is the largest study of mottling in critical care. We calculated the incidence of mottling to be 13.3% of ICU admissions, which is at the lower end of previous estimates. The lower estimates of our cohort may be due to under-reporting of mottling when a minor degree of mottling over the knee was present (equating to mottling score of 1 out of 5). Mottling is a clinical sign of poor skin perfusion and is associated with significantly increased mortality risk with OR 6.71. It is an independent predictor of ICU mortality.

INTRODUCTION. Exposure to excessive oxygen concentrations may be harmful to acutely unwell patients (Girardis 2016; Helmerhorst 2016) and new guidelines recommend avoiding an oxygen saturation (SpO2) >96% (Siemieniuk 2018). Little emerging literature and guidance is specific to patients on the intensive care unit (ICU) and robust data, describing normal practice, in this cohort is absent. We aimed to determine the standard of care for oxygenation in patients admitted to ICUs in England.
METHODS. Data was interrogated from the Critical Care Health Informatics Collaborative (CC-HIC) data infrastructure (Harris 2018; Shi 2017) - a collaboration between five National Health Service Trusts in England, aggregating high fidelity time series data on patients from 12 ICUs. SpO2 values were queried for patient episodes from January 2014 to December 2018. Raw data were presented as time-weighted mean values for SpO2 (SpO2-tw) for a number of predetermined subgroups. Statistical analysis was not performed as the sample size would be powered to detect clinically meaningless signal.
RESULTS. After applying centrally determined validation procedures, we identified 6,524,918 SpO2 values from 44,150 individual patient episodes. The median [IQR] SpO2-tw for the whole cohort was 96.7% [95.5-97.8]. When patients receiving a fractional inspired oxygen concentration (FIO2) of 0.21 were excluded, the median SpO2-tw was 96.9% [95.5-98.1]. For apriori defined subgroups the median [IQR] SpO2-tw were: invasively ventilated (97.1% [95.5-98.3]) versus patients not invasively ventilated (96.5% [95.3-97.6]) (Fig. 1); primary medical (96.4% [95.0-97.6]) versus surgical diagnosis (97.0% [96.0-98.0]); prior or current diagnosis of chronic obstructive pulmonary disease (COPD) (94.5% [92.9-96.1]) versus no such diagnosis (96.8% [95.6-97.8]) (Fig 2).
CONCLUSION. In an unselected ICU cohort, the median SpO2-tw was higher than recommended for acutely unwell patients outside of the ICU. Statistical analysis was not performed, but visual inspection of the distributions shows clear differences between subgroups. The median SpO2-tw, for patients with COPD, is higher than current guideline recommendations (88-92%)(O'Driscoll 2017). Future study design should be mindful of this standard of care.

INTRODUCTION. One of the main goals of a rapid response team (RRT) is to prevent a "failure to rescue" which is the lack of a reaction for a patient which has abnormal vital signs and could increase the probability of a serious adverse event.. The ideal trigger method should increase the accuracy for detection preventing false positives, which could result in fatigue of the team, and decreasing false negatives resulting in a "failure to rescue" and its consequences. (1–3) One of the main problems using a method developed in other hospital, country or population is the implicit heterogeneity and variance, highlighting the importance of personalized tools internally developed using a self-learning machine. We developed a personalized cell phone app based on the data collected from our RRT, showing that every hospital could develop their own tool increasing its applicability and accuracy.
METHODS. Prospective observational study including adult hospitalized non-critically ill patients, excluding obstetric patients and "do not resuscitate" order patients. Every vital sign reported by the nursing staff, age, gender and admission diagnosis was collected in a data base with the final outcome of transfer to the Intensive Care Unit (ICU) during a 3 months period. R version 3.4.0 (20017-04-21) was used for the data analysis and shinyapps.io for the cell phone app.
RESULTS. 6040 cases (set of variables) were included in the final analysis. In order to program the self-learning machine the "caret" package was used in R, using the neural network method or "nnet" with the following parameters: decay of 0.0001, 100 iterations, scaling and centering pre-processing. The final formula used for the self-learning machine was "TRANSFER (to the ICU)~ Age+ SBP (systolic blood pressure)+ DBP (diastolic blood pressure)+ HR (Heart rate)+ RR (Respiratory rate)+ SAT_O2 (Oxygen saturation)". The data frame for training contained 75% of the data and the 25% left for the testing stage.
CONCLUSION. The use of learning machine methods to develop a personalized tool for RRT activation is a promising field. Every hospital has the potential to develop their own tools based on their unique characteristics and keep enhancing it when considered necessary.

INTRODUCTION. ICU populations have increasing levels of multimorbidity. The APACHE-II model is currently used in Scotland to publicly report risk-adjusted mortality in ICUs and benchmark care quality(1,2). However, the model only accounts for severe comorbidity. In Scotland, two national population-wide datasets exist from which milder comorbidities can be derived. These are the Scottish Morbidity Record (SMR01) comprising hospital discharge records for all Scottish hospitals(3), and the Prescribing Information System (PIS), a dataset comprising all community dispensed medical prescriptions(4).
OBJECTIVES.

- To derive comorbidity measures from SMR01 and PIS, report prevalence of comorbidities and their association with mortality in a Scottish ICU population
- To ascertain whether adding comorbidities derived from the two data sources to the APACHE-II-derived risk prediction model improves mortality prediction

METHODS. Cohort study of all patients admitted to Scottish ICUs from 2010-2017 (excluding readmissions) derived from the Scottish Intensive Care Society Audit Group (SICSAG) database, comprising all admissions to Scottish ICUs(5). Comorbidities were derived from two datasets: SMR01-derived comorbidities defined by Charlson(6); PIS-derived comorbidities using British National Formulary codes, adapted from a study using Anatomical Therapeutic Chemical codes(7). Prevalence of derived comorbidities was reported. Logistic regression was used to report the univariable association of each comorbidity with ultimate hospital mortality. After excluding patients ineligible for APACHE-II risk scoring, three risk prediction models for ultimate hospital mortality were developed using multivariable logistic regression: current APACHE-II model, APACHE-II plus PIS comorbidities, and APACHE-II plus SMR01 comorbidities. ROC graphs, area under the receiver operating characteristic curve (AUROC), AIC, BIC and Brier's score were compared.

RESULTS. 99773 patients were included during the study period. 19108 (19.2%) died before ultimate hospital discharge. 17 comorbidity categories were derived from SMR01, and 20 from PIS. The most prevalent SMR01 comorbidity was cancer (15521 (15.6%)), the least was HIV (162 (0.2%)). The most prevalent PIS comorbidity was pain (42354 (42.5%)), the least was dementia (266 (0.3%)). The median number of comorbidities by SMR01 was 1 (IQR 0,1); PIS was 2 (IQR 0,4). On univariable analysis of SMR01, "moderate-severe liver disease" held the highest OR for mortality (OR 3.76 (CI 3.46,4.08), p<0.001); from PIS, the highest was dementia (OR 1.68 (CI 1.44,2.49), p<0.001). Adding comorbidity increased the predictive ability of both models compared to the APACHE-II model, as measured by AUROC, AIC, BIC and Brier's score. The best model measured by AUROC was "APACHE plus SMR01 comorbidities" (AUROC=0.871 vs 0.865, p<0.001).
CONCLUSION. Prescribing data yielded greater prevalence of comorbidities than hospital discharge records. Adding comorbidities to risk prediction models for patients admitted to ICU leads to a small improvement in prediction of mortality compared with the current APACHE II model. Current ICU risk prediction models may need to be revised to include wider comorbidity measures as increasingly multimorbid patients are admitted to ICUs.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000416

INTRODUCTION. To decide whether or not to escalate care, clinicians must accurately assess risk of patients' cardio-respiratory instability (CRI) based on continuously monitored multi-parameter Vital Signs (VS). Assessment accuracy depends on experience, and is a challenge for clinicians.
OBJECTIVES. We propose that an Artificial Intelligence (AI) model built on expert clinicians' adjudication could assist junior nurses (RN) and doctors (MD) to improve their assessments.
METHODS. VS data (heart rate, respiratory rate, blood pressure, oxygen saturation by pulse oximetry) were collected from 1087 continuously monitored step-down unit patients. We fit a multi-class random forest AI model using four-level annotation labels provided by expert senior clinicians (1 RN, 1 MD) suggestive of patients' CRI severity levels and need for care escalation. We also asked two junior clinicians (1 RN and 1 MD) to provide independent assessment of patients' severity levels, blinded to experts' annotations. To emulate scenarios where AI models may be used in practice to assist clinicians' subjective assessment, we applied a conservative adjustment rule on junior clinicians' assessment by overriding their decisions only if the severity level determined by the model was higher than theirs.
RESULTS. We computed pairwise disagreement (1-Cohen's kappa) between expert clinicians, junior clinicians, and the AI model, visualized as distances in the multidimensional scaling (MDS) plot in Fig. 1. Before adjustment, the Junior RN and Junior MD widely disagreed with expert assessment, but converged toward experts when supplemented by the model's suggestions (arrows). Changes of Cohen's kappa with respect to experts' consensus are from .28 to .56 for Junior RN, and .36 to .49 for Junior MD. Also, disagreement between the Junior RN and Junior MD decreased, with Cohen's kappa increased from .27 to .62. After incorporating the AI model's suggestions, the true positive rate (proportion of high CRI risk patients correctly identified, computed using experts' consensus as ground truth) increased (.376 to .836 for Junior RN; .633 to .907 for Junior MD), both converging towards the model's and experts' rating, at a low false positive rate (.03 for junior RN, .22 for junior MD).
CONCLUSION. Incorporating AI encoding expert opinion into the decisional process of junior clinicians' assessment of patient's propensity for severe CRI could improve their clinical decisions.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000487

INTRODUCTION. Hypernatremia is a known independent risk factor for mortality and increases length of stay in the ICU, and slow rates

of correction have also been shown to increase mortality. Most patients are undercorrected based on previous studies. Machine learning methods have the potential to improve the management of this condition.
OBJECTIVES. The study is aimed to use machine learning methods to develop a model which can predict appropriate serum sodium correction in patients with hypernatremia in 24 hours from ICU admission. The secondary aim is to identify which factors are most influential in recovery from hypernatremia.
METHODS. Using the Medical Information Mart for Intensive Care Database (MIMIC-III), we performed a retrospective analysis of patients with hypernatremia (defined as sodium >145 mmol/L) on admission to the ICU. Appropriate correction was defined as either a decrease in serum sodium by 6 to 10 mmol/L or to less than 145 mmol/L without correcting >10 mmol/L in the first 24 hours. The primary exposure was fluid volume controlled for sodium content received in the first 24 hours of admission. We calculated the total sodium content of fluids received and created categories of total free water intake and total crystalloid intake. We queried the database for clinically relevant covariates, including lab data and admission diagnoses. We trained our model in 75% of the patients and tested the model in 25% of the patients. We used both a regularized logistic regression and a random forest classifier to build predictive models. We examined the importance of the covariates in the random forest model.
RESULTS. 1902 patients met criteria for inclusion. 54.6% of patients achieved appropriate correction. Factors associated with lack of correction included older age, sepsis, higher initial sodium value, and elevated BUN. Those who did not correct had a higher mortality rate (24.6% vs. 20.2%). The volume of free water and total fluid volume were not significantly different between the groups. The logistic regression model produced an AUC of 0.74, and the random forest model produced an AUC of 0.76. By examining the variable importance of the random forest model, we identified baseline sodium and BUN as influential predictors for hypernatremia correction.
CONCLUSION. The management of hypernatremia is challenging, and inappropriate correction rates lead to worse outcomes in both the ICU and general hospital population. We were able to create a predictive model for hypernatremia correction using a random forest classifier with a 76% success rate, suggesting that machine learning can be a valuable tool in managing this condition. We also found that baseline sodium and BUN level were influential in predicting correction. Our next step will be to utilize the larger eICU Collaborative Research Database and apply similar methods to create a more reliable model. We hope to eventually develop more effective and efficient methods of hypernatremia correction.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000511

INTRODUCTION. Population pharmacokinetic (PK) model-based Bayesian analysis is playing an important role in optimizing vancomycin treatment for intensive care (ICU) patients. A strength of Bayesian analysis is the ability to include historical PK data to improve the estimation of PK parameters for the betterment of concentration forecasting. However, this strength may turn into a potential weakness due to the high PK variabilities in ICU patients which may affect Bayesian forecasting. In this study, we investigated the impact of using historical data of ICU patients on the performance of Bayesian forecasting of vancomycin plasma concentration.
METHODS. A published one-compartmental population PK model of vancomycin in ICU patients was used in this study [1]. The model has been validated in a large cohort of 839 ICU patients of our own [2]. To assess the impact of historical data in Bayesian forecasting of the vancomycin concentrations in ICU patients, we performed Bayesian analysis in a real dataset of 490 ICU patients including multiple days where PK data was available. By reorganizing the data set, the future 1-day concentrations were forecasted by using the Bayesian estimates of the last 1, 3, 5, 7, 10, and 14 days. Thereafter, we calculated the bias of forecasted versus actual plasma concentrations. Nonlinear mixed-effects modeling software (NONMEM, version 7.4.3; ICON Development Solutions, MD, USA) was used to perform the analysis. Data organization and visualization were carried out with R (version 3.5.2; R-project.org).
RESULTS. The forecasted plasma vancomycin concentration was not significantly biased (-3.8%) when using only the last 1-day samples for Bayesian analysis. However, when including further historical data (last 3 to 14 days), the concentration was increasingly underforecasted (-6.1% to -18.6%). The Bayesian estimates of every day for clearance decreased over time indicating the potential deterioration in the renal function of patients staying in ICU for long, which was in line with our clinical experience.
CONCLUSION. Through Bayesian analysis, vancomycin plasma concentration can be reasonably forecasted for ICU patients when the PK data from last 1-day was used. Inclusion of further historical data could be detrimental to Bayesian forecasting, which may mislead clinicians into treating patients inadequately.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000541

INTRODUCTION. A recent UK study of elective surgery found that one in ten patients had experienced a prior cancellation with lack of Intensive Care Unit (ICU) beds being a major contributory factor [1]. Forecasting ICU bed occupancy to prevent on-the-day cancellation could potentially curb the physical, emotional and economic costs of postponement [2]. Occupancy forecasting requires an optimal database schema to house clinical data – "Clinical Data Warehouse (CDW) design". If forecasts are to be based on real-time Electronic Health Record (EHR) data, the database powering them must integrate directly into the hospital's outward data flows. Then, once the data is stored in the CDW, the needs of data scientists creating new models differ from those of software developers looking to deploy transferable forecasting systems. Good CDW design should support both use cases.
OBJECTIVES. The core objective was to design and build a CDW to enable research into EHR-driven occupancy forecasting. As a first milestone, we focused on ingesting ADT (Admission Discharge Transfer) data as important indicators of short term occupancy. A key outcome was to demonstrate the CDW's robustness to the high data volumes leaving the hospital. To be viable, any design also has to support two major output layers for our data science users. The first was the Observational Medical Outcomes Partnership (OMOP) Common Data Model, a well-documented patient-centric data model with uptake in the ICU community for retrospective research [3,4]. The second was the Fast Health Interoperability Resource (FHIR), an emerging interoperability standard, with a clear API specification for app development [6].
METHODS. The design process began with a literature review. This informed a prototype transformation of our ICU EHR to the OMOP Common Data Model. We then formalised the CDW design, named 'Inform-DB'. This schema was load-tested in PostgreSQL 11.2 with a million fabricated patients, twice the number of yearly admission messages to our hospital.
RESULTS. The design process for Inform-DB resulted in a schema specification for ADT messages [6]. A preliminary translation to the OMOP data model has been built. This design withstood load testing across two years' worth of admission data in less than 36 hours. A standard query of patients admitted across one week was returned in less than 3 seconds, and from the third repetition onwards in less than 450 milliseconds (Fig. 1).
CONCLUSION. This early work shows that Inform-DB has the necessary speed to handle real-time data flows from a large tertiary hospital. Work is underway to integrate the schema with our hospital's live outbound messages. This will enable incorporation of real-time data into EHR-driven forecasting systems.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000551

INTRODUCTION. The MIMIC-III dataset is a large, freely-available database containing anonymised healthcare data associated with over forty thousand patients who stayed in critical care units of the Beth Israel Deaconess Medical Centre between 2001 and 2012 (1). It can be a challenging process to manipulate the data in such a way as to make it useful. Artificial neural networks (ANNs) are constructed by a set of computing units that simulate neurons linked together. An architecture for the network is established and then an algorithm is used to find the weights of the connections between the neurons. We sought to determine whether hospital outcome (e.g. alive or dead) could be predicted more accurately using an ANN or by more familiar methods (e.g. generalised linear modelling) using the MIMIC-III dataset.
METHODS. Following data cleansing (e.g. removal of all multiple admissions, selection of data recorded within first 24 hours of admission) our dataset comprised of 11,759 patients (18 to 89 years old). We chose similar physiological variables as used by the Intensive Care National Audit & Research Centre (ICNARC) Case Mix Programme ICNARCH-2018 regression model (2): age, lowest pH, highest lactate, highest urea, highest creatinine, highest sodium, lowest white blood cell count and lowest platelet count. We chose to use one hidden layer with 5 neurons for our ANN. Prior to training the neural network the dataset was normalised using a min-max scale method. The dataset was randomly divided into a training and

test subset using a 70:30 ratio respectively. To evaluate the accuracy of our predictions we used the mean squared error (MSE), confusion matrices and ROC curves for both the ANN and multivariate regression model. All data mining and statistical analyses was performed using R version 3.5.3 (packages *dplyr, lubridate, ggplot2, neuralnet, plotROC*); computation was performed using an Intel Core i7-8750H hexacore processor.

RESULTS. The median age of our dataset was 64 [IQR 52 – 76] years, with the training and testing dataset comprising of 8231 and 3528 patients respectively. The ANN training time was approximately 4 minutes and produced an MSE of 0.118 (figure 1) and ROC AUC of 0.81 (figure 2). The multivariate regression model required approximately 0.04 seconds of computational time and produced an MSE of 0.127 and ROC AUC of 0.77 (figure 2); all variables were considered statistically significant at an alpha level of 0.05. The confusion matrices for the ANN and regression model demonstrated an accuracy of 84% and 83% respectively.

CONCLUSION. The ANN performed only marginally better when compared to the multivariate regression model, suggesting little difference between the two methods for predicting hospital mortality. However, neural networks remain flexible and once trained can compute predictions as quickly as other well-known methods. In addition, given that datasets such as MIMIC-III continue to grow and encompass more and more data, being able to feed this new data into an ANN as it accumulates over time will inevitably be less resource intensive due to its nature of 'online' learning as opposed to 'batch' learning.

Trajectory of illness predicts outcome independently of illness severity at time of initial assessment of patients admitted to ICU, and is significantly different in sepsis

J. Hunter[1], S. Harris,[2]
[1]Anaesthetic department, University College Hospital, Euston Road, London, UK; [2]Critical care department, University College Hospital, Euston Road, London, UK

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000555

INTRODUCTION. Acute physiology scores (APS) are used to risk stratify patients on admission to Intensive Care (ICU), and intuition would suggest determining illness trajectories could improve prognostication. Underlying pathology is likely to be a significant factor in the trajectory of critical illness, but there is little data supporting this. The trajectory of sepsis is of particular interest as the SEPSIS-3 definition requires a change in SOFA score (1).

METHODS. This was a planned analysis of data from a prospective cohort study of consecutive deteriorating ward patients assessed for ICU admission in 49 NHS hospitals (1 November 2010 to 31 December 2011). Trajectory was defined as the change per hour in severity score between the ward assessment and first 24 hours within ICU, calculated based on the ICNARC APS score (2). A negative trajectory represents improvement. Multiple imputation via chained equations was used to manage missing data. The primary admission diagnosis was extracted from the clinical coding on admission.

RESULTS. Imputed data for 5,429 patients were analysed. 1,791 patients had a confirmed ICNARC sepsis diagnosis occurring with a frequency of greater than 1 per cent (pneumonia, septicaemia, septic shock, acute kidney injury (AKI) related to infection, or urosepsis). Patients with a confirmed ICNARC sepsis diagnosis are on an improving median trajectory of -0.5 (IQR -3.00 – 0.08) at time of admission to ICU, but show less improvement than patients without a sepsis diagnosis, with a median trajectory of -0.75 (IQR -4.00 – 0.08). The difference is significant (Kruskal-Wallis test, H = 9.49, 1 d.f., p = 0.002)

Using a binomial generalised linear model including age, lactate, presence of ICNARC sepsis diagnosis, and ward severity score, trajectory was an independent predictor of death at 28 days (odds ratio 1.084, 95% confidence interval 1.079 – 1.092, p = <2 x 10-16). The interaction between severity score trajectory and ICNARC diagnosis of sepsis, modeled in a separate binomial generalised linear model, was not significantly predictive of outcome.

CONCLUSION. This dataset reveals that patients with a sepsis diagnosis are improving on admission to ICU, which is of interest given the new SEPSIS-3 definition, and there is significant variation in trajectory between patients with sepsis and non-sepsis diagnoses. Further work is needed on the potential for trajectory before and during ICU admission as a predictor of outcome.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000584

INTRODUCTION. Cardiac arrest carries a significant rate of in-hospital mortality, which is a major catastrophic event and hard to predict. Various early warning scores have been developed, but they mostly rely on in-hospital data such as vital signs from the current events, and suffer from low accuracy and high false positive rate. Here we tested if claims data can be used to predict in-hospital mortality, because we hypothesized that historical events play a role in predicting patient outcomes. We employed a deep learning approach, which has been shown to be useful in learning hidden patterns.
OBJECTIVES. To develop models capable of predicting in-hospital mortality based on historical claim data from Taiwan National Health Insurance Research Database (NHIRD).
METHODS. Taiwan NHIRD is derived from its single payer health insurance program that covers 99% of the population. It provides nationwide longitudinal claim records from all healthcare providers. We selected 8 years of de-identified claims (2003–2010) corresponding to persons with cardiac arrest and resuscitation with at least one emergency department (ED) visit or one hospitalization event. Primary outcome was all-cause in-hospital mortality. We constructed a deep learning system involving two steps. First, we used a taxonomy mapping system Text2Node, to generate a distributed representation for each concept. Second, we applied a multilevel hierarchical deep learning model based on the long short-term memory (LSTM) architecture. The resulting model was trained using the multi-task learning approach,
RESULTS. We included a total of 1,227,739 hospitalizations and 1,346,782 ED visits involving 326,180 patients. In in-patient events, in-hospital mortality is 7% (109,131 cases).The dataset is split randomly into training (70% of the patients), test (15%) and validation (15%) sets (figure 1). Hyper-parameters for each model was optimized by maximizing the area under the receiver operating characteristic curve (AUROC) for the validation set. The optimized set of hyper-parameters was then used to train the model on all events excluding the test set. For model evaluation, the AUROC, test accuracy, and F1 score were calculated on the held-out test set. Our model achieved high accuracy, with an AUROC value of 0.96, 95% of accuracy, and an F1-score of 0.63.
CONCLUSION. Longitudinal claim databases such as NHIRD provide valuable information in predicting rare catastrophic events when employing a deep learning approach. To implement this system in a real-world ED setting, a study on interpretability is underway.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000675

INTRODUCTION. Sepsis mortality is still unacceptably high and an appropriate prognostic tool may increase the accuracy for clinical decisions. Several techniques of artificial intelligence (AI) are currently providing efficient ways for data mining and analysis. Thus, sepsis is a very attractive area for implementation and evaluation of several models of AI
OBJECTIVES. To develop and to evaluate several supervised techniques of data mining and AI for classification and prediction of mortality in adult patients hospitalized by emergency services with sepsis diagnosis
METHODS. Secondary data analysis of a prospective cohort conducted between June 2014 and February 2016 in three emergency services of university hospitals in Medellin, Colombia. Patients 18 years older were included, provided they were hospitalized because of suspected or confirmed infection and any organ dysfunction according to SOFA score. The outcome variable was hospital mortality and the prediction variables were grouped in either those related with treatment and initial clinical attention or those that measure directly physiological derangements. Five supervised classification techniques were analyzed: C4.5 Decision Tree (C4.5), Random Forest (RF), Artificial Neural Network (ANN) and Support Vector Machine (SVM) by either *dot* or ANOVA. Their performance was evaluated by the concordance between observed and predicted mortality (accuracy) and by the discrimination according to AUC-ROC
RESULTS. The study cohort was composed of 2510 patients with a median age of 62 years (IQR=46-74) and an overall hospital mortality rate of 11.5 % (n=289). The best discrimination was provided by the ANN using physiological variables (Table).
CONCLUSION. Deep learning and artificial intelligence are increasingly used as supporting tools in clinical medicine. Their performance in such a complex and heterogeneous syndrome as sepsis may be a new a horizon in clinical research. Artificial Neural Networks seem promising for improving sepsis classification and prognosis

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000716

INTRODUCTION. The target for optimal glycemic control in the intensive care setting remains uncertain, despite more than a decade of debate. Randomized clinical trials suggest that different patient populations may benefit from different targetss. Van den Berghe et al. showed that glucose targets of 80 – 110 mg/dL resulted in a decrease in morbidity and mortality for surgical ICU patients, without the same effect observed in medical ICU patients. Meanwhile Finfer et al. showed that an intensive blood glucose target of 81 – 108 mg/dL compared to the conventional target of ≤ 180 mg/dL resulted in significantly higher 90 day mortality in both medical and surgical patients. Current research is limited with regards to evidence supporting specific glucose targets for heterogeneous patient populations.
OBJECTIVES. We hypothesize that dynamic glucose targets (based on variables such as patient physiologic parameters, duration of ICU stay and disease trajectory) may improve outcomes in the ICU patients. Since randomized controlled trials for different glucose targets and sub-populations of patients are impractical, we have utilized observational data in large publicly available datasets. To begin to analyze outcomes, we have first curated the database and performed descriptive analysis of current practices.
METHODS. This study utilized the publicly available MIMIC-III database which contains over 58,000 ICU admissions between 2008-2012 for a cohort of approximately 38,600 adults. Retrospective data were extracted in the following categories: blood glucose measurements (finger-stick glucometer and serum values), dextrose inputs, and insulin inputs (short, intermediate and long acting). Glucose and insulin values were paired to match them according to timestamp criteria. Data extraction and alignment was performed with SQL queries executed in Python.
RESULTS. A combined 373,239 glucose values were extracted between 155,168 laboratory chemistry readings and 218,071 finger-stick readings. 151,184 total insulin values were extracted; 138,561(91%) short-acting, 3,982(3%) intermediate-acting and 8,641(6%) long-acting. When frequency of insulin dosing was plotted it was shown that the majority of short acting insulin administered was in the range of 2 to less than 4 units (nearly 35,000 occurrences). After applying the algorithm for alignment, 41,387(95.9%) of short-acting intravenous infusions and 84,070(94.6%) of short-acting subcutaneous boluses were matched to corresponding glucose values. Dashboards were created for each ICU admission (plotting glucose and insulin values over time) to clinically validate the alignments. To evaluate the quality of glucose control, glucose values after short-acting subcutaneous insulin administration were plotted for the following intervals, <60 min, 60-120 min and 2-6 hours.
CONCLUSION. Blood glucose control in the ICU does not meet the current recommended guidelines. Despite suggested targets, glucose often falls outside of this range, and patients often experience hyperglycemia. For research on targets to be effective, we need to be able to control glucose well. Strategies for management need to be developed in tandem with accurate personalised targets if we are to improve outcomes. Future analysis with this dataset will seek to find trends between glucose control and clinically meaningful intermediary outcomes, such as indices of illness severity such as SOFA scores.

Deep-learning neural networks for accurate diagnosis of sepsis using microarray gene expression data

D. Schaack, T. Brenner, M. Weigand, F. Uhle
[1]Department of anesthesiology, University Hospital Heidelberg, Heidelberg, Germany
Correspondence: D. Schaack
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000956

INTRODUCTION. Sepsis is a life-threatening condition, arising from a dysregulated and harmful host response to infection [1]. Due to its syndromic nature, no solitary biomarker with sufficient clinical performance is available and reliable diagnosis of sepsis remains challenging. Apart from rapid identification of the causative pathogen, the bloods' immune system is proposed to contain important information, especially on gene expression level. In recent years, machine learning approaches revolutionized the way of using high-dimensional data and also proved its diagnostic value when integrating electronic health record data of ICU patients [2].
OBJECTIVES. We performed a pilot study utilizing deep-learning artificial neural networks based on a large set of public microarray data and aiming to evaluate its performance for the accurate diagnosis of sepsis.
METHODS. Public repositories (NCBI GEO, EMBL-EBI Array Express) were searched for microarray data series containing septic patients (n=1,354), trauma patients (n=478), and healthy controls (n=383). Those were integrated into a comprehensive meta-dataset, containing gene expression values of a consensus of 5,932 genes for further analysis. After data preprocessing, samples were randomly divided into subsets for training (65%), validation (20%), and testing (15%). Training and validation samples were used as input for the step-wise training process of neural networks within the Google TensorFlow framework to learn binary discrimination of the entity of patients with sepsis and "controls" (trauma patients and healthy controls). Classification performance of trained neural networks was subsequently tested with the unknown samples. The full process of random data splitting, network training and prediction was repeated 250 times to test the robustness. Furthermore, stratified ShuffleSplit cross-validation of the whole approach was used to verify the reproducibility.
RESULTS. A total of 250 iterations resulted in an area under the curve (AUC) of 0.999 (Min=0.998, Max=1.000), with a corresponding sensitivity of 0.98 (Min=0.94, Max=1.00), specificity of 0.99 (Min=0.95, Max=1.00), and diagnostic accuracy of 0.96 (Min=0.96, Max=1.00). Random limitation of the provided genes to a fraction of 25% still enables reliable classification with nearly unaltered performance (n=250; AUC=0.99 (Min=0.99, Max=1.00), sensitivity=0.98 (Min=0.91, Max=1.00), specificity=0.97 (Min=0.90, Max=1.00), accuracy=0.97 (Min=0.94, Max=0.99)).
CONCLUSION. The presented approach surpasses the most advanced solutions for sepsis classification and closes the gap to comparable studies on cancer diagnosis. By limiting the number of available genes for prediction, we can prove that, instead of learning idiosyncratic features tailored to specific data series, generalized

strategies for sample discrimination have developed in the trained artificial neural networks. The combination of artificial neural networks and microarray gene expression data is therefore capable of achieving sepsis diagnosis with superior accuracy and thus augments the current diagnostic scope.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001065

INTRODUCTION. With the rise of the electronic health record (EHR), new data resources have become available to explore the dynamics of sepsis through longitudinal physiology. The Critical Care Health Informatics Collaboration (CC-HIC) is a multicentre research project, aggregating high-fidelity, time-varying data on critical care patients from 12 intensive care units across five Biomedical Research Centres in the UK (1). 263 fields are available including demographics, bedside monitoring, drug infusions, microbiology and organ support. We set out to explore the impact of organ dysfunction trajectories, measured as the Sequential Organ Failure Assessment (SOFA) score, on outcomes in sepsis.
OBJECTIVES. To determine how the rate of change of organ dysfunction (organ dysfunction trajectory) impacts upon prediction of death in sepsis from a respiratory source. Particular focus is given to addressing the methodological aspects of informative censoring and measurement error that characteristically bias analysis of this type.
METHODS. Joint models allow simultaneous modelling of time-to-event and mixed effects models through shared latent parameters (2). Joint models are a class of model that account for informative censoring, and error-prone repeated measures biomarkers. We applied joint models to a sample of patients with a diagnostic label of pneumonic sepsis between 1st January 2014 and 31st December 2018.
RESULTS. A pilot cohort of 611 patients met the entry criteria. There was a 1.17 fold increase ($p = 1.32 \times 10\text{-}6$) in the hazard for death for every 1 unit increase in organ dysfunction severity (absolute value of SOFA). The same model describes a 4.93 fold ($p = 5.67 \times 10\text{-}4$) increase in the hazard for death for every 1 unit increase in the trajectory of SOFA. The likelihood ratio comparing this model to a model omitting the trajectory term was 13.57 ($p = 0.0002$, chi-square, 1 d.f), suggesting a significant improvement in model fit from the addition of the trajectory parameter.
CONCLUSION. In pneumonic sepsis, the trajectory of organ dysfunction (measured as the rate of change of SOFA) not only adds important information for predicting outcomes, but exerts a substantially greater effect size over death than organ dysfunction severity alone.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001080

INTRODUCTION. Patients are commonly admitted to the intensive care unit (ICU) in the absence of historical baseline laboratory blood results, with derangements in hemoglobin and creatinine levels being particularly common. However, the chronicity and therefore clinical significance of the derangement is often unknown (Pivovarov et al., 2014). The richness of data collected in the electronic health record presents an opportunity to deploy machine learning techniques to impute baseline hemoglobin and creatinine values. This lends context to abnormal laboratory results to distinguish between acute and chronic conditions and can aid optimal medical decision making.
METHODS. ***Design & Participants:** Data from the Medical Information Mart for Intensive Care (MIMIC-III) was used. The MIMIC-III database is compiled from adult and neonatal ICU stays at an urban tertiary care center between 2001 and 2012. Adult patients with pre-admission ("baseline") hemoglobin and creatinine values available were selected (6,435 and 5,470 patients respectively). Demographics, vital signs, and admission laboratory results obtained within two hours of ICU admission were extracted as model inputs. Patient cohorts were split into training (75%) and testing datasets (25%). Prediction was done as both a classification task, using a threshold of 10 g/dL for hemoglobin and 1.2 mg/dL for creatinine, and as a regression task, for which the actual baseline value was predicted. We trained and compared several different types of model: linear regression, logistic regression, gradient boosting, random forest, and optimal classification trees.
***Outcome measures:** Model performance on the classification task was evaluated with the accuracy and AUC. Performance on the regression tasks was evaluated using different metrics: R2, MAE, and MSE. Models were also qualitatively assessed for interpretability. Strong predictors of baseline hemoglobin and creatinine were identified via the machine learning techniques.
RESULTS. For the classification task, the AUC across the models developed was 0.87-0.88 for hemoglobin and 0.88-0.92 for creatinine. For the regression task, the best-performing model yielded a mean absolute error (mean difference between predicted and observed value) of 1.0 g/dL for hemoglobin and 0.30 mg/dL for creatinine, and with a mean squared error of 1.68 g/dL for hemoglobin and 0.54 mg/dL for creatinine. R2 values ranged from 0.55-0.58 for hemoglobin and 0.78-0.81 for creatinine. Given that inter-analyzer laboratory variability for hemoglobin measurement has been reported at 0.3-1.5 g/dL,36 and for creatinine at 0.1-0.2 mg/dL,37 these results are quite significant. We provided an optimal trees diagram (Decision Tree) and ready-to-use application that shows how the predictions are made (with an AUC of 88-89%).

CONCLUSION. This study is proof-of-concept that machine learning methods can predict pre-admission laboratory values when historical data are lacking. It also proposes a workflow that could be applied to predict other types of laboratory results. Expansion of these tools promises to add a new dimension of clinical parameters, help to differentiate acute from chronic conditions using limited data, and aid in real-time clinical decision making.

INTRODUCTION. Healthcare-associated infections (HAIs) remain a major issue among critical ill patients in the intensive care unit (ICU), associated with substantial morbidity and mortality. Even if the use of contact precautions (CPs) is highly recommended for patients who have Multi-Drug Resistant Organisms (MDROs) (1), and considered a Quality Indicator in Intensive Care Medicine (2), Health Care Workers (HCWs) effective compliance with its practice seems to be low. Outbreaks of MDROs strengthened the role of improving adherence to CPs as part of a multifaceted infection prevention strategy, which may be a controversial recommendation for some (3). Auditing and giving feedback may be a strategy to improve professional practice (4).
OBJECTIVES. Auditing the HCWs (senior physicians, residents, nurses and healthcare assistants) compliance with indications for isolation (either preventive or documented) and with supplemental measures; to evaluate the effects on HCWs practice of giving them feedback and performing an educational intervention.
METHODS. This is a single ICU study. The ICU includes: 10 level 3 beds and 12 level 2 beds; protocols for preventive isolation and active screening for carbapenem-resistant *Enterobacteriaceae* (CRE) on ICU admission, hand hygiene (HH) and documented isolation. The audit tool was developed and approved institutionally. The observation methodology was explained to the auditing team and had 2 periods of 2 weeks to collect data (November/December 2018 and March/April 2019), once on each nurse shift, 1 to 3 shifts a day, for 30 minutes, either in level 2 and level 3 ICU beds. In between the two periods, results of the first audit were disclosed to ICU HCWs, followed by an intervention (educational sessions with targets and action plan included).
RESULTS. On the pre-intervention audit, data were collected in 57 shifts (228 observations of patients assigned to contact isolation precautions); after the educational intervention, data were collected in 37 shifts (162 observations). Main results are presented (pre-intervention %; post-intervention %). Documented isolation was mostly related to CRE (64%; 72%) and *Methicillin-resistant Staphylococcus aureus (*18%; 12%). Personal protective equipment (gown, gloves, mask) was available at the isolation unit (48%; 57%); was adequately wore (77%; 87%) and removed (73%; 90%). Glove use was appropriate (84%; 91%) more often than mask (46%; 92%).
Supplemental measures included barriers (69%; 61%) and isolated rooms (32%; 39%), waste sorting bags next to the bed (98%, 90%). Concerning HCWs groups, nurses were the most audited (46%; 43%) and the most compliant with CPs and senior doctors the least audited (6%; 6%).
CONCLUSION. The adherence of HCWs to CPs was low. Audit and feedback resulted in practice improvement, however we still seem to be far from the desirable target of 100%.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000926

INTRODUCTION. Immobilization during hospitalization stimulates a complex adaptative response that results in muscle atrophy and loss of functional performance. Immobility is a frequently understimated phenomenon during ICU stay and it could be associated with worse outcomes. Its prevalence and association with mortality is unknown.
OBJECTIVES. To estimate the prevalence of severe ICU-immobility and its association with 28-day mortality
METHODS. Retrospective study. Over a 6-month period we included all adults who were admitted to ICU and stayed for more than 48 hours. Patient mobilization was carried out according to local protocol. Mobility status was assesed daily using the Intensive Care Unit Mobility Scale (IMS). We considered severe ICU immobility as the inability to sit with active trunk control (over edge of bed) or IMS <3 during all over ICU stay (may be assisted by staff). Observed outcomes were 28-day mortality and ICU lenght of stay (LOS). We performed a multivariate analysis and Kaplan Meier plots with log-rank test.
RESULTS. 178 patients were included, mean age 60 years old (±18), APACHE II 16 (±9). The main diagnosis was sepsis (n=60 % 33,7). 96 patients (53,9%) required mechanical ventilation. ICU LOS was 7,2 days (±6), 28-days mortality was 24% (n=42). Severe ICU-immobility prevalence was 68,5% (n= 122) and was independently associated with both 28-days mortality OR 6,0 CI 95% 1,8 -19,8 (Figure 1) and longer stay in ICU (6,2±5,4 vs 9,1±6,8). Requirements of mechanical ventilation and emergency surgery were independently associated with severe ICU-immobility (Table 1).
CONCLUSION. Severe ICU- immobility defined as the inability to sit actively during hospitalization has a high prevalence and is independently associated with a higher 28-days mortality.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000936

INTRODUCTION. The evolvement of airway pressures (Paw) within the mechanical ventilation may reflect the modifications of the viscoelastic properties of the respiratory system and may predict difficult weaning.
OBJECTIVES. To investigate the impact of airway pressures trends on weaning in mechanically ventilated (MV) patients.
METHODS. Medical records were abstracted for all consecutive MV patients who were admitted from November, 2015 to February, 2018 in the MICU of Farhat Hached teaching hospital, Sousse,Tunisia. Data regarding demographics, clinical variables, trends of Paw (Paw at day 4 of hospitalization - Paw upon admission) and outcomes were recorded from chosen eligible charts. Poor outcomes were defined as : a ventilator-free days at day 28 (VFDs) = 0 and a composite outcome : death or length of stay ≥ 14 days. Univariate and multivariate regression analyses were used to identify factors independently associated to difficult weaning.
RESULTS. A total of 304 MV patients were included. Their main characteristics were : mean age, 56±18 years; male sex ratio, 64.8%(n=197); mean SAPS II, 34.9±14.3; pH, 7,3±0,1; pCO2, 50± 23mmHg; P/F ratio, 204±101; AE/COPD, 105(34.5%); ARDS, 25(8.2%); restrictive lung disease, 20(6.6%); pneumonia, 14(4.6%); pulmonary edema, 11(3.6%); median mechanical ventilation duration, 3[6-14] days; tracheostomy, 44(14.5%); median length of stay, 13[6-21] days; median VFDs, 0[0-2] days; mortality, 173(56.9%). Median differential airway pressures for delta peak, delta plateau, delta driving and delta auto-PEEP were respectively : 0[-5;5], 1[-2;3], 0[-2;3] and 0[-2;0] cmH2O. Univariate analysis than multivariate logistic regression showed that an elevated delta plateau is associated with a zero VFDs

(OR, 1.05; 95%CI, [1.002-1.11]; p=0.041) and an elevated delta peak is associated with poor composite outcome : (OR, 1.05; 95%CI, [1.009-1.09]; p=0.017). In COPD patients : an elevated delta plateau was associated with zero VFDs (OR, 1.1; 95%CI,[1.01-1.21]; p=0.028) and poor composite endpoint (OR, 1.13; 95%CI, [1.01-1.27]; p=0.026). While in non-COPD patients it was the elevated delta peak that was associated with poor outcomes : zero VFDs (OR, 1.06; 95%CI, [1.01-1.12]; p=0.016) and composite outcome (OR,1.1; 95%CI, [1.03-1.18]; p=0.002).

CONCLUSION. The trends of airway pressures (delta peak and delta plateau) in mechanically ventilated patients could predict difficult weaning and so poor outcomes.

Comparison of two ultrasound guided approaches, distal internal jugular vein and subclavian vein for central venous catheterization: a randomized controlled open-label pilot trial

C. Fournil[1], S. Bastide[2], JY. Lefrant[1], L. Muller[1], C. Roger[1]
[1]Department of intensive care medicine, Nimes University Hospital, Nîmes, France; [2]Department of biostatistics, Nimes University Hospital, Nîmes, France
Correspondence: C. Roger
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000945

INTRODUCTION. Internal jugular vein (IJV) and subclavian vein (SV) approaches are commonly used for central venous catheterization (CVC) under ultrasound (US) guidance. However, the lateral short axis approach of distal IJV has been poorly described and never compared to SV approach.

OBJECTIVES. The aim was to describe the lateral short axis in plane technique of distal internal jugular vein catheterization and to compare this approach to the SV approach.

METHODS. Single centre randomized controlled open-label pilot study. All patients requiring CVC in intensive care unit (ICU) were randomly assigned to US-guided IJV or to SV approach (Figure 1). After two unsuccessful punctures, an alternative CVC site was considered. The primary outcome was the success rate at the second puncture. The secondary outcomes were procedure characteristics and complications.

RESULTS. A total of 210 patients were included over 18 months. Nine patients were excluded leading to 201 patients analyzed: 100 in the IJV group, 101 in the SV group. 33% were female, mean (SD) age was 63 ± 15 years, median (IQR) BMI was 26 (23-30) and median SAPS II was 44 (35-56). The success rate at the second puncture was 96% (IC 95% 90-99) for IJV and 89% (IC 95% 81-94) for SV, p=0.06. In the IJV group, 7 complications occurred: 2 hematoma, 1 arrhythmia and 4 arterial punctures whereas 14 complications were observed in the SV group: 1 pneumothorax, 2 hematoma, 3 arterial punctures and 8 catheter misplacements. The first puncture success rate was 90% for IJV and 81% for SV, p=0.05. The duration until guidewire insertion was 60 sec in IJV group and 96 sec in SV group.

CONCLUSION. US-guided IJV and SV approaches are safe and efficient techniques for CVC insertion. The lateral short axis in-plane IJV approach deserves first consideration when CVC is performed in ICU patients given its high success rate, low complication rate and its facility to perform. US-guided SV approach is a good alternative when no IJV vascular access is possible.

Neuroradiological Investigation and Outcomes in Post Cardiac Arrest ICU Patients: a Clinical Audit

J. Kirk, S. White, N. Robin
[1]Intensive care, Countess of Chester Hospital NHS Foundation Trust, Chester, UK
Correspondence: J. Kirk
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000957

INTRODUCTION. Following cardiac arrest and return of spontaneous circulation patients are frequently admitted to the intensive care unit (ICU) for cardiovascular support and neuroprotection followed by neuroprognos itication1. This process involves neuroradiological imaging demonstrating hypoxic brain injury along with other indicators of poor neurological outcome. Anecdotally, lack of concordance of local reporting of neurorad iological imaging with clinical and other neurophysiological findings causes delay in clinical decision making, pending specialist radiological reporting.
Any improvement in this process is likely to improve timely decision making and lighten the burden of delay and uncertainty for relatives.

OBJECTIVES. A clinical audit to assess for the incidence of discrepancy between neuroradiological reporting, clinical assessment and specialist neurological opinion and its impact on definitive management of post cardiac arrest ICU patients.

METHODS. A retrospective clinical audit was performed on post cardiac arrest patients admitted to a 15 bed district general ICU over a 3 year period. Data was collected to evaluate for neuroradiology reporting by general radiologist, neurologist opinion, neuroradiologist reporting; whether there was any discrepancy between the opinions and with clinical findings or other prognostic tests; whether such discrepancies incurred a delay in definitive management.

RESULTS. 68 applicable patients were identified of which 7 (10.3%) were found to have a discrepancy between neuroradiology reporting by general radiologist, neurologist opinion or neuroradiologist reporting. 3 patients experienced a delay in definitive management as a direct result of this (mean delay 3.3 days).
Discrepancies between neuroradiology reports by general radiologists and other modalities of assessment were not fed back to the radiology department and the quality of clinical information supplied in scan requests was variable. There was a lack of consistency in the approach to investigating patients post cardiac arrest which may also have contributed to delays in definitive care.

CONCLUSION. Although only a small population stands to benefit from improved management of post cardiac arrest hypoxic brain injury on ICU, the individual burden is high and potential benefits are to the patient, their relatives and the efficient use of ICU resources.

In order to improve this management a local guideline has been designed to streamline the investigation and treatment of post cardiac arrest hypoxic brain injury and a referral pathway for neuroradiology MDT for general radiologists with an interest in neuroradiology has been created.

Stress Ulcer prophylaxis audit in the Intensive Care Unit

S. Millington[1], A. Wilkinson[2]
[1]William Harvey Hospital, Kennington Road, Willesborough, Ashford, UK, Sevenoaks, UK; [2]Intensive care, William Harvey Hospital, Willesborough, UK
Correspondence: S. Millington
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000971

INTRODUCTION. Previously, stress ulcer prophylaxis was prescribed routinely for all patients admitted to the William Harvey Hospital (WHH) intensive care unit (ICU). Recent RCT and meta-analyses question the rationale behind the recommendation of stress ulcer prophylaxis in ICU as the incidence of gastrointestinal (GI) bleeding in these patients is low(1). Furthermore, evidence suggests this approach may not reduce incidence of upper GI bleeds, and may contribute to increased risk of hospital acquired pneumonia and mortality (2). Many factors put patients at higher risk of GI bleeding; including mechanical ventilation, coagulopathy, and recent GI bleed. For those patients, evidence suggests stress ulcer prophylaxis outweighs the negatives.
OBJECTIVES. An audit in 2017 aimed to compare the practice at WHH ICU against published best practice. The findings showed that many patients admitted to the ICU were prescribed ulcer prophylaxis unnecessarily. As a result, local guidelines were updated and rolled out. After 3 months, a re-audit was conducted to assess whether these guidelines were being followed.
METHODS. Data was collected from patient notes and prescription charts over two cycles, 1 year apart. Each assessed whether patients met the accepted criteria for ulcer prophylaxis. Also, if prophylaxis was prescribed, the drug chosen and route were audited. Finally, we assessed whether the prescription overall adhered to the guidelines. In total 97 adult ICU patients were included, 47 in the first cycle, and 50 in the second. Standards are based on Guidelines for the Provision of Intensive Care Services, edition 1, 2015. The guidelines state that stress ulcer prophylaxis should be used judiciously, and only in patients considered to be at high risk of upper GI bleeding. Risk Factors are: Coagulopathy, (platelet count <50,000, INR >1.5, or PTT >2 times control value); Mechanical ventilation for >48 hours; History of GI ulceration or bleeding within the past year; Traumatic brain injury, traumatic spinal cord injury, or burn injury; Two or more of the following minor criteria: sepsis, ICU stay >1 week, occult GI bleeding, or glucocorticoid therapy (>250 mg hydrocortisone).
RESULTS. In the first cycle ulcer prophylaxis was appropriately prescribed in 15 patients (35%), and prescribed inappropriately in 28 (65%).
This improved in the second cycle as ulcer prophylaxis was appropriately prescribed in 40 patients (80%), and inappropriately in 10 (20%)
CONCLUSION. These findings show a 45% increase in patients that have ulcer prophylaxis prescribed appropriately between the initial audit and this repeat.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000979

INTRODUCTION. To describe the results of the early attention of critical patients outside the ICU, through a team of intensivists intended for the "ICU without walls (ICUWW)" from 8 a.m. to 8 p.m. in a hospital of 400 beds in Lleida, Spain.
METHODS. A descriptive study from January to December of 2018. Developed in 4 phases: 1: elaboration of the project of ICUWW. 2: establish activation criteria. 3: dissemination to the services involved 4: implementation and evaluation of the results. The IWW is formed by a team that is activated with calls from the ER and other services of the hospital; for the assessment, assistance and follow-up of patients with clinical impairment and/or risk patients previously assessed by the ICU night shift or after the discharge of the ICU. The variables are described as mean± standard deviation or percentage. For the comparison of the variables the statistical test of Chi-squared ($\chi 2$) was used for categorical variables, and the Mann- Whitney test for the continuous variables.
RESULTS. The ICUWW attended 932 patients, with a total of 1496 interventions. 63% were men and 37% women, with an average age of 61±17 years. The average time of attention was 81±60 minutes/patient with one average follow-up of 1.36 days. 52% had medical pathologies, 38.2% surgical and 9.8% traumatic. The 29.7% were assessed at the ER, 13.2% at the general surgery unit and the rest in other areas. 49.3% of the attention was made by a direct call; 5.6% was a follow-up of patients assessed in the previous ICU night shift, 11,4% required central venous catheter placement, 14.2% any other procedure, 5.7% were the follow-up of fragile patients after the ICU discharge and the rest 19,5% by other causes. The 17.2% required admission to ICU, 13.5% did not require admission because of the absence of criteria or for having completed adequate management outside of the ICU. A limitation of therapeutic effort was decided in 8.5%. Of the patients that required follow-up (N=193), 20.7% needed more than 2 days; 14% admission to ICU and the rest avoided the admission. Only (N=53) 24.5% of the patients with a follow-up after the discharge from ICU required re-entry out the global of our unit (N=1053) that is 6,12%.

CONCLUSION. The number of patients treated outside of the ICU justifies the creation of the ICUWW. We also describe different groups of patients attended by the ICUWW. During the study period, the ICUWW avoided admission to ICU in 26.3% of cases thanks to the early care of patients with clinical deterioration and the management of these by an intensivist regardless of the location and pathology.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000992

INTRODUCTION. Practitioners have limited evidence to guide them in the use of extracorporeal membrane oxygenation (ECMO) for adult patients with septic shock. Studies suggest the mortality of septic shock not on ECMO can be greater than 40% while the mortality of septic shock on ECMO may be as high as 70%. Given the high incidence of sepsis in intensive care units (ICUs), it's important to understand the impact of ECMO on resource utilization and survival.
OBJECTIVES. Our primary objective was to determine the mortality difference in septic shock patients in those requiring ECMO and those who did not. Secondary outcomes included the rates of blood product transfusions, subsequent organ failure, and ICU. We then sought to determine the risk factors for death in the ECMO group using multivariate analysis.
METHODS. A single center retrospective study was performed on adult patients (≥ 18 years) at Mayo Clinic Rochester with septic shock between 01/01/2009 and 06/30/2018. Post-cardiotomy patients were excluded. Data extraction was accomplished using digital queries from the institutional data repository and included demographic, laboratory, blood product transfusion, and outcome data. Patients were categorized into those with septic shock and those with septic shock subsequently requiring ECMO and assessed for differences in the primary and secondary outcomes. Multivariate analysis was performed on the ECMO patients exploring risk factors for death.
RESULTS. Of the 3335 patients with septic shock, 52 of them underwent ECMO. Significant differences existed between the two groups with those requiring ECMO being younger and having an elevated SOFA score as well as increased lab derangements at baseline. In-hospital mortality in the ECMO group was 50% as compared to those not on ECMO with 32% (P=<0.0074). Secondary outcomes in the ECMO and non-ECMO groups respectively included: i) packed red blood cell use of 10,567.25 ± 9572.46 ml vs 1136.60 ± 4094.56 ml (P=<0.0001) ii) acute kidney injury incidence during the hospital stay was 69% vs 29% (P=<0.0001) with 77% patients requiring hemodialysis vs 26% iii) the median ICU length of stay of 20.56 ± 33.8 vs 6.01 ± 8.34 days (P=<0.0001) and hospital length of stay of 37.74 ± 38.35 vs 16.32 ± 23.99 days (P=<0.0001). Multivariate analysis of risk factors for death on ECMO included association of diabetes (P=0.0575), maximum total serum bilirubin concentrations > 10.9 mg/dl (P=0.0146), maximum lactate elevation > 11.9 mmol/L (P=0.0319) and charlson score >2.8 (P=0.0250). Area under the curve with these four variables was 0.89.
CONCLUSION. Mortality is significantly increased in patients with septic shock requiring ECMO compared to those not requiring ECMO with mortality of 50% while also suffering from increased rates of blood product transfusion, multiorgan failure and overall length of stay. Risk factors for mortality in septic shock patients supported on ECMO included lactic acidosis, hyperbilirubinemia, diabetes and high charlson score.

Factors influencing long term-mortality of ICU patients

C. Mendes Silva, JP. Baptista, P. Martins
[1]Intensive care medicine service, Hospitalar and Universitary Center of Coimbra, Coimbra, Portugal, Portugal
Correspondence: C. Mendes Silva
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000993

INTRODUCTION. Advances in intensive care medicine is increasing patient survival in Intensive Care Units (ICU) and outcome assessment should shift from short-term mortality to long-term outcomes of ICU survivors (1). Long-term mortality after acute critical illness can be considered a patient-centered outcome (2).
OBJECTIVES. This study aimed to evaluate factors influencing survival of ICU patients 5 years after hospital discharge.
METHODS. A retrospective study was conducted in adult patients admitted to a 20-bed multipurpose ICU of a tertiary center during 6 months.
RESULTS. Of a total of 209 patients, 21.5% died during ICU stay. Factors statistically associated with death in ICU were age (p= 0.005), Charlson Score (p<0.001), SAPS II (p<0.001), APACHE II (p< 0.001), SOFA at admission (p<0.001), need for vasoactive drugs (p=0.015), invasive mechanical ventilation (<0.001) and need for renal replacement therapy (p=0.024). All these factors were also associated with in-hospital mortality in ICU survivors (cumulative mortality of 36.3%). In addition, late readmission (>72h) in ICU (p=0.008), but not early readmission, was associated with in-hospital death. Overall mortality of ICU patients was 46.9%, 53.6% and 56.9%, 1, 3 and 5 years after hospital discharge, respectively. Mortality in patients surviving hospital admission (N=133) at 3 and 5 years after discharge was associated with age (p<0.001) and Charlson Score (p<0.001).
CONCLUSION. Long-term mortality of critically ill patients was associated with age and comorbidities, but not with factors of acute illness that were associated with ICU and in-hospital mortality.

INTRODUCTION. Since its first description in humans, increased blood lactate levels have been related to morbidity and mortality (1). Although lactate is mistakenly considered a biomarker for sepsis, there are many other causes for hyperlactatemia in Intensive Care Unit (ICU) general population (2).
OBJECTIVES. To evaluate the influence of patient and clinical characteristics on blood lactate values in a non-infected versus an infected population at ICU admission and define differences in outcomes.
METHODS. Post-hoc analysis on hyperlactatemia in the INFAUCI study, a prospective, observational, cohort, multicenter study, conducted in 14 Portuguese ICUs with data collected between 1

May 2009 and 31 December 2010. Continuous variables were dichotomized around the median values for all the patients.
RESULTS. A total of 3766 patients were admitted to INFAUCI study, with 1619 patients being included in the non-infected group and 1640 patients in the group infected at admission for the purpose of this post-hoc analysis, having a median lactate of 2.0 and 2.15 mmol/L (p<0.001), respectively. In both non-infected and infected groups, lactate significantly increased with SAPS II score, SOFA score and Charlson score. Only in infected group lactate was also higher with age. Longer ICU length of stay was not associated with differing lactate at admission in the non-infected group, but a significant decrease in lactate was observed in the infected group. ICU survivors had a median lactate at admission of 1.9 mmol/L [1.1-3.0] in the non-infected group and 2.0 mmol/L [1.2-3-1] in the infected group, while non-survivors had significantly higher values of 3.3 mmol/L [1.8-7.0] and 3.4 mmol/L [1.9-7.0], respectively. This difference between survivors and non-survivors was higher in both groups when ICU length of stay was less than 6 days. The ROC curve for ICU mortality in the non-infected group had an AUC of 0.679 [0.637-0.722] compared with 0.865 [0.838-0.892] for SAPS II. In the infected group, the AUC for lactate was 0.667 [0.63-0.70] compared with 0.734 [0.710-0.767] for SAPS II.
CONCLUSION. Lactate is a predictor of mortality for both non-infected and infected patients, showing similar variations in both groups. Lactate levels were similar in both groups meaning that is not a good biomarker to differentiate between infection and other causes of admission.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001015

INTRODUCTION. The shared decision making(SDM)has became the major care model enbodying patient centered care and physician-patient equality interaction. Tracheostomy creation was not well accepted in critical patients due to mis-understanding of patients or their family, espcially in Taiwan. The aim of this study is to investigate the impact of novel interactiveSDM on early tracheostomyin prolonged intubated critical patients.
METHODS. Medical record ofconsecutive patients with respiratory failure in adult intensive care unitof tertiary medical centerfrom 2016 to 2017 was retrospectively reviewed. These patients were further divided into pre-SDM (2016) and post-SDM(2017) intervention period for analysis. Prolonged intubation was defined as duration of mechanical ventilation more than 14 days and sub-acute respiratory care center transferal needed. Early tracheostomywas defined as tracheostomy created within 14 days since being intubated and ventilated. Conversely, late tracheostomy was defined as tracheostomy created beyond the 14th day after intubation and mechanical ventilation. Patient who was successful weaning, chronic ventilator dependent before admission, post tracheostomy creation surgery, or expired were excluded. Data including total tracheostomy rate, early and late tracheostomy rate, ventilator weaning rate and ventilator days, in-hospital mortality, and length of hospital stay of prolonged intubated patient were collected. SPSS was applied for statistically analysis, and a p value less than 0.05 was considered significant difference.
RESULTS. Total 1253 patients with 7137 patient ventilator days were enrolled. Total tracheostomy rate improved from 8.8% in pre-SDM(2016) phase to 9.6% in post-SDM(2017) phase. Among 1253 patients, there were 128 patients with prolonged intubation in2016 and 112 patients in 2018for further analysis.After introducing SDM, late tracheostomy rate reduced from 43.8% to 40% and ventilator weaning rate improved from 69.5% to 74.1%in prolonged intubated patients. However there was no significant difference in in-hospital mortality(4% v.s 5%), and length of hospital stay(65.2 v.s 64.5) in prolonged intubated patients. In comparison late tracheostomy, the early tracheostomy patients had lower ventilator days(34.6+/-17.6 v.s 47.5+/-28.4, p: 0.004) and the length of hospital stay(57.2+/-21.8 v.s 68.4+/-26.8, p: 0.028). However, there was no difference in the ventilator weaning rate(69.2% v.s 76.7%, p: 0.389) and in-hospital mortality(10.3% v.s 8.2%, p: 0.737) between early tracheostomy and late tracheostomy of prolonged intubated patient.The tracheostomy decision making time delay in post-SDM phage was shown 5 days less than pre-SDM phase.
CONCLUSION. This studydemonstrated that introducing novel interactive shared decision making can shorten the tracheostomy decision time delay, further improve total tracheostomy rate,late tracheostomy rate and ventilator weaning rate.The latetracheostomy patients had higher ventilator daysand length of hospital stay than early tracehostomypatients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001022

INTRODUCTION. Critical illness is strongly linked to malnutrition and diaphragm dysfunction (DD) in intensive care unit (ICU) patients. Bedside ultrasonography is a useful tool to detect DD with high specifity. In this study, we aimed to adress the relationship between malnutrition risk and diaphragmatic measurements in medical ICU patients.
METHODS. We measured the diaphragmatic excursion, thickness and thickening fraction (TF) in all patients with B-Mode ultrasonography. Nutritional risk screening-2002 (NRS-2002), Subjective global assesment (SGA), Modified Nutrition Risk in Critically ill (MNUTRIC) scores and measurement of Mid-upper arm circumference (MUAC) were used to differentiate the nutritional status. Patients with NRS-2002≥3, SGA<6, mNUTRIC score>4, MUAC<22 cm for female and<23 cm for male were accepted under malnutrition risk. Definition of DD was accepted TF≤20% and/or tidal DE<10 mm, diaphragm atropy (DA) was accepted diaphragm thickness of <0.2 cm measured at the end of expiration. Comparisons between DD, DA and nutritional status were analyzed by using Fisher's exact and Chi square test.
RESULTS. Median age was 71 [60-72], 52% were female, 62% were mechanically ventilated and ICU mortality was 32% in 50 study patients. APACHE-II score was 20±6, SOFA score was 6±2. The most common cause of ICU admission was pulmonary diseases (68%) and the most common comorbidity was heart failure (40%). Malnutrition risk rate was varied between 54% and 78%. 28% of the patients had DA and 24% had DD. Malnutrition risk

diagnosed by all scoring systems were significantly correlated with DD ($p<0.05$) but was not correlated with DA ($p>0.05$). Inversely, malnutrition risk diagnosed by MUAC was not correlated with DD but it was correlated with DA. Malnutrition risk according to mNUTRIC score was an independent risk factor for DD (OR:6.6, 95%CI, 1.3-34; p=0.026). DD, DA and malnutrition risk as mNUTRIC score were more frequent in non-survivors ($p<0.05$) but none of them were independent risk factors for mortality ($p>0.05$)

CONCLUSION. Diaphragmatic measurements can be a good indicator for malnutrition risk or nutritional status in medical ICU patients.

Table 1 (abstract 001022). Relationship between diaphragmatic measurements and malnutrition risk in medical ICU patients

According to diaphragmatic dysfunction (DD)			
	Patients with DD, n% n=12	Patients without DD, n% n=38	p value
Malnutrition risk

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001028

INTRODUCTION. Chronic critical illness (CCI) is defined as prolonged length of stay (LOS) in the intensive care unit (ICU) (longer than 21 days) due to mechanical ventilation dependence or other intensive care treatments[1].
OBJECTIVES. We aimed to determine CCI rates and its cost for our hospital.
METHODS. A retrospective cohort study was designed in patients admitted between 1 January 2017 and 31 December 2018 in Dr. Suat Seren Chest Disease and Surgery Teaching and Research Hospital ICU, İzmir, Turkey. Patients with a LOS less than 24 hours in ICU were excluded. We collected patient data from the hospital electronic system.
RESULTS. Data are expressed as median (25th-75th percentiles). 1015 patients were included to the study and 152 of them (15%) were chronic critically ill. Age, APACHE-2 score, LOS and daily cost were higher in patients with CCI (Table 1). LOS of patients with CCI was 31 (25-48) days. Daily cost for patients with CCI was 1020 (212$) Turkish Liras (TL) and 956TL (199$) patients without CCI ($p<0.001$). The need for vasopressor drugs and renal replacement therapy (RRT) in patients with CCI was 73% and 22%, respectively ($p<0.001$).
CONCLUSION. The rate of CCI was 15% in our ICU. More use of vasopressor drugs and RRT in patients with CCI may result in a slightly higher daily cost.

Table 1 (abstract 001028). Characteristics of Patients With and Without CCI

	Patients without CCI	Patients with CCI	p
Age (yr), median (IQR)	68 (59-76)	71 (62-79)	0,019
APACHE-2, median (IQR)	18 (14-23)	20 (16-25)	0,001
LOS (Days) median, (IQR)	6 (4-9)	31 (25-48)	< 0,001
Tracheostomized patients n, (%)	32 (4%)	77 (51%)	< 0,001
Day of Tracheostomy, median (IQR)	7 (6-11)	16 (9-22)	0,001

Altered risk of malignant disease after sepsis, a register-based study

J. Hästbacka[1], A. But[2], G. Strandberg[3], M. Lipcsey[4]
[1]Intensive care units, department of anaesthesiology, intensive care and pain medicine, University of Helsinki and Helsinki University Hospital, Helsinki, Finland; [2]Depatrment of public health, University of Helsinki, Helsinki, Finland; [3]Intensive care unit, department of surgical sciences, Uppsala University Hospital, Uppsala, Sweden; [4]Intensive care units, department of surgical sciences, Uppsala University Hospital, Uppsala, Sweden
Correspondence: J. Hästbacka
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001034

INTRODUCTION. Sepsis survivors are at increased risk of death up to 10 years after their ICU treatment.(1)The reasons are not fully known, but post-sepsis abnormal immune function may play a role. Acute inflammation may be followed by a chronic anti-inflammatory state with a severely impaired immune function which could associate with increased morbidity.(2) The immune suppressed state may last long and could lead to an increased risk for malignant disease as has been reported in other immune suppressed states, such as organ transplantation.(3, 4) Sepsis and cancer may also share common risk factors.
OBJECTIVES. To study the incidence of cancer in patients admitted to intensive care units for the treatment of sepsis and compare it with that of the general population.
METHODS. The study cohort was formed of adult patients admitted to an intensive care unit (Swedish Intensive Care Registry) in 2005-2015 and who had a diagnosis of sepsis (ICD-10 codes A41.9, R57.2, R65.1). Patients with no record in the population register or aged <20 years at the index admission were excluded. The data on cancer diagnoses were obtained by linking the cohort to the Swedish Cancer database of The National Board of Health and Welfare. The individuals were followed from the index admission until death, emigration or end of 2015, whichever occurred first. We calculated the standardized incidence ratio (SIR) of any cancer and ten most frequent cancer types as the ratio between the observed and the expected number of cancers. The Swedish population served as the reference and cancer statistics on this population was retrieved from the NORDCAN database.(5, 6) To account for the potential detection bias and reverse causation, we assessed the SIRs by follow-up time divided into smaller intervals and focused the SIR calculated among 6-month survivors.
RESULTS. After applying the exclusion criteria, the study population comprised 30051 individuals, of whom 841 patients died on admission day. The median follow-up time was 2.2 years (IQR 0.25-4.86). A total of 6928 patients died within six months and 10091 during the whole follow-up period. Six-month survivors contributed to the follow-up with 85321.3 person years. The median age at the beginning of the follow-up was 69 (IQR 60-77). New cancer diagnoses

were found on 1801 patients. Focusing on new diagnoses six months after sepsis and later, we found an increased SIR in non-melanoma cancer of skin and cancer of liver and gallbladder. Decreased SIRs were observed in colorectal, prostate, lung, bladder, breast and ovarian cancers. Forest plots demonstrating the standardized incidence ratios for each gender are shown in Figure 1.
CONCLUSION. Long-term incidence of malignant disease in patients treated in intensive care units for sepsis is altered, as compared with age and gender-matched general population.

Fluid overload is associated with an increased risk mortality in the critically ill and post-operative patient in Bogotá, Colombia

EL. Rojas Diaz, JA. Carrizosa, E. Celis
[1]Critical Care, Fundación Santa Fe de Bogotá, Bogotá, Colombia
Correspondence: E.L. Rojas Diaz

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001044

INTRODUCTION. The most frequent management strategy in critically ill patients is intravenous fluids. There is still debate about the amount administered, becoming a problematic intervention. For this reason, it is recommended to perform a liquid therapy guided by goals, given that the fluid overload, defined as an increase of 15% of the body weight of the income (equivalent to approximately 2.5 liters of absolute balance), is associated with increased morbidity, mortality, over-cost and prolonged hospital stay.
OBJECTIVES. To determine if a positive balance of fluids is an independent factor of mortality in the postoperative critically ill patient in the Intensive Care Unit at the University Hospital Fundacion Santa Fe de Bogotá in Colombia, between January and December 2017.
METHODS. We conducted a retrospective, cross-sectional, observational study in an Intensive Care Unit in Colombia for one year. We collect data on patient characteristics. The primary outcome was hospital mortality. Bivariate and logistic models were done to explore the association between Fluid overload and mortality in this cohort
RESULTS. Three hundred sixty-four patients were meeting the inclusion criteria. Three hundred thirty-five patients with complete data on fluid balance. Mean age was 60 years; 51,9% were women. The acute physiologic and chronic health evaluation (APACHE) II score was nine at ICU admission, and median ICU stay duration was 6,4 days. The fluid balance median in 24 hours is 1200 ml, and 60 % of patients had a fluid overload at ICU discharge. Overall mortality was 6%, and statistically association was found between the positive balance of fluids and mortality at ICU admission, at 24 hours, at seven days after admission, and a total balance of 3.5 liters or more with inhospital mortality.
CONCLUSION. Positive fluid balances more than 3.5 liters lead to negative outcomes for patients, in this case in the critically ill and post-operative should be goal directed therapy, maintaining a neutral fluid balance. In case that not check this therapy in your bundles it could be negatively impacted in mortality, especially at the 7th day ICU stay.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001059

INTRODUCTION. End of life practice (EOLP) – i.e. care of ICU patients with an end-of-life decision (EOLD) to limit life-sustaining therapies – is common practice nowadays. Critical Care Physicians face these decisions nearly every day However, data on the organizational burden accompanying this procedure is sparse.
OBJECTIVES. We evaluated ICU days spent on patients with an EOL decision order (EOLD).

METHODS. This study presents data from our ICU which participated in the worldwide Ethicus-2 study on ICU end-of-life care practices (EOLP) in ICUs.
RESULTS. During a 6 month period 1958 adult patients were admitted to a 42 bed surgical ICU of a tertiary hospital. In 183 (9,34%) - 115 male; mean age 71,7 ± 11,7 SD; 68 female; mean age 74,3 ± 11,2 SD - EOLP was applied. 26 left the ICU alive and 16 survived the hospital stay which corresponds to an ICU mortality of 85,8% and a hospital mortality of 91,3% respectively. The ICU stay (LOS) until the EOLD was 104,36 hours [mean, 95% CI 128,57-80,15] and 47,86 hours [mean, 95% CI 61,65-34,07] elapsed between the decision and death or discharge. The mean LOS in the EOLD patients was 6,7 ± 9,3 days (mean, SD). The LOS from EOLD until ICU demission corresponded to 364,17 patients days.
CONCLUSION. In times of shortage of ICU beds in level 3 hospitals this may be an important finding. Since the mean LOS in this particular ICU is 3,3 days this means that during the 6 month observation period about 110 additional patients did not get access to the ICU and thus possibly received suboptimal care. This capacity strain (1) may further impede the process of triage recently recommended by a Task Force of the World Federation of Societies of Intensive and Critical Care Medicine (2). The considerable organizational burden of palliative care in the ICU calls for alternative resource allocation and end-of-life care pathways.

MET implementation evaluation - education as a cornerstone for success
I. Jesus Pereira, P. Barbosa, I. Hubert, C. Granja

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001073

INTRODUCTION. Medical Emergency Teams (METs) provide assessment and early intervention for patients outside critical care areas. The implementation of METs led to the decrease of resuscitations, critical care transfers, overall mortality and cost.
In 2015 the authors implemented a MET in their hospital. Activation criteria were adapted to the local reality and were grouped under: airway, ventilation, circulation, neurological status and clinical criteria. After 3 years of implementation, the results obtained from the present and previous studies (1,2) are worrying. The future interventions are now set to improve education and early recognition of signs and symptoms of patient clinical deterioration.
OBJECTIVES. To evaluate the MET implementation adequacy.
METHODS. Observational prospective study of the MET activity, from October 2015 to December 2018. Data was obtained from the MET registry and from the patient clinical charts. Categorical variables were described as absolute frequencies (n) and relative frequencies (%). Median and interquartile range were used for continuous variables. Statistical analysis was performed using the software Statistical Package for the Social Sciences v. 25.0.
RESULTS. During this period, 1672 primary activations were registered, 56.1% of which for male patients. The median age was 76 years (IQR 65, 84); the youngest patient was 1 year old and the oldest was 99 years old.
The surgical department was responsible for the majority of activations, representing 47.2% (n= 789) of the total events.
Going through the evolution of the number of activations there was a progressive decrease since the first quarter of activity (2015: n=185; 2016: n=628; 2017: n=410: 2018: n=449).
Mortality was evaluated at 30 days, with 773 deaths (46.2% of total activations), of which 43.9% were under the event Circulation and 38.6% under Airway/Ventilation. Of the total deaths, 66.8% occurred within 72 hours of the MET intervention. The MET was activated 197 times for the event Cardiac Arrest, with an increase in the relative frequency from 2015 until 2017 and a slight drop in 2018 (2015: 8.4%, 2016: 11.3%, 2017: 13.6%, 2018: 12.0%). This subgroup of events presents a 30-day mortality of 94%. Available hospital mortality rate data are 7.46 in 2015; 8.35 in 2016 and 8.64 in the first quarter of 2017.
CONCLUSION. Hospital mortality is high and consistent with MET data. However, it should be emphasized that it was not possible to exclude end-of-life decisions from both the hospital and the MET mortality.
The activation decline over time reinforces the importance of continuous education.
The mortality results, even after the MET intervention, point towards a delay in activation, with a small benefit to the intervened population.
A multidisciplinary intervention is necessary. A certified training center has already been set in 2019 and the official training program has started. Besides basic and advanced life support formation, the team activation criteria will be recalled, and emphasis will be given on the need for early recognition of signs of clinical instability.

INTRODUCTION. Sepsis still represent a major health issue. Many sepsis biomarkers have been tested in the past years. Pentraxin-3 (PTX-3) has been proposed as a valuable diagnostic tool.
OBJECTIVES. To compare PTX3 and Procalcitonin (PCT) in the diagnosis and prognostication of sepsis in medical critically ill patients in a medico-surgical intensive care unit.
METHODS. PTX3 and PCT plasma concentrations were measured in prospectively adult medical intensive care unit (ICU) patients within 24 hours from admission and thereafter daily. Their levels were compared in infectious and non-infectious conditions. The ability of PTX3 and PCT to discriminate sepsis was evaluated using receiver operating characteristic (ROC) curves and the respective areas under curves (AUCs). The best cut-off values of both sepsis markers were calculated using diagnostic odds ratio (DOR). To assess the prognostic value of the day-by-day changes of PCT and PTX3 plasma levels wecomparedthe incidence of ICU- and in-hospital mortality in patients with and without two consecutively increases of these markers above the value exceeding the cut-off level.
RESULTS. We included 37 consecutive patients who were admitted to our ICU for an expected time longer than 48 hrs (186 patient-days-pd). The mortality rate was 21.6%. Patients with sepsis (66 pd) and septic shock (29 pd) had higher PTX3 (3.69± 2.83 μg/L and 5.35 ± 3.13 μg/L) and PCT plasma concentrations (7.82 ± 13.6 μg/L and 8.45 ± 11.5 μg/L), compared to those without infection (91 pd, 3.18 ± 2.9 and 0.88 ± 0.93 μg/L, respectively, $p < 0.01$). The area under the ROC curve for PCT was greater than the one for PTX3: 0.89 (CI 95%: 0.83-0.93) vs 0.65 (CI 95%: 0.57-0.72) (p=0.037). The cut-off values of 2.4 μg/Lfor PTX-3, and of 1.4 μg/Lfor PTX3 yielded the highest DOR for sepsis diagnosis. Patients who survived had lower values of PCT and PTX3 compared to the group of patients that died, both at admission time (7.14 ± 15.08 μg/L vs 12.3 ± 14.3 μg/L p=0.4 for PCT

and 5.08 ± 3.42 μg/L vs 9.03 ± 1.0 μg/L p<0.009 for PTX3), anddaily (PCT: 4 ± 9.6 μg/L vs 7.1 ± 10.7 μg/L p=0.09 and PTX3: 3.1 ± 2.7 μg/L vs 6.2 ± 3.2 μg/L p<0.001). Patients with two consecutive daily increases of PCT and PTX3 had in-hospital mortality rate of 66.7% and 61.5% respectively, compared to patients without two consecutive daily increases of PCT and PTX3 that had an in-hospital mortality rate of 8.0% and 8.3% (p < 0.01) respectively.
CONCLUSION. In our small cohort of medical ICU patients, both PCT and PTX3 could discriminate sepsis, PCT being a highly better diagnostic tool. Both marker time course revealed to have some prognostic power to be further investigated.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001330

INTRODUCTION. Patients with septic shock have a catabolic state that leads to a depletion of the skeletal muscle compartment early. The loss of muscle mass is associated with an increased risk of nosocomial infections, prolonged mechanical ventilation, longer ICU and hospital stays, and increased mortality.
OBJECTIVES. To determine the loss of muscle mass in patients with septic shock by ultrasound evaluation of the right rectus femoris muscle, and its correlation with morbidity and mortality.
METHODS. Prospective study that includes 11 patients with septic shock of different focus. Ultrasound measurement of the area of the rectus femoris muscle (CSA RF) was performed on admission and after 7 days, as well as a qualitative assessment using Heckmatt Score. Demographic variables were collected, time MV, ventilator-associated pneumonia, weaning failure, tracheostomy, ICU and hospital stay, mortality.
RESULTS. The average age was 60.6 years +/- 11.9. 72.7% were male. Reason for admission: Respiratory (72.7%), abdominal (18.2%) and urological (9.1%) sepsis. Apache II mean at admission was 23.73 +/- 9.27; the mean SOFA upon admission was 10.64 +/- 2.76. The median time on mechanical ventilation was 18 days. 45.5% had VAP and 72.7% required a tracheostomy. The median stay in the ICU was 24 days. The mortality in the ICU was 27.3%, the survival at 6 months was 54.55%.
We observed significant differences between the loss of muscle mass during the first 7 days and mortality (Test Chi2 p 0.027), however, when performing the ANOVA analysis we found no significant relationship between the variables (F 3.4, p 0.102). We did not find significant differences with the duration of mechanical ventilation, VAP or stay. It is a small sample, so it is not yet possible to draw conclusions.
CONCLUSION. - Muscle ultrasound is a useful tool at bedside and easy to perform, specifying a small learning curve
- Wasting muscle plays a fundamental role in the evolution of the critical patient, so its monitoring and minimization is key to modify the prognosis of our patients.

Interleukin-8 is a major factor in inducing Neutrophil Extracellular Traps (NETs) in sepsis

M. Alsabani[1], S. Abrams[1], Z. Cheng[1], Y. Alhamdi[1], B. Morton[2], G. Wang[1], CH. Toh[1]

INTRODUCTION. Neutrophil extracellular traps (NETs) formation is a novel mechanism by which neutrophils immobilise and kill pathogens and are increase in critical illnesses such as sepsis (1, 2). Recent studies highlight the harmful effects of NETs by providing a scaffold for thrombosis, resulting in microvascular occlusion and multiple organ failure (MOF) (3). Interleukin-8 (IL-8) is a potent factor for neutrophil recruitment and activation during sepsis, and has recently been demonstrated to induce NETs *in vitro*(4, 5).
OBJECTIVES. To establish the pathophysiological role of IL-8 induced NETs formation in a murine model of sepsis.
METHODS. Sepsis was induced in mice by caecal ligation and puncture (CLP) or intraperitoneal (i.p) injection of *Escherichia coli*without and with anti-IL-8 therapy. Histopathological analysis was used to measure NETs formation and Acute Lung Injury (ALI). Blood Urea Nitrogen (BUN) and Alanine aminotransferase (ALT) were measured to investigate the levels of organ injury. Survival analysis was observed in CLP septic mice.
RESULTS. We specifically observed NETs positive staining (cit-H3) in the lung tissue of mice following sepsis, which was associated with increases in lung injury scores compared to control mice. Ten hours following induction of both sepsis models, lung injury was significantly attenuated by anti-IL-8 therapy (CLP: P<0.001, E.coli: P<0.001), along with circulating markers of both liver (BUN [CLP: P=0.005, E.coli: P<0.001]) and kidney (ALT [CLP: P= 0.01, E.coli: P=0.002]) injury. Finally, we observed significantly improved survival times in septic mice treated with anti-IL-8 therapy compared to septic mice without therapeutic intervention (P=0.004).
CONCLUSION. Targeting IL-8 reduced NETs-induced organ injury and increases survival rates in mice with sepsis. This could provide a novel therapy in improving clinical outcome in critically ill patients.

Alfatorquetenovirus: a new sepsis biomarker?

N. Segura-Marín[1], E. Albert[2], S. Martinez[1], P. Pardo[1], D. Navarro[2], G. Aguilar[1]
[1]Anaesthesia and critical care, University Hospital, València, Spain; [2]Microbiology, University Hospital, València, Spain

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001366

INTRODUCTION. The use of biomarkers in sepsis is very useful for the early diagnosis of and to establishing a prognosis. The desired marker should be sensitive, specific, fast and accurate. Procalcitonin (PCT) is one of the measurements approved by the FDA, although its efficacy is still questioned1. The determination of alfatorquetenovirus (TTV) could be a useful marker2.
OBJECTIVES. 1. Establish a relationship between the viral TTV load and the prognosis of sepsis
2. Relate the viral TTV load with inflammatory parameters
METHODS. We analyzed 55 samples from 23 patients admitted to intensive care with clinical suspicion of sepsis. Analytical data of C-reactive protein (CRP), neutrophils and procalcitonin were collected. The SOFA and APACHE II scores were calculated, and the patients were stratified according to these five values in good and poor prognosis.
A quantitative determination of TTV was carried out from each sample using a quantitative PCR3. We calculate the area under the curve of the TTV plasma values as a function of time.
The differences between medians were compared using the U-Mann-Whitney test. The correlation between variables was measured using the Spearman correlation. The relationship between qualitative variables was studied through Chi2 analysis. The value of P <0.05 was considered statistically significant.
RESULTS. We have found an inverse relationship, not significant, between the TTV AUC and the patient´s proinflammatory level and therefore with the disease´s prognosis.
A tendency (not significant) was found between poor prognosis and the procalcitonin´s median values and CRP being higher in the group with poor prognosis.
A trend was observed indicating that at a lower TTV DNAnemia is related to worse prognosis.
An inverse relationship was found between procalcitonin and CRP values and the TTV copies / ml in plasma, (rho = -0.132 and -0.349 respectively) nonsignificant correlation in the case of procalcitonin.
There was a clear trend between the neutrophils´ expansion and the regression line slope, obtained between the TTV loads in the first two study times.
The results obtained indicate a possible relationship between immune exacerbation degree and TTV DNAemia.
CONCLUSION. The TTV quantitative determination could be useful as a proinflammatory marker in sepsis, both for its low cost and its ease in the determination as for its relationship with the functionality of the patient's immune system. It is necessary to carry out a study with a larger sample size to corroborate the validity of our hypothesis and in turn to establish a TTV threshold that allows us to anticipate the disease clinical outcome.

Proteomic profiling of lysine acetylation reveals SIRT3 deficiency exacerbates sepsis-induced myocardial dysfunction via inducing mitochondrial dysfunction

S. Zhang[1], J. Rong[2], Y. Xu[2], Y. Wang[1], Z. Zhang[3]
[1]College of pharmaceutical sciences, Zhejiang University, Hangzhou, China; [2]Department of cardiology, cardiovascular key laboratory of zhejiang province, Second Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, China; [3]Department of intensive care unit, Second Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, China
Correspondence: Z. Zhang
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001370

INTRODUCTION. Sepsis-induced myocardial dysfunction (SIMD) leads to increased mortality in septic patients. Mitochondrial dysfunction is confirmed to be involved in the development of SIMD. Sirt3 is identified as one of the major mitochondrial deacetylases, whose activity is necessary to prevent mitochondrial dysfunction. However, the role of Sirt3 in the development of mitochondrial dysfunction associated with SIMD have not been determined.
OBJECTIVES. To investigate the potential role of Sirt3 in SIMD and identify the key protein post-translational modifications related to mitochondrial dysfunction.
METHODS. In a lipopolysaccharide (LPS)-induced sepsis mouse model, animals were divided into 4 groups: WT-PBS, WT-LPS, Sirt3(-/-)-PBS, and Sirt3(-/-)-LPS. Cardiac function of animals was evaluated by echocardiography, and the indicators of cardiac hypertrophy and inflammatory factors were detected in heart tissues. The level of mitophagy in the hearts by examining the expression of autophagy-related proteins and autophagosome, as regulated by LPS and/or SIRT3 was also detected. Furthermore, label-free quantitative proteomic analysis by using mass spectrometry was performed to characterize the acetyl-proteome of hearts and the role of SIRT3-dependent regulation of the acetylation under LPS stimulation.
RESULTS. LPS-induced cardiac dysfunction was more severe in Sirt3(-/-) mice compared with WT mice. The indicators of cardiac hypertrophy as well as the inflammatory mediators including IL-1β, IL-6, and TNF-α in LPS groups increased significantly compared with those in PBS groups. The expression of autophagy-related protein LC3 and the number of autophagosomes increased in Sirt3(-/-) mice and aggravated under LPS stimulation. A total of 1600 unique sites were identified as acetylated, most belonged to mitochondrial proteins. Several metabolic pathways including fatty acid catabolic process were significantly hyperacetylated in Sirt3(-/-) mice (WT-LPS vs WT-PBS, Sirt3(-/-)-LPS vs Sirt3(-/-)-PBS). Finally, we identified that key enzymes in the tricarboxylic acid (TCA) cycle could be commonly regulated by acylation and exacerbated by Sirt3 deficiency in sepsis, among which malate dehydrogenase (MDH2) and isocitrate dehydrogenase (IDH2) might be the key targets for further intervention.
CONCLUSION. These findings established Sirt3 as a global regulator of lysine acetylation in mitochondria. Sirt3 deficiency exacerbates SIMD via changing the level of mitochondrial proteins acetylation, which enriched in the metabolic pathways including fatty acid degradation and TCA cycle.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001391

INTRODUCTION. Post-sepsis mortality has been related to a syndrome with persistent inflammation, immunosuppression and catabolism (PICS) [1], Among varying alterations, septic associated cognitive dysfunction is a common condition [2] and a change in sympathetic nerve activity (SNA) during the acute sepsis, such as an increase in cardiac SNA and the display of a biphasic pattern of renal SNA (rSNA). However, little is known about the role of the sympathetic nervous system over abdominal organs commonly compromised in sepsis and after sepsis recovery.
OBJECTIVES. Evaluate the renal (rSNA) and splanchnic (sSNC) baseline sympathetic nerve activity kinetics in the acute sepsis phase and in post-sepsis survivals
METHODS. Female Wistar rats (250-300g) underwent DL50 sepsis model induction (2mL *E. coli* 108 CFU/mL, iv.) After 6 hours of sepsis induction (S8-6h group), 1 month (S8-1mo group) and 3 months (S8-3mo group) surviving rats had their femoral vein and artery cannulated. After 24h of cannulation, BP and HR were recorded in conscious rats and then they were anesthetized with urethane (1,2 g/Kg, iv) and underwent rSNA and sSNA monitoring.
RESULTS. All animals showed no clinical signs of illness in 1- and 3-months post-sepsis, and their BP and HR were within the normal range. However, there was a clear trend to the increase in SNA in post-sepsis periods, the sSNA was augmented in the S8-1mo and both rSNA and sSNA were significantly increased in the S8-3mo.
CONCLUSION. These preliminary findings suggest that there is a sympathetic overactivation state after sepsis which may contribute to a handicapped cardiovascular physiological response to overcome the new pathological challenge events in post-sepsis recovery periods. Ongoing studies are in course to check other neurological mechanisms related to PICS.

Role of Presepsin in Diagnosis and prediction of mortality in ICU patients with infection

A. Al Tayar, E. Abdelshafey, M. Rashwan, M. Fawzy, A. Gohary
[1]Icu, SFHD, Dammam, Saudi Arabia
Correspondence: A. Al Tayar
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001445

INTRODUCTION. sepsis is defined as life-threatening organ dysfunction caused by dysregulated host response to infection. The systemic inflammatory response syndrome (SIRS) criteria are replaced now by SOFA score inside intensive care unit (ICU) and quick SOFA (qSOFA) for patients outside ICU to identify patients who are potentially at risk of dying from sepsis. Soluble CD14 subtype (sCD14-ST), known as presepsin, is an immunological biomarker which can be considered as an indicator of activated innate immune effector cells in response to invasive pathogens.
OBJECTIVES. The aim of this study is to evaluate significance of presepsin for early identification of sepsis and prediction of mortality in ICU patient in comparison to SIRS criteria and qSOFA scores.
METHODS. 40 patients were selected randomly after admission to adult ICU department from ER in Security Forces Hospital Dammam in the period from June to December 2018 without respect of admission diagnosis. Data from ER triaging and initial laboratory results were gathered to calculate qSOFA score, SIRS criteria and SOFA score. Presepsin measurement in full blood sample was performed within 6 hours from ER triaging.
After complete course in ICU patients were divided retrospectively into 2 groups; group A (patients with sepsis) and group B (patients with no sepsis) depending on clinical and microbiological criteria and SOFA score changes
RESULTS. 26 patients were diagnosed as sepsis 16 males and 10 females with average age of 68.04 ± 18.60 years while 14 patients were remarked as non-septic 8 males and 6 females and average age was 51.71 ± 24.88 years with significant difference regarding Age and APACHE 2 score being higher in septic group while no significant difference was found regarding sex.
With significant AUC of 0.848 ($p<0.001$), prespsin with cutoff value >640 pg/ml identified septic cases with sensitivity of 73.08% and specificity of 92.86% compared to non-significant SIRS criteria (AUC 0.670, sensitivity 69.23% and specificity of 57.14%) or qSOFA (AUC 0.652, sensitivity 38.46% and specificity of 78.57%).
Also, with significant AUC of 0.920 ($p<0.001$) prespsin with cutoff value >775 pg/ml predicted mortality with sensitivity of 100.0% and specificity of 76.67 % compared to non-significant SIRS criteria (AUC 0.540, sensitivity 70.0% and specificity 43.33%) or qSOFA (AUC 0.670, sensitivity of 60% and specificity of 76.67%)
CONCLUSION. Early presepsin measurement in ICU patients has significant role in diagnosis of sepsis and prediction of mortality compared to SIRS criteria or qSOFA score

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001448

INTRODUCTION. Severe sepsis and septic shock are frequent and serious complications in critically ill patients. Timely diagnosis and treatment are highly important in reducing the morbidity and mortality associated with sepsis. Serum biomarkers are very helpful tools in the early diagnosis and management of sepsis. PCT has been reported as a useful biochemical marker to differentiate early sepsis from other non-infectious causes of systemic inflammatory response syndrome, and its clearance is useful to check the response to therapy (1). However, the use of PCT as a prognostic marker is still uncertain.
OBJECTIVES. To evaluate the association between serum PCT and RCP levels on ICU admission and ICU-mortality in patients with community-acquired respiratory sepsis.
METHODS. Prospective cohort study of critically ill patients with confirmed Influenza pneumonia admitted to 184 ICUs in Spain, between June 2009 and April 2018. Only patients with determination of PCT and CRP levels on ICU admission were included. We analyzed global population, and differentiating those with primary viral pneumonia (PVP) and those with bacterial co-infection (BC). We recorded demographic characteristics, comorbidities, outcomes, as well as clinical variables and complications during admission. The statistical analysis was performed using chi-squared test (categorical variables) and Student *t* test (continuous variables). The multivariate analysis (binary logistic regression) was performed to determine variables independently associated with ICU-mortality.
RESULTS. We included 1610 patients, 1186 (73.6%) with PVP and 424 (26.3%) with BC. The median age was 56 years old (IQR 46-67), with median APACHE II and SOFA scores of 17 (IQR 12-22) and 6 (IQR 4-9) respectively. The most frequent comorbidity was chronic obstructive pulmonary disease (20.4%); 32.9% (530 patients) developed acute renal failure, 57.1% had shock on admission and 81.9% required mechanical ventilation. Overall mortality was 23.7% (n = 382). Patients with BC had higher PCT levels (4.25 [0.6-19.5]) and CRP (36.7 [20.23-118]) compared with PVP group (PCT 0.6 [0.2-2.3, p=0.001], and CRP (28.05 [13.3-109, p=0.001]). PCT levels were lower in survivors compared with non survivors, in both groups: PVP (0.53 vs 0.82, p <0.001), BC (3.88 vs 6.94, p=0.03). However, no differences were found in RCP levels between both groups. The multivariable analysis showed that PCT and RCP were not variables independently associated with mortality in global population neither at differentiating PVP from BC.
CONCLUSION. Serum PCT and RCP levels on ICU-admission in patients with viral pneumonia and/or bacterial co-infection are not factors independently associated with the prognosis.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001494

INTRODUCTION. We analyse whether there is an association between high levels of initial IL-6 and the development of multiorgan dysfunction (MODS) and higher mortality in septic shock patients admitted to ICU.
METHODS. Retrospective analysis of prospectively collected data of patients with abdominal, respiratory and urinary septic shock that were activated by Sepsis Code (SC) in the hospital and admitted to ICU, whose samples were stored in the Sepsis Bank during the period 2015-2017.
The cohort was divided into two groups depending on IL-6 levels > 1000 pg/mL (1, 2). We analyse demographic variables, severity (APACHE II), the development of MODS defined through the Sequential Organ Failure Assessment score (SOFA) >9, at ICU admission (ICU-SOFA), and its evolution through the highest levels (H-SOFA) during the first 96 hours, the mortality, the levels of Procalcitonin (PCT) and Lactate.
The data has been expressed in the form of "n" (%) if they are categorical, median and interquartile range if they are quantitative. The comparison of qualitative data was done with the Chi-square test. The comparison of quantitative data has been made with the Mann Whitney U test. The study was authorized by CEIC (PR (AG) 11/2016, PR (AG) 336/2016) and the patients or their representatives have signed the informed consent
RESULTS. During the study period, 72 activated patients by SC presented the inclusion criteria. Characteristics of the study population: 66.7% men, age= 61.9 (54.2-73) years, APACHE II= 23.1 (18.2-28), ICU- SOFA= 8.9 (7-10), H-SOFA=10.5 (7-13).
63.9% of patients had IL-6 > 1000 pg/ml, their most frequent focus was the respiratory (38.9%), the mortality rate was 27.8% and in the ICU (16.7%). High IL-6 levels was associated with the development of MODS at admission (58.7% vs. 41.3% p = 0.09), ICU-SOFA= 9.7 (7-10) vs. 7.5 (6-7) p=0.01, and tend to be associated with a worsening evolution H-SOFA= 11 (8-10) vs 9.5 (6.7-10) p = 0.06.
We found no association between high IL-6 levels and hospital Mortality (32.6 % vs 19.2 % p = 0.24), and ICU Mortality (21.7 % vs.7.6 % p = 0.11).
The highest levels of IL6 were observed in patients with abdominal focus (91.3% vs 53.6 and 47.6 % p = 0.02). There was association between IL 6 and PCT =43.5 mg/dl (7.1-18) vs 28.9 mmol/L (0.3-3) p = 0.00 and Lactate= 5.1 mmol/L (2.6-4.2) vs 2.2 mmol/L (1.3-1.9) p= 0.00.
In multivariate analysis, high levels of IL 6 are associated independently with high levels of lactate OR=2.4 (1.4 – 4,1) p= 0,01.
CONCLUSION. Elevated initial levels of IL 6 in septic patients are not associated with the development of MODS and is not associated with an increased in the mortality. Only the high levels of lactate are associated independently with high levels of IL 6.

INTRODUCTION. Serum lactate is an interesting biomarker that allows the clinician a diagnostic, prognostic and therapeutic approach. Therefore, at present, it is included in the most commonly used prognostic scales in the Intensive Care Units.[1 2]
We have created an alert system in which the LAB contacts us when they detect a serum lactate >4 mmol/L in a blood test. After that, we review individualy each case in order to know if there is a change in the approach of the patient that could be done.
OBJECTIVES. To determine the adequacy of the therapeutic rescue measures performed in the first hour of patients whose serum lactate is greater than 4 mmol/L in a blood test.
METHODS. Emergency patients and inpatients with AL levels> 4 mmol / L were included. The period of analysis was from August 10th, 2018 to February 4 th, 2019. Post anesthesia Unit Care, obstetric, pediatric and palliative areas were excluded. The measures evaluated in case of septic patients are those promoted by the guidelines of the Surviving Sepsis Campaign. We determine descriptive parameters by means, medians and frequencies. The computer program used was IBM SPSS v.20
RESULTS. 114 patients were included with a mean age of 68.25 years (18-95), 37.7% were women and 62.3% were men. 93% of the cases obtained the sample by venipuncture with mean values of 6.58 mmol / L (4-17).
After all cases were evaluated by two physicians, 69 of them would met criteria for admission to Intensive Care in case of requiring it. Thirty-three of them were admitted to ICU.
The diagnoses were sepsis (33%), cardiological pathology (15.2%), neurological (15.2%), renal (15.2%), digestive (12.1%) and bleeding (9.1%). 81.8% of cases of sepsis received all the required measures of fluid therapy with crystalloids, antibiotherapy and taking cultures prior to admission; 90.9% of patients with other pathologies also received appropriate treatment. A total of 3 patients who were candidates for invasive therapy were admitted to intensive care days after admission to the hospital ward.
CONCLUSION. We have been able to observe a possible room of improvement in 18.2% of the cases of sepsis and 9.1% for other pathologies, about the measures that could be adopted in the first hour.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001521

INTRODUCTION. Sepsis still represent a major health issue, mostly in intensive care medicine. Among the available diagnostic tools, Presepsin (P-SEP) has been proposed as a valuable point-of-care biomarker.
OBJECTIVES. We investigated the potential role of P-SEP during the diagnosis of sepsis and as an early prognostic tool in an acute care setting within our medico-surgical intensive care unit (ICU).
METHODS. From May 2016 to February 2018 we evaluated all consecutive patients admitted to our ICU with an expected length of stay of more than 48 hours. We reported demographic characteristics, daily clinical and laboratory data. For each patients we recorded procalcitonin (PCT) and P-SEP levels. P-SEP assay was obtained with luminescent monoclonal antibodies (the so called "pathfast method). At admission and every day during the ICU stay we assigned every patient according to the last published sepsis criteria (Sepsis 3). Daily SOFA score was used to categorize patient-days in three different quartiles (SOFA <6, SOFA 7-12, SOFA >=13). At the fifth day we used SOFA score variation (delta SOFA score) to divide patients in good or unfavourable clinical performance.
Primary and secondary aims were to evaluate diagnostic and prognostic ability of P-SEP, compared to PCT.
RESULTS. 284 patients (1912 patient-days) were included. Mean P-SEP levels in septic shock patients (343 patient-days) were significantly higher than those classified as septic (955 patient-days) or not-septic (614 patient-days)(mean and 95% CI): 3763 (3290,778 - 4235,810) vs 2081 (1911,970 - 2251,574) vs 767 (673,40 - 860,61) pg/ml, respectively. PCT showed the same trend and indeed PCT and PSEP had similar accuracy (AUC ROC curves for sepsis diagnosis were 0.784 for P-SEP and 0.787 for PCT). The best diagnostic cut-off for P-SEP was 1039 pg/ml.
We did not find a correlation (r=0,29) with APACHE score at admission. Both markers presented significantly different values when patient-days were divided in the three SOFA quartiles. During the first five days P-SEP trend was significantly different (two way ANOVA) between survivors and non-survivors: 1187 (1058-1315) vs 2726 (1816-3636) pg/ml respectively. PCT trend was conversely not statistically different between the two groups. Patients with unfavourable outcome presented a continuous and progressive P-SEP increase, meanwhile this was not found for PCT.
CONCLUSION. This study confirms that P-SEP has similar diagnostic potential as PCT, but is far more rapid in its execution and point of care. P-SEP trend may represent a promising early prognostic marker of recovery and mortality.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001522

INTRODUCTION. The gut as a motor of sepsis hypothesis was first investigated in trauma patients 30 years ago. Although the hypothesis is well accepted among physicians, there has been a lack of evidence so far that bacterial translocation directly causes the development and perpetuation of systemic inflammation.
OBJECTIVES. Quantification of bacterial translocation and correlation with markers of gut barrier failure, systemic inflammation and severity of illness in an ICU patient cohort with major trauma.
METHODS. Prospective monocentric observational cohort study (ethical approval Göttingen University 22/1/14) in 14 subsequent ICU patients with major trauma. Inclusion into the study was within eight hours after hospital admission. Quantification of Bacteroides and Enterococcus species DNA und surrogate parameters for altered epithelial permeability (iFABP, Claudin 3, sCD14) in patient blood and urine was performed on admission (d0), d1, d2, d3, d5, d7, d10, and

d14 of ICU stay. Severity of illness scores were calculated on admission, organ failure scoring was used in the further course of ICU stay.
RESULTS. Enterococcus or Bacteroides DNA was detected in 54% of patients with major trauma and in 45% of those patients, who developed sepsis. Patients with bacterial translocation developed sepsis in 63 % of cases, whereas all patients without bacterial translocation developed sepsis. Neither disease severity scores nor organ failure scores differed between patients with or without bacterial translocation. iFABP concentration in urine was comparable in patients with and without bacterial translocation (466 [121; 3435] vs. 674 [208; 3758] pg/mL) as well as in patients with and without sepsis (505 [128; 3520] vs. 514 [263; 6513] pg/mL). This also applied for Claudin 3 and sCD14.
CONCLUSION. Bacterial translocation of two gut-specific bacteria into the blood was present in approximately half of patients with major trauma. There was no association between bacterial translocation and the development of sepsis in this cohort of patients. Neither iFABP nor other surrogate markers for gut barrier failure were associated with bacterial translocation or sepsis.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001523

INTRODUCTION. Statins have anti-inflammatory effects that are independent of their lipid-lowering abilities, but their role in critically ill patients is still a matter of debate. On the other hand lower levels of cholesterol and a higher level of triglycerides are usual findings in that population oh patients especially in patients with sepsis.
OBJECTIVES. Aim of this study is to examine the survival of critically ill patients with or without previous taking statins in regular therapy and also compare levels of cholesterol and triglycerides in these patients.
METHODS. We provided a retrospective analysis of 311 patients who were hospitalized in the medical intensive care unit.
RESULTS. We analysed data of 311 patients. Forty-two (13.5%) of them were taking statins (statin group- SG) as regular therapy before their hospitalization in MICU. Two hundred and eight patients (73.31%) have infection and/or sepsis. Survival rate of SG was 80.95%, whilst survival rate of the rest of the patients (non-statins group- NSG) was 68.4%. Mean APACHE II score in SG was 19.79 (SD 9.814) and in NSG group 18.66 (SD 9.945). Mean GCS was 13.45 (SD 3.964) in SG, and 12.97 (SD 3.464) in NSG. The average level of the lowest values of cholesterol was 3.878 mmol/l in SG, and 3.853 in NSG. Mean level of the lowest values of triglycerides was 1.510 mmol/l in SG, and 1.709 mmol/l in NSG. We didn't find statistically significant difference in levels of cholesterol and triglycerides, mean APACHE II score or GCS. When we compare APACHE II score in the group of patients with infection and/or sepsis according to their taking or not taking statins we also didn't find statistical significance. But in the rest of patients (critically ill without infection and/or sepsis (83 patient, 26.68%) – patients with statins had mean APACHE II core 17.85, and without statins 12.51 which was statistically significant (p= 0.009). The mean age of patients in SG was 70.74 years (SD 12.445) and in NSG 66.17 years (SD 16.323) which wasn't statistically significant but there was a trend to higher age in SG (p= 0.084).
CONCLUSION. Although SG in the population of analysed patients was small, our findings could show some trends towards the benefits of statins. Survival of SG was better despite they were older and despite the fact that some of them had statistical higher APACHE II score than NSG. Also, it is very interesting that the levels of cholesterol and triglycerides weren't statistical significant between SG and NSG. That fact could speak towards the protective effect of statin. During inflammation we usually can see the trend to lower cholesterol and higher triglycerides. We couldn't prove reverse effect in our SG but can maybe see some nonsignificant trends towards that. It would be necessary to provide further research with more patients.

The neutrophil activation product heparin-binding protein, suggested biomarker of sepsis, is markedly increased during cardiopulmonary bypass

A. Olsson[1], S. Berg[2]
[1]Cardiothoracic surgery, Blekinge Hospital, Karlskrona, Sweden; [2]Cardiothoracic Intensive Care, University Hospital, Linköping, Sweden
Correspondence: S. Berg
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001528

INTRODUCTION. Heparin-binding protein (HBP) is a bactericidal protein stored in granule of neutrophils and released upon neutrophil activation. It alters endothelial barrier function and induces plasma leakage. HBP has been recognized as a possible marker for sepsis and high circulating levels of HBP have been demonstrated early in septic patients.
Cardiopulmonary bypass (CPB) during heart surgery is associated with a pronounced inflammatory reaction with activation of leukocytes. This reaction is thought to be induced by contact activation of the CPB circuit, and is elicited without any exposure to bacterial agents.
OBJECTIVES. To study how non-infectious activation of leukocytes during CPB affects plasma levels of HBP and to correlate this to changes in plasma myeloperoxidase (MPO), a neutrophil granule product known to be released during CPB.
METHODS. Forty adult patients undergoing coronary artery bypass surgery with CPB were studied. Plasma samples were obtained at baseline, before induction of anesthesia, at the end of CPB before protaminisation and at 4 hours after surgery. HBP was measured by an ELISA assay and MPO by a multiplex bead assay. Friedmans ANOVA on ranks followed by Wilcoxon paired test with Bonferroni correction and Spearmans rank correlation was used for statistical analysis, results are presented as median and interquartile range.
RESULTS. HBP increased from normal low levels at baseline 5.9 (5.9-5.9) µg/L to very high levels at end of CPB 513 (436-688) µg/L and decreased to 44.9 (31-62) µg/L at 4 h after surgery (all $p<0.001$). MPO increased in parallel from 30 (0.2-44) µg/L at baseline to 3034 (2292-3763) at end of bypass and 457 (290-602) µg/L at 4 h after surgery (all $p<0.001$). Plasma HBP correlated with MPO levels at end of CPB $R=0.64$ and at 4 h after surgery $R=0.84$ (both $p<0.001$).
CONCLUSION. CPB is accompanied by a marked, up to 100-fold, increase in plasma levels of HBP. These concentrations are approximately 10 times higher than those seen in sepsis and septic shock. The increase in plasma HBP is parallel to increased plasma MPO and presumably reflects activation of neutrophils by the extracorporeal circle. Increased plasma HBP seems therefore not to be a marker of neutrophil activation exclusively by bacteria or infection, but rather a non-specific marker of neutrophil activation. Whether heparin present in the blood during CPB influences the high HBP levels seen requires further studies.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001533

INTRODUCTION. Recently was proposed for the Surviving Sepsis Campaign a 1-hour bundle for the treatment initial of patients with sepsis and sepsis shock. The Impact in-hospital mortality in comparison with the 3-hour bundle stills unclear.
OBJECTIVES. To evaluate the accomplished of the 3- hour bundle vs. 1-hour bundle in patients admitted in the emergency department (ED).
To assess the impact on the mortality between 1-hour vs. 3 -hour bundle.
METHODS. We collected prospective data from patients admitted in the emergency department from January 2016 to December 2018 with the diagnosis of sepsis and septic shock activated with the informatics system. General characteristics of patients and the time in minutes from admission until the completion of the 1-hour and 3-hour bundle was analyzed.
RESULTS. 497 patients were collected from the informatic activation system, were men 58,4%, mean age was 68 years +/- 15,5 (SD). From advanced medical ED were 62%, basic medical ED 26,6% and from advanced surgical ED 8%. Mainly patients were medical in 64%, surgical 11,9%, hematological 7,5% and neoplastic 16,5%. Respiratory sepsis was the principal diagnosis in 39% of patients, urinary sepsis 27,5%, abdominal sepsis 16,2% and medical sepsis (soft-tissue, endocarditis, etc.) 12%, blood cultures were positive in 34%. The mean SOFA was 7,87 +/- 2,27SD. Patients with hypotension and lactate > 4mmol/l were 65% and had septic shock in 19%. Received hydrocortisone in 33% and fluid bolus 30ml/kg in 51% of patients with hypotension. Mechanical ventilation was required in 4,5% of patients, non-invasive ventilation in 10,9%, renal replacement therapy 5,1% and was admitted to the ICU in 21%. In-hospital mortality was 13,3%. Time from admission to complete the bundle was 350min +/- 822 SD. For each item of the bundle, from admission to antibiotic administration 211min +/- 353 SD, to lactate obtention 192min +/- 567 SD and blood cultures obtained in 276min +/-1474 SD. The initial bundle was completed in 82,9% of patients, in less of 3-hour in 76,9% and less of 1- hour in 38,1%. In-hospital mortality was 13,8% in less 1- hour bundle vs. 14,4 % in less than 3-hour group without statistical significative differences between groups.
CONCLUSION. In this series of septic patients seems there is no impact in mortality between 1-hour bundle vs. 3-hour bundle, but the use of 1- hour bundle is still low, and patients probably were sicker.

INTRODUCTION. Optimal timing for starting vasopressors (VP) in septic shock has not been widely studied since it is assumed that fluids must be administered in advance
OBJECTIVES. To evaluate whether a very early start of VP (preceding or simultaneously to the first resuscitation fluid load) could impact clinical outcomes in patients with septic shock
METHODS. Retrospective analysis of 337 patients with sepsis requiring vasopressor support. The attending physician decided in each case when start VP support according his clinical judgment. Very early start of VP (VE-VPs) was defined as VP support initiatedbefore or within the next hour of the first fluid load with resuscitative intention (FRLoad). A VP start >1hour after the FRLoad was considered as delayed (D-VPs). A propensity score was fitted using the age, previous chronic hypertension; lactate, heart rate, systolic and diastolic pressure at VPs; source of admission (emergency room, general wards, intensive care unit); andthe heart rate/diastolic blood pressure ratio at the first fluid load. Then, a nearest neighbor-matching algorithm extracted 1:1 matched pairs of VE-VPs (n=93) and D-VPs (n=93) individuals. A risk-adjusted Cox proportional hazard model was fitted to assess the association between VE-VPs and day-28 mortality. A p<0.05 was considered as significant
RESULTS. Patients subjected to VE-VPs received significantly less fluid at the VP start (0[0-510] vs. 1,500 [650-2,300] mL, p<0.001) and at 6-hours (1,000[500-1,680 vs. 1,965[1,200-3,050] mL, p<0.001). VE-VPs strategy was related with significant lower net fluid balances at VP start, 6-hours and 24-hours after. The Cox-proportional hazard model revealed a significant lower risk of death for VE-VPs at day-28 (HR:0.44, CI95% 0.24–0.79, p=0.006). There were no significant differences for renal replacement therapy requirements between VE-VPs and D-VPs groups
CONCLUSION. Very early start of VP, even preceding initial resuscitation fluid load, seems to be safe and it could be related with better clinical outcomes in sepsis-related cardiovascular dysfunction

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001542

INTRODUCTION. Sepsis is a severe condition in which a patient's hemodynamics are compromised in response to a generalized infectious insult(1). Its prognosis is often ill-fated, and various indices

have been investigated to predict response to therapy, including the shock index (SI), a ratio of systolic pressure (SP) and heart rate (HR)(2). We hypothesize that modified shock indices based on the diastolic (DP), mean (MP), or pulse pressure (PP) could be as good in predicting survival in sepsis.
OBJECTIVES. The purpose of the analysis was to compare the discriminative ability of modified shock indices with regard to response to therapy of septic patients.
METHODS. The Medical Information Mart for Intensive Care version III (MIMIC-III)(3) database was used for the analysis. Patients in the 18-89 age range, admitted for at least 48 hours and fulfilling the international consensus sepsis-3 criteria(4) were included. In-ICU mortality was chosen as a surrogate outcome for response to therapy, and patients dying within 48 hours from admission were excluded. Clinical data relative to the first 6 hours of ICU stay were used to formulate predictions. Patients were stratified in 5 subcohorts of increasing severity using mean dosage of vasopressor equivalents (VPE), and divided in survivors (S) and non-survivors (D). The discriminative ability of SI, diastolic shock index (DSI = DP/HR), mean shock index (MSI = MP/HR) and pulse pressure shock index (PPSI = PP/HR) was compared. In addition, machine learning models including routinely measured values were built and validated for outcome prediction.
RESULTS. A common pattern was observed when plotting the mean of the selected indices across the 5 subcohorts of patients (figures 1-4): none was able to distinguish between survivors and nonsurvivors in the 'no vasopressor' subcohort, while a significant difference appeared in the 'low VPE' subcohorts (with survivors showing higher values than nonsurvivors), becoming again non significant for higher VPEs. For MP and DP, a significant difference was found in the 'very high VPE' sub-cohort, although reversed for survival classes (i.e. with survivors showing lower index values than nonsurvivors). Machine learning models considering these indices and other routinely measured values showed poor discrimination.
CONCLUSION. All modified shock indices significantly stratify survivors and nonsurvivors of sepsis on low vasopressor dose, suggesting that they could be used to predict the response to or guide the treatment with vasopressors in the early phases of septic shock. Indices based on MP and DP also significantly stratify septic patients receiving very high VPE.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000959

INTRODUCTION. Sedation guidelines are widely available, but international surveys have shown low compliance with them. In our ICU, we implemented a quality improvement strategy to achieve appropriate sedation levels.
OBJECTIVES. To evaluate the effect of an educational program to improve consumption profile and dosing of analgosedative (AS) drugs, and sedation level in patients on mechanical ventilation (MV)
METHODS. Before-after study in a 14-bed medical-surgical ICU in Argentina. We included consecutive patients on MV>2 days, and recorded characteristics and outcomes, prescribed doses of midazolam and fentanyl, level of sedation (RASS), midazolam and fentanyl consumption -as equivalents of benzodiazepines (BZD) and opioids-, propofol and dexmedetomidine. A special team (pharmacists/intensivists) designed nomogram templates for each drug, as a tool for proper prescription (maximum doses, adequate ranges/dilution, encouragement for not using BZD). After an educational session, nomogram templates were implemented. We compared prescribed doses of AS drugs, level of sedation, and consumption (mg of AS drug/100 occupied bed days) among Pre-I/Post-I. P value<0.05 significant for comparisons.
RESULTS. We included 231 and 186 patients in Pre-I/Post-I periods respectively; age was 44±20, 44±18; APACHEII 16±7,16±8; MV-days 10[3-24], 7[2-27] respectively; ICU mortality was 74(32%) and 58 (31%). RASS scale - 4[- 2 to -5], - 2[-0.5 to -4](p<0.01); midazolam prescribed dose (mg/kg/h): 0.23 [0.1-0.4], 0.12[0.04-0.2] and fentanyl prescribed dose(mg/kg/h): 1.04[0.7-2.4], 3[2-5.6] (p<0.01) respectively.The evolution of consumption drugs for AS is shown in Table 1. In Post-I, consumption profile was significantly higher, for propofol, dexmedetomidine, and opioid equivalents, and lower, for BZD equivalents.
CONCLUSION. After an educational intervention with nomogram templates as main tools, it was possible to decrease the level of sedation, to better adjust the prescription doses of AS drugs, and to modify their consumption profile.

Table 1 (abstract 000959). Consumption profile of AS drugs (expressed as mg/100 occupied bed day)

AS drug	Year 2014	Year 2015	Year 2016	Year 2017	p value
Opioid eq. (mg x 10^3)	0.4 [0.3-0.6]	0.5 [0.4-0.9]	1.7 [1.1-1.8]	2.3[1.4-2.6]	<0.01
BZD eq. (mg x 10^3)	26 [16-30]	25 [22-29]	20 [16-27]	12 [8-13]	<0.01
Propofol (mg x 10^3)	0.5 [0-15]	33 [31-41]	71 [39-89]	89 [70-99]	<0.01
Dexmedetomidin(mg)	0 [0-0]	0 [0-0.02]	2 [0.5-8.5]	28 [18-43]	<0.01

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001007

INTRODUCTION. Patient tolerance is critical for non-invasive ventilation (NIV) success. However, sedation is not routinely used in agitated patients during NIV, due to lack of specific protocols and safety concerns (1,2). Literature on the topic is scarce and no studies are available on sedation in patients treated with NIV outside intensive care units.
OBJECTIVES. To assess characteristics of patients treated with NIV in our high dependency units (HDU) and outcome of agitated patients requiring sedation.
METHODS. A single centre observational prospective study was performed in adult patients receiving NIV, in a medical HDU in Città della Salute e della Scienza Hospital (Turin, Italy) from April 2018 to March 2019. Patient and ventilation characteristics were collected. Richmond Agitation Sedation Scale was used to classify agitation during observation time (48 hours since start of NIV) and pharmacological/behavioural interventions were recorded. The escalation plan to intubation was collected from clinicians on admission (not routinely or formally done in Italy): patients were classified accordingly as "for full escalation" or "do not intubate" (DNI). NIV and sedation were started/continued in some patients as part of palliative care ("palliation" group). Primary outcomes were rate of intubation, discontinuation of NIV and mortality.
RESULTS. 104 patients were screened and 99 included. Mean age was 75 and mean Apache II 20. Indications for NIV were chronic obstructive pulmonary disease exacerbation (21%), acute pulmonary oedema (26%), pneumonia (25%), mixed diagnosis or neuromuscular diseases (28%). 45% of patients were considered "for full escalation", 42% were classified as DNI (remaining 13% unknown). 40% of patients had at least one episode of agitation during the first 48 hours, 71.6% of which received pharmacological sedation. Only 17% of agitated patients required discontinuation of NIV (3 patients were not sedated, 7 after sedation). 11% of patient received NIV and sedation for palliation and were excluded from mortality analyses. Overall 4 patients required intubation, two of which were agitated. Agitation was not correlated with higher intubation rate, mortality during HDU admission and at 30 days, both in DNI and full escalation group. Mortality was higher in patient with pneumonia.
CONCLUSION. In our study, agitated patients receiving sedation during NIV did not present a greater rate of intubation or mortality during HDU-stay and at 30 days.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001014

INTRODUCTION. In the environment of intensive care unit, the incidence rate of delirium is 16-85%, 63~75% of patients have pain experience and 71% have had agitation, which might be related todisease, treatment, noise, lighting or other multiple factors. Therefore, the assessment and management of pain, agitation, and delirium are critical for the quality of care in critical patients.The aim of this study is to investigate the impact of Innovative*artificial intelligence system on quality care of pain, agitation and delirium (PAD) in critical patients*
METHODS. A multidisciplinary team among intensivists, cardiologists, surgeon and nursing staffs in a tertiary medical center was organized since May 2017. The key interventions include analgesic and sedative drug dosage *artificial intelligence*information system, smart healthcare digital communication platform among patients, family, nursing and intensivists, wisdom situation lighting system, PAD information system, and PADIS integrated information monitoring dashboard.All patients admitted between January 2017 and December 2018 were enrolled. The patientswere divided into three groups: pre-interventional group from Jan to July 2017, Interventional group from August to September 2017 and post-interventional group from October 2013 to December 2018.
RESULTS. The pain assessment rate improved from 75.7%in pre-interventional group, to 98‰ in interventional group and to 102% in post-interventional group ($p<0.05$). The agitation assessment rate increased from 0%, 96% to 102% in post-interventional group ($p< 0.05$).The delirium assessment rate increased from 0%, 77% to 103% in post-interventional group ($p<0.05$). The pain control rate improved from 55.8%, 66.6% to 84.3% in post-interventional group ($p<0.05$). The agitation control rate improved from 91.5% to 95.1% in post-interventional group ($p<0.05$). The delirium control rate also improved from 70.8% to 85.3% in post-interventional group ($p<0.05$).
CONCLUSION. The study demonstrated that implementation of *artificial intelligence system* could increase pain, agitation and delirium assessment rate. Furthermore, pain, agitation anddelirium control rate also significant improved.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001039

INTRODUCTION. Neuraxial anesthesia represents the clinical standard for hip fracture surgery. However, lumbar puncture is contraindicated in coagulation disorders. The most common alteration of coagulation in the elderly patient is the prophylactic or therapeutic use of anticoagulant drugs. Indications for New Oral Anticoagulants (NOACs) have increased: NOACs has become the first choice in many diseases such as non-valvular atrial fibrillation and deep vein thrombosis.
Common laboratory test cannot detect the anticoagulation activity of these medications. However, monitoring of NOAC plasma concentration has become widely available, and was recently implemented in our clinical practice together with standard laboratory tests and tromboelastography (TEG) for urgent orthopedic surgery. Concentration cutoff depends on laboratory technique and at our institution it was fixed at 30 ng/mL as a safe threshold for surgery[1]. Contrarily, anesthesiology societies only suggest a temporal criterion to define the security of neuraxial blocks after NOAC discontinuation[2,3]. NOACs, like all drugs, have an inter-individual variable metabolism time, and a great variability in drug clearance has been reported. The aim of the study is to verify if the monitoring of NOAC plasma concentration could guide the clinical decision more precisely than the timing criteria alone.
METHODS. We included in our retrospective single center study patients on NOACs admitted to Emergency Department (ED) of ASST Monza for hip fracture. NOAC concentration, Kaolin TEG, aPTT, PT, platelets and serum creatinine were collected at the admission. NOAC levels and TEG tracings were recorded up to 96 hours after the last anticoagulant administration.

RESULTS. 38 patients on NOACs (4 on Dabigatran, 23 on Apixaban and 11 on Rivaroxaban) were enrolled. Average age was 80 ± 10 years, serum creatinine at ED admission was 1.0 ± 0.3 and calculated creatinine clearance 57 ± 26. Decrease of NOAC levels over time is shown in Figure 1. Interestingly, DOACs concentration was already less than 30 ng/mL at 24 h in 4 patients, whereas in 7 patients the concentration was higher than the threshold at 72 hours. Kaolin TEG R time did not correlate significantly with DOAC levels, except for dabigatran (p=0.19, R2 0.9).
CONCLUSION. Interindividual difference in metabolism of the drugs affects the NOACs half-life. Measuring NOAC concentration may support the clinical decision of the anesthesia strategy, regardless the time from the last administration.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001064

INTRODUCTION. Acute Pancreatitis (AP) is a low incidence disease with high mortality rates. It is characterized by a systemic proinflammatory state many times associated with distributive and hypovolemic shock. Several studies report a better outcome when high volume of fluids is given in the first hours of disease.1
OBJECTIVES. We conducted this study to assess if the amount of fluids given in the first 24h of admission in the Intensive Care Unit (ICU) had impact in AP's outcome.
METHODS. We included all patients admitted between 2017 and 2018, with AP as main diagnosis and made a retrospective analysis using IBM SPSS V20 (2011). Comparison between groups was made using the non-parametric test Mann-Whitney.
RESULTS. There were 19 patients with diagnosis of AP (11 male), 5 of whom died. The average age was 56.4±21.2. The majority of cases occurred in Portuguese people (16). There were 3 cases in foreigners from Argentina, Finland and Honduras. The most common cause of AP was lithiasis (10 cases) followed by alcohol (4 cases); 2 cases occurred in context of hypertriglyceridemia and 1 after endoscopic retrograde cholangiopancreatography; in 2 cases no etiology was found. The APACHE score at admission ranged from 7 to 34 (15.7± 6.3). We found that the APACHE score of patients who died was higher and had statistic significance (U=13, p<0.05). Nine of the 19 patients were directly admitted from the Emergency Room (ER) to the ICU. The mean APACHE score in those was 18.2 ± 7.14 (vs 13± 4.37 in those who were admitted later in the course of disease) but this difference had only borderline statistic value (U=23, p=0.07). Those who died had a greater fluid balance (FB) in the first day after admission than those who survived (4302±5020 vs 783±1666mL), but that difference was not statistically significant (U=15.5 p=0.71). Patients with local AP complications had a FB in the first 24h superior to those who did not (1791±3848 vs 1531±960mL), whereas in patients with systemic complications, FB was smaller than in those without such complications (1495±2960 vs 2076±3757mL). In both comparisons, no statistical difference was found (U=38, p=0.93; U= 38.5, p=0.767).
CONCLUSION. In sates of shock, FB is an important tool in aiding monitoring and adjustment of tissue O2 delivery. However, it is known that excess intake of fluids can negatively affect the outcome of such patients. We report a higher FB in patients who died, fact that can be justified by a greater complexity and severity of disease in those patients. In such cases, hemodynamic monitoring can be challenging. Invasive tools can be helpful and may be useful in guiding clinical decision. International guidelines recommend aggressive fluid resuscitation in the first hours of disease. Given the timming of admission, we weren't able to access this point, and cannot draw conclusions related to the outcome.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001074

INTRODUCTION. Inadequate microcirculatory perfusion during cardiac surgery with cardiopulmonary bypass (CPB) contributes to postoperative organ failure. Several techniques have been proposed to estimate microcirculatory perfusion during CPB, of which intraoperative lactate measurement is widely used. Lately, oxygen derived parameters are suggested as even better predictors of anaerobic metabolism. As a first step, we compared the course of oxygen delivery (DO2) with lactate levels during cardiac surgery with CPB.

METHODS. This single-center, prospective cohort study included 109 adult patients undergoing elective cardiac surgery with CPB. Intraoperative DO2 was calculated via the heart-lung machine (System M - M4) at the start, during and the end of aortic cross-clamping. Lactate measurement was performed at the same time-points by arterial blood gas analysis.
RESULTS. The study population consisted of 83 male and 26 female patients, aging 69 [63-74] years and had a mean body mass index of 26±4 kg/m2. Hypertension (n=65) and hypercholesterolemia (n=59) were the most common comorbidities. Mean duration of CPB and aortic cross-clamping was 117 [91-144] and 84 [62-102] minutes, respectively. When compared to the start of aortic cross-clamping, DO2 increased during (315±44 mL/min/m2 vs. 310±49 mL/min/m2; *P*= 0.001) and up to the end of aortic cross-clamping (325±52 mL/min/m2 vs. 310±49 mL/min/m2; *P*=0.026). Lactate levels showed an initial decrease mid cross-clamping compared to starting levels (1.06±0.49 mmol/L vs. 1.25±0.49 mmol/L; *P*<0.001). At the end of cross-clamping, the lactate level returned to baseline level (1.24±0.56 mmol/L vs. 1.25±0.49 mmol/L). Only at the start of aortic cross-clamping a weak correlation between DO2 and lactate level was present (r=-0.25; *P*=0.017). No correlation was found between DO2 and lactate levels at any other time-point.
CONCLUSION. DO2 and lactate levels have a divergent course and a merely weak correlation during cardiac surgery with CPB. This difference suggests that one parameter could be a superior predictor of postoperative complications when compared to the other.

Blood transfusion improves skin blood flow when initially impaired

E. Cavalcante dos Santos, W. Mongkolpun, P. Bakos, FS. Taccone, JL. Vincent, J. Creteur
[1]Department of intensive care, Erasme Hospital, Brussels, Belgium
Correspondence: E. Cavalcante dos Santos
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001107

INTRODUCTION. Red blood cell transfusion (RBCT) increases tissue oxygen delivery (DO2) and may improve microcirculation. However, the effects on blood flow are inconsistent.
OBJECTIVES. To assess the effects of RBCT on tissue perfusion and identify the hemodynamic variables predicting such response.
METHODS. We studied 36 ICU patients with stable hemodynamic status (mean arterial pressure (MAP) ≥ 65 mmHg for at least 6 hours) and without active bleeding, who required RBCT. Skin blood flow (SBF) was determined (Periflux System 5000, Perimed, index finger; perfusion unit, PU) together with MAP, heart rate (HR), hemoglobin (Hb), lactate levels and ScvO2 before and after RBCT. In each case, SBF was measured at basal temperature (BT) for 3 min. According to previous data indicating an SBF of 151 PU in non-infected patients, all patients were analyzed according to the baseline SBF (i.e. <151 PU - low SBF vs. ≥151 PU – high SBF). A positive RBCT responder was defined as a > 10% increase in SBF. Data were expressed by median (25th-75th percentile).
RESULTS. In all patients, RBCT was associated with increases in Hb, MAP, and ScvO2 but no change in SBF (Table 1). At baseline, there were no difference in Hb (p=0.6), MAP (p=0.5), lactate (p=0.2), and ScvO2 (p=0.3), between the patients with low and high SBF (Table 1). During the transfusion, MAP and Hb increased in both groups (Table 1) but SBF rose only in patients with an initially low SBF (Table 1). Baseline ScvO2 was somewhat lower in the responders (n=19) than in the non-responders to RBCT (p=0.07).
CONCLUSION. RBCT increases skin blood flow when it is low at baseline.

INTRODUCTION. Critically ill patients are subject to a multitude of environmental changes in the Intensive Care Unit (ICU) which contribute to the development of delirium, ultimately affecting their long-term morbidity and mortality in the ICU. ICU patients may register these environmental changes through their five senses including their auditory sensation. One way of enhancing auditory sensation is through music either with or without self-controlled patient-directed music (PDM).
OBJECTIVES. To investigate whether a novel music delivery system produced by Yamaha with capabilities of self-controlled PDM can prevent ICU delirium.
METHODS. We performed a randomized controlled open-label trial with intubated and non-intubated patients in the ICU at a tertiary university hospital between December 2017 and June 2018. Patients in the intervention group were allowed to choose their preferred genre of music at any time and listen to it as much as they like through Yamaha's sound system under development for medical use until ICU discharge. The control group was not able to listen to music through the Yamaha sound system. For patients who had altered level of consciousness or who were unable to operate the system by themselves, ICU nurses instead chose the music genre and the duration of music delivery for their patients. Delirium was assessed every 3 hours by ICU nurses using the Confusion Assessment Method for the ICU. A competing risk survival analysis was used to examine the relative risk of delirium in the intervention group vs the control group. We performed additional analyses with data stratified by the length of ICU stay and the age of the patients.
RESULTS. A competing risk survival analysis indicated that the protective effect of the intervention on delirium incidence was not statistically significant (subdistribution hazard ratio: 0.79, 95% CI 0.42-1.51) in the whole sample with intubation. Stratified analysis by the

length of ICU stay and the age of the patients suggested that the intervention may reduce the risk of delirium among intubated elderly (> 70 years old) patients who stayed in the ICU ≤ 7 days (Figure; subdistribution hazard ratio: 0.11, 95% CI 0.02-0.63). Among patients without intubation no effect of the intervention was detected.

CONCLUSION. PDM did not reduce delirium progression in the ICU, however subgroup analysis showed that PDM may reduce the onset of ICU delirium in intubated elderly patients.

Association of post-operative fluid balance with mortality and morbidity in critically ill patients with complicated intra-abdominal infection

SS. Hong, J. Shim, HJ. Shin, YT. Jung
[1]Surgery, Ajou University Hospital, Suwon, Republic of Korea
Correspondence: Y.T. Jung
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001126

INTRODUCTION. Fluid resuscitation is one the most influential aspects in perioperative management for critically ill patients with complicated intra-abdominal infection (cIAI). However, fluid overload may increase risk of developing pulmonary complications and result in adverse outcomes. Therefore, we evaluated the impact of excessive fluid administration on mortality and morbidity of the post-operative patients with cIAI in surgical ICU (SICU).

METHODS. We reviewed medical records of 320 patients administered to SICU after emergency abdominal surgery for cIAI between January 2013 and December 2018. Firstly, fluid balance of the patients was reviewed for maximum of seven days including the day of operation. Next, average fluid balance over body weight per day was calculated. Then, the patients were divided into two groups with a cut-off value of 20mL/kg/day. Baseline differences of patients in each group are matched using propensity score matching method.

RESULTS. Fluid-overloaded patients (≥20mL/kg/day) were associated with higher rates of 30-day mortality (11.8% vs 2.4%; p = 0.036) than those who received less fluid (<20mL/kg/day). Kaplan-Meier survival curves for 30-day mortality in these groups also showed a statistical significance (p = 0.020). Pneumonia occurrence (47.1% vs 24.7%; p = 0.004) were also higher in fluid-overloaded group. Rate of pleural effusion development (61.2% vs 57.7%; p = 0.755), reintubation (18.8% vs 10.6%; p = 0.194), and infectious complication (55.3% vs 49.4%; p = 0.539) showed no significant differences between two groups.

CONCLUSION. Fluid overload in patients after emergency surgery for cIAI was associated with higher rates of 30-day mortality, and pneumonia. Postoperative fluid balance in these patients should be carefully adjusted to avoid adverse clinical outcomes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001130

INTRODUCTION. Recent evidence suggests that a lower than recommended range for anticoagulation during ECMO may be safely used without major side effects [1]. There are also a few case reports of heparin-free ECMO runs in polytrauma patients indicating that ECMO could be performed without systemic anticoagulation even for prolonged periods of time in the presence of an high bleeding risk [2]. The safety of prolonged (> 24hours) periods of anticoagulation-free veno-venous (vv) ECMO in non-trauma patients has not been studied yet. The aim of this study was to evaluate the complications occurred during anticoagulation-free vvECMO in our cohort of patients with respiratory failure.

METHODS. We retrospectively reviewed our digital database on patients supported with vvECMO for severe respiratory failure from January 2012 to February 2019 at Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico di Milano and selected vvECMO patients not receiving heparin or any other anticoagulant drug for at least 24 hours (and a concomitant aPTT ratio in the normal ranges). Thrombotic adverse events defined as cannula related thrombosis, deep vein thrombosis (DVT) checked at ultrasonography within 24 hours after ECMO removal and exchange of the ECMO circuit due to induced coagulopathy (defined as hypofibrinogenemia, elevation of DDimers and decrease of platelet count, once ruled out other causes) during the anticoagulation-free period are reported.

RESULTS. Ten out of 148 (6.8%) patients supported with vvECMO from 2012 to 2019 were identified and reviewed. Heparin coated circuits were used in all patients. Median time of vvECMO without anticoagulation was 42.25 (range 28.5-617.5) hours and median total ECMO time was 17 days. Main reasons for withholding anticoagulation are reported in table 1. Six (60%) patients died on ECMO or after removal. No cannula related thrombosis nor DVT were observed. The ECMO circuit was exchanged in 3/10 (30%) of patients during the anticoagulation-free period.

CONCLUSION. Prolonged periods of vvECMO without anticoagulation occurred rarely in our cohort and mostly because of uncontrolled bleeding. Although it was not possible to assess thrombosis in all patients, its incidence was low.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001158

INTRODUCTION. Vasoplegia is a frequent complication after cardiac surgery with cardiopulmonary bypass (CPB) and is associated with increased complications. As most healthcare structures do not allow for intravenous vasopressors outside of the intensive care unit (ICU), midodrine, an orally administered alpha agonist, could potentially reduce intravenous vasopressor use and accelerate ICU discharge of otherwise stable patients.
OBJECTIVES. We aimed to explore the clinical contexts in which midodrine is used in a high-volume cardiac surgery center as well as the prescription patterns and safety of this strategy.
METHODS. This is a retrospective cohort study that included all consecutive patients having received midodrine while being on vasopressor support in the ICU within 72 hours after cardiac surgery with CPB, between January 2013 and January 2017 at the Montreal Heart Institute. Outcomes included time on intravenous vasopressors, ICU length of stay, ICU readmission rate, occurrence of kidney injury and in-hospital mortality.
RESULTS. A total of 72 patients fulfilled inclusion criteria during the study period. Surgical interventions consisted of revascularization (N=39, 54.4%), valve surgery (N=13, 18.1%), combined surgery (N=15, 20.8%) and other (N=5, 6.9%). Median Euroscore II [IQR] was 1.94 [0.98-2.78], and median CPB duration was 77 [61-111] min. The median norepinephrine dose at midodrine initiation was 0.04 [0.03-0.08] mcg/kg/min with a cumulative vasopressor index1 at that time of 2.5 [2-4]. The first dose of midodrine was administered at a post-operative median time of 24 [20-44] hours at an initial dose of 10 [8.75-10] mg and treatment duration was 37 [22-73] hours. Median increase in creatinine after midodrine initiation was 5 [0-26.5] µmol/L and acute kidney injury (AKIN stage 1 or more) occurred in 18 patients (25%). Intravenous vasopressors were stopped 17 [4-40] hours after midodrine initiation, for a total of 52 [36-72] hours post-op. In 16 patients (22.2%), intravenous vasopressors had to be reinstituted after more than 2 hours of cessation. ICU length of stay was 93 [53-120] hours and 17 patients (23.6%) were still receiving midodrine on the surgical ward after ICU discharge. A total of 7 patients (9.7%) had to be readmitted to the ICU, of which one (1) was initially discharged while still receiving midodrine. Overall in-hospital mortality was 8.3% (N=6).
CONCLUSION. We report the practice of midodrine administration as an adjunct to intravenous vasopressors for vasoplegia syndrome after cardiac surgery. In a selected cohort of patients, this therapeutic approach appears to be associated with higher than expected ICU readmission rate and mortality. Even though these results may represent confounding by indication, routine prescription of midodrine to hasten ICU discharge after cardiac surgery should be done very cautiously until further prospective study is conducted.

PRE-DELIRIC model as predictor of delirium development in patients in Intensive Care Unit (ICU)

R. Carbajal Serrano, OE. Palacios Calderon, CA. Rojas Gomez, J. Franco Granillo, AG. Camarena, J. Aguirre Sánchez
[1]Intensive care unit, The American British Cowdray Medical Center, Mexico City, Mexico
Correspondence: R. Carbajal Serrano
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001162

INTRODUCTION. Delirium is a neuropsychiatric disorder that affects patients in the ICU, is associated with increased mortality, prolonged hospitalization and long-term cognitive impairment. There are few tools that evaluate the risk of presenting it. The prediction model PRE-DELIRIC contains 10 risk factors, age, APACHE-II score, type of admission, coma, infection, metabolic acidosis, use of sedatives and morphine, urea, and urgent admission. The model had an area under the receiver operating characteristics curve of 0.87 (95% confidence interval 0.85 to 0.89) and 0.86 after bootstrapping. It is divided into 4 groups of low, moderate, high and very high risk.
OBJECTIVES. To determine whether the PRE-DELIRIC model is a good predictor of delirium in patients admitted to the ICU.
METHODS. Observational, analytical, prospective longitudinal study in 400 patients admitted to the ICU to whom PRE-DELIRIC was applied at 24 hours of admission, during the period from June 2018 to January 2019, sociodemographic and clinical data were obtained, in addition to risk factors of the predictive scale. To identify the presence of delirium, patients were evaluated with the CAM-ICU scale. The information was analyzed by descriptive statistics. The variables were evaluated on a numerical scale and reported in terms of percentages and standard deviation.
RESULTS. Low risk 136 (34%), moderate 96 (24%), high 48 (12%), very high 120 (30%), of the latter group 73% male, age: 63.8 ± 16.82 years, with diabetes 7%, hypertension 33%, 70% developed delirium, 50% with sepsis, APACHE-II 18 ±7.5 points, SOFA 8.3 ± 3.8, use of sedatives 83%, use opioids 77%, 75% with metabolic acidosis, 50% with neoplasia, emergency admission 77%, medical 43%, surgical 20%, neurological or neurosurgical 30%, mortality 37% in this group.
CONCLUSION. PRE-DELIRIC is a static model that shows calculated probability for delirium 24 hours after admission, it is a useful tool to detect risk of delirium in ICU. However, it was found that it is not a good predictor of delirium for cancer patients. A predictive scale is needed for this group of patients. By using this predictive scale

routinely we could establish non-pharmacological preventive measures to reduce mortality and days of hospital stay due to delirium.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001180

INTRODUCTION. Patients undergoing emergency laparotomy for intra-abdominal infection experience high peri-operative risk. Mortality rate remains high despite of advancement of surgical technique, antibiotic therapy and intensive care support. In the UK, 30-day mortality is one in seven overall, and for the elderly (age ≥ 80 years), almost one in four (1). Perforative peritonitis is linked with Multiple Organ Dysfunction Syndrome (MODS) in up to 73% patients and mortality reaches 30% in such cases (2, 3). Early identification of patients of severe peritonitis with higher risk of mortality will helpful earlier institution of intensive care management (4)

OBJECTIVES. In this study we have evaluated the risk factors for in-hospital mortality in peritonitis patients who are undergoing emergency laparotomy.

METHODS. This study is a secondary analysis of a previously conducted randomized controlled trial (5). Briefly, in that trial n=100 adult patients of either sex undergoing emergency laparotomy for clinically proven or suspected peritonitis were included. Patients were randomized in two arms; in group A mechanical ventilation was achieved with 6-8 ml/kg of tidal volume, 6- 8 cm H2O of PEEP with additional recruitment maneuver at thirty minutes. In group B, mechanical ventilation was delivered with 10 ml/kg of tidal volume, PEEP of 5 cm H2O and maximum allowable plateau pressure of 30 cm H2O. All patients were followed till hospital discharge and baseline preoperative demographic and laboratory parameters were noted.

RESULTS. During hospital stay, 25 patients died, and 69 patients were discharged from the hospital. Rate of in- hospital mortality (95% CI) was 26.6 (18, 36.7) %. Median [IQR] duration of ICU/ HDU stay was 6 [3- 11] days and duration of total hospital stay was 13 [9-21] days. Non survivors had similar length of ICU/ HDU stay (p=0.16) but shorter length of hospital stay (p=0.001). Non- survivors had longer duration of symptoms before surgery (p=0.003), lower platelet count (p=0.02), higher international normalized ratio (p=0.009) and higher arterial lactate (p=0.001). We have found that only duration of symptoms before surgery [adjusted odds ratio (95% CI) 1.61 (1.14, 2.27); p=0.007] and arterial lactate [adjusted odds ratio (95% CI) 2.25 (1.08, 4.70); p=0.031] were significant predictor of mortality (p=0.22, goodness-of-fit for the model) in a binary logistic regression model.

CONCLUSION. Perforation peritonitis still carries a high hospital mortality and duration of symptoms before surgery and baseline arterial lactate was found to be a significant predictor of mortality in these patients.

Hospital-induced delirium associated with post-intensive care syndrome one year after discharge in severe trauma patients

N. Saito, Y. Takanori, K. Okada, M. Kujo, M. Hisashi

[1]Shock and Trauma Center, Nippon Medical School Chiba Hokusoh Hospital, 1715 Kamagari, Inzai, Chiba, Japan, Inzai, Japan

Correspondence: N. Saito

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001189

INTRODUCTION. Patients with severe trauma often experience delirium due to head injury, pain, and surgery. Hospital-induced delirium is a risk factor for increased long-term mortality. Additionally , post-intensive care syndrome (PICS) in a critically ill patient is a long-term health problem, but the hospitalization-related factors are unknown.

OBJECTIVES. We aimed to clarify the association between hospital-induced delirium and PICS, one year after discharge, in severe trauma patients.

METHODS. This single-institutional prospective study included 213 injured patients who were admitted to the trauma surgical intensive care unit (TSICU) and survived until discharge to home between 2016 and 2017.We evaluated the activities of daily living one year after the discharge using physical and mental component scores of SF-36®and defined physical dysfunction and mental disorder as a score of less than the 25thpercentile of the national standard value for the same age. Further, cognitive impairment was determined by self-administered screening. PICS was diagnosed when one of the following three components was recognized: physical dysfunction, mental disorder, and cognitive impairment. We divided the patients in the PICS and control (without PICS) groups and compared the groups.

RESULTS. The patients had experienced blunt injuries, including pedestrian injuries (19.7%) and falls (34.3%). The mean age was 61.6 years (men: 70%); the median injury severity score (ISS) was 21 (interquartile range: 16–29); and the mean length of TSICU stay was 4.3 days. The average period from the injury until the investigation was 17.9 months. The PICS group included 121 patients (56.8%), of which 99 (46.5%), 46 (21.6%), and 28 (13.1%) had physical dysfunction, mental disorder, and cognitive impairment, respectively. More patients in the PICS group were transferred to a rehabilitation facility and were receiving outpatient treatment at the time of the study compared to the control group. Furthermore, they had more health-related and financial problems ($P< 0.01$). The frequency of emergency surgery (50.4% vs. 33.7%) and mechanical ventilation (37.2% vs. 23.9%) in the PICS group were significantly higher compared to the control group. The incidence of delirium in the PICS group was significantly higher compared to the control group (33.1

% vs. 12.0%). A multivariate analysis, which was adjusted for age, severity, and gender, revealed the factors affecting PICS: delirium (odds ratio [OR]: 3.54; 95% confidence interval [CI]: 1.54–8.16; *P*=0.003), emergency surgery (OR: 2.36; 95% CI: 1.24–4.46; *P*=0.08), and spinal cord injury (OR: 4.42; 95% CI: 1.48–13.12; *P*=0.07).
CONCLUSION. In severe trauma patients, hospital-induced delirium was independently associated with PICS, lasting up to one year after discharge.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001197

INTRODUCTION. Heat stroke is a high fever associated with systemic inflammatory response, which can lead to multiple organ dysfunction syndrome, mainly encephalopathy[1]. High heat stimulation causes intestinal ischemia, mucosal barrier dysfunction and release of inflammatory factors[2], eventually leading to systemic inflammatory response. Mesenchymal stem cells have many mechanisms, such as immune regulation and repair of tissue damage. Many studies have found that MSCs can regulate the level of inflammatory factors through paracrine effect, and also affect regulatory T cells[3] and macrophages[4], thus playing an anti-inflammatory role. MSCs can also repair tight junctions[5] and alleviate ischemia-reperfusion injury, thereby improving intestinal mucosal barrier function.
OBJECTIVES. To explore whether MSCs can reduce intestinal damage and systemic inflammation caused by heat stroke, and ultimately improve survival rate.
METHODS. Sprague-Dawley (SD) male rats were used to establish heat stroke injury model, and MSCs were infused into HS rats treated with MSC. Rats in model group and treatment group were divided into early, middle and late stages. The levels of biochemical markers (ALT, AST, etc.), inflammatory factors (IL-1beta, IL-6, TNF-alpha) and chemokines (Eotaxin, Rantes, MIP-2) in intestine and blood were detected respectively. The intestinal injury was compared by intestinal histopathology. The intestinal injury was compared by intestinal histopathology. Survival rate was estimated by 28-day observation.
RESULTS. The 28-day survival rate of rats in the treatment group was significantly higher than that in the model group, and the level of biochemical markers was significantly better than that in the model group. According to Chiu's score of intestinal mucosa, the treatment group was significantly lower than the model group. In intestinal tissue and blood, the level of anti-inflammatory factors in the treatment group was higher than that in the model group, and the level of pro-inflammatory factors was lower than that in the model group, with statistical difference. The change trend of chemokine levels in the two groups was the same, but the overall level in the treatment group was lower than that in the model group.
CONCLUSION. In animal models of heat stroke, MSCs can play an anti-inflammatory role, reduce organ damage and improve survival rate. MSCs can also reduce stress injury of intestinal mucosa and promote tissue repair.

Albumin mass balance in pancreatic surgery

A. Komáromi[1], J. Wernerman[1], O. Rooyackers[2], Å. Norberg[1]
[1]Clintec, Karolinska Institutet, Stockholm, Sweden; [2]Perioperative medicine and intensive care, Karolinska University Hospital Huddinge, Stockholm, Sweden
Correspondence: A. Komáromi
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001241

INTRODUCTION. In major abdominal surgery plasma albumin concentration decreases more than explained by bleeding, presumably due to increased transcapillary leakage into the interstitial space and alterations in plasma volume. The contribution of compromised lymphatic return to net albumin leakage has not been investigated. Here we study this contribution by using pancreatic Whipple surgery with aortocaval lymphadenectomy as a model for compromised lymphatic return in the postoperative period.
METHODS. Patients scheduled for pancreatic resection were studied in two groups, A (n=12, Whipple procedure) and B (n=13, Whipple + aortocaval lymphadenectomy), Albumin mass balance was assessed from start of anesthesia until postoperative day 3 (POD 3). Endpoints were albumin net leakage at end of surgery (EOS) and on POD 3.
RESULTS. Plasma albumin decreased from 35.0 ± 3.6 g/L and 32.7 ± 3.6 g/L at start of anesthesia to 28.6 ± 4.4 g/L (p<0.0001) and 27.9 ± 4.8 g/L (p=0.0002) at EOS for groups A and B respectively, corresponding to decreases of 18 ± 8 and 15 ± 10 %, respectively. At EOS this corresponds to an albumin shift from plasma of 22 ± 10 g and 23 ± 12 g in group A and B, respectively. At POD 3 the shifted amount in group A was 9 ± 29 g (p = 0.34 compared to EOS) and 23 ± 29 g (p = 0.99) in group B.
CONCLUSION. Plasma albumin decreased by 16 % until EOS. The decrease in albumin leakage in group A postoperatively failed to reach statistical significance, indicating that lymphatic return might not be the main contributor. The large variability suggests a multifactorial explanation behind the postoperative shift of albumin.

Impact of noninvasive hemoglobin-level measurement by Radical 7 Pulse Co-Oximetry on clinical decision: a prospective observational study

A. Herner, I. Hartter, R. Schmid, W. Huber
[1]Medizinische klinik und poliklinik ii, Klinikum rechts der Isar; Technische Universität München, Munich, Germany
Correspondence: A. Herner
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001298

INTRODUCTION. Accurate measurement of hemoglobin (Hb) concentration is a major target of monitoring in critically ill. Furthermore, it guides decision making regarding blood transfusion. Standard laboratory hemoglobin measurement requires time and

resources. Therefore, noninvasive real-time Hb measurement devices as Radical 7 Pulse Co-Oximeter (MASIMO, USA) are of high interest. Despite a number of attempts to validate this device, its accuracy especially at low Hb values remains unclear.
OBJECTIVES. Therefore, we investigated, if noninvasive pulse-oximetry Hb (SpHb) appropriately indicates the need for blood transfusion according to invasive hemoglobin measurements (primary endpoint) in critical ill patients.
METHODS. This prospective observational study was performed on a general ICU of a University Hospital in Munich. Only patients with a need to blood transfusion (Laboratory Hb <7mg/dl; in case of pre-existing cardiovascular disease: Hb <8 mg/dl) were included in this study. All patients (n=44) were equipped with Radical 7. Reference laboratory Hb (Hb_BGA) values were determined by RAPIDPoint 500 Blood Gas analyzer (Siemens, Germany). 35 out of 44 patients were equipped with transpulmonary thermodilution monitoring (PiCCO, Germany). All measurements were performed prior and after the transfusion of two units of red blood cells. Statistics: Fisher´s exact test. Wilcoxon-test for paired samples. IBM SPSS 25.
RESULTS. All 44 patients fulfilled the pre-defined criteria for blood transfusion according to Hb_BGA. Pre-transfusion Hb_BGA was 6.7± 0.6 mg/dl. In 8 out of these 44 patients (18%) Radical 7 was not able to generate a hemoglobin value. In none of the remaining 36 patients SpHb would detected the need for blood transfusion. Consequently, the need for transfusion was detected in 0/44 (0%) by SpHb compared to Hb_BGA (44/44 (100%); p<0.001).
SpHb prior to transfusion significantly overestimated Hb according to the gold standard laboratory measurement (9.3±1.3 vs. 6.7±0.6 mg/dl, p<0.001) with a bias of 2.6±1.2 mg/dl, lower and upper limits of agreement f of 0.02 and 4.97 mg/dl, and a percentage error of 30%.
Similarly SpHb overestimated Hb_BGA after transfusion of 2 units of red cells (10.2±1.5 vs. 8.8±0.8mg/dl, p<0.001), with a bias of 1.4±1.5 mg/dl and limits of agreement of -1.4 and 4.2 mg/dl, and a percentage error of 29%.
Also trending capacities of SpHb were poor: Changes in SpHb after transfusion did not correlate with changes in Hb_BGA (r=0.206; p= 0.220).
While Hb_BGA increased in 44 of 44 patients (100%), SpHb increased in only 32 of 37 displayed mesaurements (p=0.017).
Increases in Hb_BGA after transfusion compared to baseline were significantly higher than changes in SpHb (2.1±0.6 vs. 1.0±0.9g/dl; p< 0.001).
CONCLUSION. 1.) Radical 7 Pulse CO-Oximeter does not accurately measure decreased Hb-values in critically ill patients.
2.) SpHb is not appropriate to trigger transfusion and and to track changes in Hb critically ill patients with a low hemoglobin values.

Patient Survival Rates and their Correlated Factors in a Dust Explosion Incident

CC. Chao
[1]{street_address}, Taipei, Taiwan
Correspondence: C.C. Chao
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000070

INTRODUCTION. Triage plays a critical role in mass casualty incidents by optimizing the use of medical resources. The Formosa Fun Coast (Baxian Water Park) dust explosion incident in 2015 revealed the lack of resources for mass burn and scald casualties in the Taiwanese medical system, however mortalities in this incident were only 3% (15/499) by the end of 2015.
OBJECTIVES. This study examined the key feature of the prehospital settings of the 15 mortalities.
METHODS. This was a retrospective cohort study, and all the patients from the Formosa Fun Coast incident (N = 499) were enrolled. The follow-up period was from June 27, 2015 to December 31, 2015. We first examined the correlation between patient survival and various variables and then tested the correlation between the survival-correlated variables and the level of the hospitals that provided treatment.
RESULTS. The survivor and nonsurvivor groups shared similar distributions of all the study variables.The patients were divided into two groups: survivors (N = 484) and nonsurvivors (N = 15). The two groups shared a similar average age and sex division. Most of the patients were sorted to more severe levels; this is evident from both the emergency severity index and EMT-performed triage assessment. Regarding the emergency severity index, the majority of the patients were Level 1 or Level 2 (100% of nonsurvivors; 74.7% of survivors). For EMT-performed triage assessment, most of the patients' conditions were of high or medium severity (100% of nonsurvivors; 79.6% of survivors). The burn and scald classification and Baux score were higher in the nonsurvivor group; the majority of nonsurvivors had a third-degree burn (86.7%) and a Baux score of more than 50 (100%).
CONCLUSION. The lack of effect of hospital level on patient mortality indicated that in addition to a satisfactory EMT-performed triage system, all hospitals, regardless of their level, are equipped with adequate medical capacity for handling patients with burns and scalds.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000077

INTRODUCTION. Major burn injury can cause massive tissue destruction and initiates cytokine-mediated inflammatory response, impaired coagulation and fibrinolysis. This condition features an initial transient thrombocytopenia followed by normalization of platelet count and eventual reactive thrombocytosis.
OBJECTIVES. Our aim was to investigate the kinetics of platelet antisedimentation rate (PAR), C reactive protein (CRP) and procalcitonin (PCT) levels in the early period after burn and to assess whether these parameters can predict development of septic complications and ICU outcome.
METHODS. In a prospective, observational study 23 consecutive patients with more than 20% body surface burn injury were followed

for five days (T1-T5) after admission to ICU. PAR was measured by one-hour gravity sedimentation indicating the percentage of platelets had crossed the half line of blood sample column. Serum CRP and PCT values were measured by standard laboratory methods and sepsis diagnosis was based on American Burn Association guideline.
RESULTS. Ten patients developed septic complications. In the whole group platelet concentration decreased by time and became significant at T3 ($p<0.001$) in survivors (n=16) and at T2 ($p<0.05$) in non survivors comparing to T1. In survivors mean PAR continuously increased between T1 and T5. Mean PAR of survivors were significantly higher than that of non survivors at T1, T4 and T5 (all $p<0.05$). In non survivors PAR increased significantly ($p<0.05$) from T3 and reached its peak at T5. PAR had showed a decreasing tendency in septic patients during three days before clinical diagnosis of sepsis was made. Drop of mean CRP was significant ($p<0.05$) just a day before sepsis was clinically evident. Serum PCT increased right on the day of sepsis commencement ($p<0.05$).
CONCLUSION. In patients with a significantly higher PAR value on T2 ($p<0.05$) were more likely to survive ICU treatment. A sudden drop in the PAR levels may predict the onset of sepsis earlier than conventional clinical signs. Earlier detection of septic complications can result in earlier therapeutic interventions. Ten patients who developed sepsis as a consequence of burn injury do not provide enough data required for the complete description of sepsis kinetics. A greater number of patients will be needed in the future.

Incidence Of Multidrug-Resistant Organisms (MDRO) And Association With Worse Outcome In Severely Injuried Patients

A. Nohl[1], U. Hamsen[2], M. Dudda[3], TA. Schildhauer[2], A. Wegner[3]
[1]Department of trauma surgery and orthopedics, BG Klinikum Duisburg, Duisburg, Germany; [2]Department of general and trauma surgery, BG University Hospital Bergmannsheil, Bochum, Germany; [3]Center for orthopedics and traumatology, University Hospital Essen, Essen, Germany
Correspondence: A. Nohl
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000081

INTRODUCTION. MDRO are an increasing problem in hospitals and especially in intensive care units(1). Furthermore, infections with MDRO have significant economic effects(2). Taking into account the increasing health and socioeconomic issues, recent findings show that up to 37% of healthcare facilities in a rich industrialized country do not perform any screening at admission(2). An effect of MDRO in injured patients is not yet described.
OBJECTIVES. This study describes for the first time the rate and impact of MDRO in severely injured patients.
METHODS. Retrospective, multicenter study from three trauma level-1 centers in Germany. The study was approved by local ethics committees.
All patients treated in the trauma room and admitted to an intensive care unit between 2013 and 2017 were included. Data were extracted from the german trauma registry(Traumaregister DGU ®) and completed with data of microbiological screening. Data are presented as mean +/- standard deviation.
RESULTS. We included 3887 trauma patients, mean ISS was 16.25 (+/- 13.18). Incidence of positive screening for MDRO was 1.4 %. Comparing MDRO positive vs MDRO negative patients , MDRO positive patients showed an extended length of stay in icu (26.80 days +/- 24.29 vs. 6.42 days +/- 12.21; p=<0.001), duration of mechanical ventilation (395.3 hours, +/- 455.9 vs 64.94 hours, +/-194.7 ; p=<0.001), sepsis (n=25=45,5% vs n=214=5,5%, p=<0.001), multi organ failure (n=9=16,4% vs n=271=7%, p=<0.007), Glasgow Outcome Scale (median 2 vs median 1, p=<0.001).
CONCLUSION. MDRO are rare in severely injuried patients but they are associated with a devasting worser outcome . We strongly recommend extented screening for MDRO in critically ill trauma patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000137

INTRODUCTION. Oxidative stress induced by ischemia, mechanical stress or toxins is a condition that results from the imbalance between the production of oxygen species and free radicals as well as inappropriate antioxidant function. The dexmedetomidine (DEX) is a highly selective alpha-2 adrenergic receptor agonist that is commonly used in the clinic as a sedative and anesthetic. In addition, DEX protective effects against oxidative damage in both in-vitro and in vivo conditions have been demonstrated. The Alkali Comet Method is an in-vitro method that allows the determination of single strand fractures of DNA.
OBJECTIVES. It was aimed to evaluate the protective effects of DEX and Ascorbic Acid (AA) on DNA against alkali-induced DNA damage caused by Hydrogen Peroxide (H2O2) induced oxidative stress in human lymphocyte cell cultures in vitro by alkaline comet method.
METHODS. Lymphocyte cell cultures were divided into five groups as negative control; solvent control; positive control; H2O2 (150 μM) + DEX (1μM; 2.5μM; 5μM); H2O2 (150μM) + AA (1μM; 2.5μM; 5μM) and incubated at 37°C for 1 hour. Cell viability was measured by Trypan Blue test. DNA damage was measured by Alkali Comet Technique and % tail intensity was evaluated. Statistical analysis was performed by one-way analysis of variance and Tukey's multiple comparison test.
RESULTS. It was observed that H2O2 significantly induced DNA damage in lymphocytes and this damage decreased significantly with AA and DEX. It was observed that AA at 1μM and 2.5μM doses had a significantly stronger antioxidant effect, but there was no significant difference between the antioxidant effects of AA and DEX in 5μM doses. The concentration of 5μM DEX was found to be most effective in reducing oxidative DNA damage.
CONCLUSION. The anti-oxidative effects of dexmedetomidine have been reported to be associated with extracellularly signal-regulated kinase signaling pathways. It has been reported that produces protective effects by suppressing in toll-like receptor, nuclear factor-kappa B like and phosphoinositide-3 kinase signaling pathways against oxidative injury. Our results showed that dexmedetomidine is

a protective against H2O2 induced in vitro oxidative DNA damage in lymphocyte cell cultures in a dose-dependent manner.

The impact of the use of Oxandrolone in the adult burn patient

J. Goethals[1], K. Claes[2], J. Fierens[3], S. Witdouck[4], L. De Bus[5], K. Colpaert[5]
[1]Faculty of medicine and health sciences, Ghent University, Ghent, Belgium; [2]Plastic surgery, Ghent University Hospital, Gent, Belgium; [3]Intensive care, Ghent University, Ghent, Belgium; [4]Burn center, Ghent University Hospital, Gent, Belgium; [5]Intensive care, Ghent University Hospital, Gent, Belgium

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000169

INTRODUCTION. Burn patients experience a hypermetabolic response that induces several pathophysiological changes leading to catabolism. This response can be potentially countered with optimal fluid resuscitation, excision and grafting, early enteral nutrition and physical rehabilitation. Pharmacological modulation of the hypermetabolic response due to severe burns can help improve the prognosis. The anabolic steroid, Oxandrolone, possibly finds its place here.
OBJECTIVES. The objective of this systematic review on the use of Oxandrolone in adult burn injury patients is to provide an overview of the effectiveness on weight, nitrogen balance, metabolism, length of stay, side effects and mortality.
METHODS. PubMed, Google Scholar, Web of Science, Embase and Cochrane Library databases were searched up to November 2018. Forest plots were created in Review Manager.
RESULTS. Six randomized controlled trials (RCTs) and two retrospective studies with a total of 541 patients were included in this study. The RCTs had a total of 257 patients; 5 single centre studies from one author (total of 176 patients), and 1 multicentric study from a second author (total of 81 patients). The systematic review on the six RCTs showed that Oxandrolone had a potentially beneficial effect on the healing process of the adult burn patient in a dosing of 2 times 10mg Oxandrolone per day. No additional side effects could be observed by the use of oxandrolone on liver function (P=0.41), glycemic control or hirsutism. There was less weight loss in the acute phase (P<0.001) as well as a better increase in weight in the rehabilitation phase (P<0.001). This beneficial effect on weight remained noticeable up to six months after discontinuation of Oxandrolone. Furthermore, there was a better nitrogen balance (P<0.001). No effects on metabolism could be observed (P=0.47). There was a significant faster wound healing (P< 0.001). No impact on length of stay or mortality could be demonstrated.
CONCLUSION. Although this systematic review clearly shows a significant benefit towards adequate weight control and wound healing, currently no clear recommendation can be made. The low quality nature of the evidence does not allow for therapeutic advices to be drawn. Further methodologically robust research including more patients as well as centres needs to be conducted.

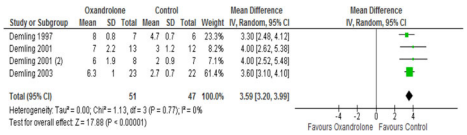

Fig. 2 (abstract 000169). Forest plot of the gain of weight in the rehabilitation phase.

ALEC STUDY : Analysis of phenytoin use in acute seizures at Chicoutimi Hospital, Canada

A. Noël[1], A. Bouchard[2], C. Côté[2], A. Lavoie[2], G. Babin[2], F. Calon[3]
[1]Pharmacy, Hôpital de Val-d'Or, Val-d'Or, Canada; [2]Pharmacy, Hôpital De Chicoutimi, Saguenay, Canada; [3]Research, Centre recherche CHU de Québec, Quebec City, Canada
Correspondence: A. Noël
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000206

INTRODUCTION. Phenytoin (PHT)is frequently used in the treatment of acute seizures. Inadequate dose or wrong interpretation of the total phenytoin plasma level (TPPL) could lead to significant consequences. Five different formulas can be used to estimate the concentration of free PHT, but no clinical guidelines are available to determine which formula to use(1).
OBJECTIVES. The main objective was to determine the proportion of therapeutic TPPL within the first 48 hours of treatment. The secondary objectives were to describe the doses of PHT used and the TPPL interpretation, evaluate the proportion of patients to whom a TPPL is prescribed, the impact of different loading doses (LD) and interventions of a clinical pharmacist.
METHODS. A descriptive, longitudinal and retrospective study design was used. The health records from a single university hospital of all adult patients receiving intravenous PHT were included. The exclusion criterias were therapeutic hypothermia and pregnancy. The TPPL was analysed if the patient file contained one albumin and creatinine plasma concentration measured within 72 hours of the TPPL. The adequacy of the formula used was determined by an algorithm developed by the authors after a literature review.
RESULTS. 401 patients from January 3rd 2014 to April 19th 2018 were included. After excluding files with missing data, 156 patients and 383 PHT dosages were included in the analysis. 60.7% of the TPPL were within the therapeutic range at 48 hours. The mean initial LD was 12.4 ± 3.7 mg/kg. A TPPL was ordered for 44.1% of patients in the first 7 days of treatment. The TPPL were corrected with the appropriate formula in 53.4% of cases by pharmacists and in 10.9% by physicians. The initial LD of 1g resulted in 65.5% therapeutic dosages at 48 hours and those between 15-20 mg/kg in 80.6% (p= 0.04).
CONCLUSION. The PHT levels of four out of ten patients were subtherapeutic due to insufficient initial LD. Drug monitoring of PHT was inadequate in a large proportion of patients because the wrong formula was used. Less than half of the patients had a TPPL prescribed and even less had an analysable result without missing

data. This is worrisome, seeing as it could lead to therapeutic failure or adverse events with this narrow therapeutic index drug. This study demonstrates that education is still needed to insure an optimal treatment of seizures with PHT.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000271

INTRODUCTION. Shock index (a ratio between heart rate and systolic blood pressure, SI) has been shown to predict transfusion requirements and the need for hemostatic resuscitation in severe trauma patients. Trauma-induced coagulopathy frequently occurs in patients with traumatic shock and increases mortality by up to four times. Fibrinogen is the first clotting factor that reaches critical levels. Resuscitation strategy based on early fibrinogen supplementation has recently been shown to be superior in coagulopathy reversal compared to fixed plasma to packed red blood cells ratio approach. In the present study, we aimed to determine whether prehospital and on-admission shock index values can be used to predict low plasma fibrinogen in trauma patients.
METHODS. Between January 2016 and February 2017, all trauma patients whose prehospital vital signs record was available were assessed for demographics, injury characteristics, shock index and admission plasma fibrinogen level. An area under the receiver operating characteristics curve (AUROC), sensitivity, specificity, positive and negative predictive values and accuracy were calculated. Clinicaltrial.gov ID: NCT0269539 (registered 27 November 2015).
RESULTS. AUROC for prespecified cut-offs of plasma fibrinogen concentrations and the worst prehospital shock index was 0.7 (95% CI 0.63 - 0.76) for fibrinogen 2.3 g.l-1, 0.78 (95% CI 0.71 - 0.84) for 2.0 g.l-1 and 0.76 (95% CI 0.64 - 0.86) for 1.5 g.l-1. For the admission SI, AUROC was 0.65 (95% CI 0.59 - 0.71), 0.8 (95% CI 45 0.68 - 0.91) and 0.8 (95% CI 0.68 - 0.91) for the same levels of fibrinogen as above. For the worst prehospital shock index $\geq$ 1 and plasma fibrinogen $\leq$ 1.5 g.l-1 sensitivity was 0.54 (0.25 - 0.81), specificity 0.87 (0.83 - 0.91), positive predictive value 0.16 (0.10 - 0.25), negative predictive value 0.98 (0.96 - 48 0.99) and accuracy 0.86 (0.81 - 0.90).
CONCLUSION. Shock index is an easy-to-perform clinical tool, which may help identify adult trauma patients at risk of hypofibrinogenemia from the very early contact with the patient. Levels < 1 excluded severe hypofibrinogenemia with 98% predictive value. Taken to the patient's bedside, this means that whenever the systolic blood pressure remained higher than the heart rate, the risk of critical hypofibrinogenemia was low. These findings should prompt emergency physicians to consider early fibrinogen administration when fibrinogen levels are not available, and shock index is high.

Septic shock as major predictor for mortality in critically ill patients admitted due to burn injuries in Catalonia

C. Vizcaino Urresta[1], M. S.[2], A. Rey-Pérez[2], J. Baena[2], L. Pérez[2], L. Lagunes[3], M. Baguena[2], J. Barret[4]

Correspondence: C. Vizcaino Urresta

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000272

INTRODUCTION. Burn injury is a complex process with high mortality with a high economic burden and social implications. Specific risk factors for mortality has been outlined in recent reports, including the total body surface area (TBSA) of burns, the TBSA of full-thickness burns, age, and presence of inhalation injury. However information on our environment is scarce.
OBJECTIVES. To assess mortality risk factors and to update the epidemiological distribution of patients with major burns treated in Catalonia.
METHODS. Retrospective monocentric cohort study of patients admitted to Burns ICU (BICU) at Vall d'Hebron university Hospital in Barcelona between February 2009 and January 2017 were included. Demographic data, presence of inhalation injury defined by the presence of facial burns, singed nasal vibrissae, soot in the mouth or sputum, history of closed space injury and patient`s history of breathed smoke. Infection related variables and resuscitation related variables as hemodilution were recorded, Multivariate stepwise logistic regression was performed to identify factors associated with mortality.
RESULTS. 276 patients were admitted in the BICU during the study period. All population mortality was around 18% (51) patients. Septic shock was identified as number one predictive factor of mortality in this cohort (OR 46.7; IC95% 6-363.8; p=0.001), followed by age (OR 1.12; IC95% 1.07-1.17; p=0.001) and TBSA (OR 1.07; IC95% 1.04-1.12; p=0.001). A total liquid balance near to 0 measure by hemodilution on deltaHb at first 48h and an initial management in the ICU with a shorter length of stay in this unit were identified as protective factors for mortality.
CONCLUSION. Septic shock was identified as major risk factor for mortality, other non modifiable factors such as age and higher TBSA

were identified. Further studies are necessary to early detect sepsis in this group of patients. Neutral liquid balance in the first 48h was associated with a better survival.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000280

INTRODUCTION. S-100 B Protein has been identified as a biomarker for traumatic brain injury, but studies suggest that extracranial injuries lead to elevated S-100 B levels as well. Hence, the impact of different concomitant injuries on S-100 B levels in trauma and its role in multiple trauma patients remain unclear.
OBJECTIVES. . In this study, we therefore aimed to quantify the impact of concomitant injuries on S-100 B levels in trauma patients and further investigate the role of S100-B levels to predict mortality and injury severity.
METHODS. All patients with suspected multiple trauma treated at a Level 1 Trauma centre in Switzerland over a three-year period were included in this retrospective cohort analysis. The extent of injuries and their severity, reflected by the abbreviated injury scale (AIS) and injury severity score (ISS), was assessed and S-100 B levels on admission were obtained. Potential predictors of pathological S-100 B levels (>2.0 µg/L) were identified through uni- and multivariable analysis.
RESULTS. In total, 1,338 patients with suspected multiple trauma, 76.5% of them with pathological S-100 B levels, were included in the analysis. In multivariable logistic regression adjusting for sociodemographic characteristics, concomitant injuries and trauma severity, the following predictors showed a significant association ($p<0.001$) with pathological S-100 B levels: Longbone fracture (OR 3.0, 95% CI: 2.2-4.3, $p<0.001$), non-longbone fracture (OR 2.3, 95% CI: 1.3-4.1, $p=0.004$), thoracic injury (OR 2.6, 95% CI 1.6-4.2, $p<0.001$), flesh wounds (OR 1.9, 1.4-2.6, $p<0.001$). Head trauma with intracerebral bleeding was only weakly associated (OR 2.0 (1.19 - 3.45) $p< 0.010$) and head trauma without intracranial bleeding was not associated with increased S-100 B protein levels at all ($p< 0.706$). Trauma severity was also related to S-100 B protein increase (OR per ISS: 1.1, 95% CI 1.0-1.1, $p<0.001$). In-hospital death was strongly associated with pathological S-100 B levels (OR 24.8, 95% CI: 3.4-179.4, $p<0.001$).S-100 B levels below 0.575 µg/L had a high diagnostical value to rule out in-hospital mortality (negative predictive value: 0.99, 95% CI: 0.98-1.00).
CONCLUSION. Fractures and thoracic injuries are the main predictors for elevated S-100 B levels. Despite common perception, head injuries play a minor role in S100-protein elevation in multiple trauma patients S-100 B has a good negative predictive value for in-hospital mortality and is associated with trauma severity and hence might be of use as a prognostic marker in trauma patients.

Is Haloperidol Safe in the Presence of Other QT Prolonging Drugs in the Intensive Care Unit?

J. McLuckie, K. Puxty, L. Jarvie, M. Shaw
[1]Intensive care unit, Glasgow Royal Infirmary, Glasgow, UK
Correspondence: J. McLuckie
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000286

INTRODUCTION. ICU delirium is a neuropsychiatric disorder, characterised by an acute fluctuation in consciousness, which affects between 30-50% of the critically ill [1]. Haloperidol is the most commonly used pharmacological agent in the management [2]. However, the European Medicines Agency recently suggested that Haloperidol is now contraindicated for utilisation in combination with other QT prolonging drugs due to the risk of ventricular tachyarrhythmia [3].
OBJECTIVES. However, before practice changes to another potentially harmful alternative, it is essential to understand the influence of Haloperidol in combination with other QT prolonging drugs on VT in comparison to Haloperidol alone. It is also necessary to correct for the influence of other risk factors including age, gender, electrolyte disturbances such as mild hypokalaemia, severe hypokalaemia, hypomagnesaemia or hypocalcaemia and a past medical history of Ischaemic Heart Disease or previous arrhythmia on VT. To ascertain if episodes of VT are clinically significant, it is important to determine the odds of VT requiring intervention in relation to each factor.
METHODS. A case control study involving 4,189 admissions was performed. Electronic records for each were interrogated to provide information pertaining to the aforementioned factors and receipt use of Haloperidol or other QT prolonging drugs. It was also documented as to whether the patient experienced VT during their stay. Multivariate logistic regression analysis calculated odds ratios to ascertain factors associated with VT and to determine if these episodes were clinically significant, odds ratios were calculated for VT requiring treatment.
RESULTS. Our results identified that 2.1% of patients in ICU developed VT and that hypocalcaemia, IHD, previous arrhythmia and the administration of QT prolonging drugs were all associated with VT. The effect was strongest for Haloperidol administration without another QT prolonging drug (OR 12.309, 95% CI 3.396 – 44.618). The administration of a QT prolonging agent in combination with Haloperidol did not further increase this (OR 8.599, 95% CI 3.175 – 23.291). Intervention was required for 48.3% of patients that developed VT and included electrolyte replacement, antiarrhythmic drugs and DCCV. The administration of any QT prolonging drug resulted in the greatest odds of VT requiring treatment (OR 4.373, 95% CI: 1.337 – 14.299).
CONCLUSION. Despite concerns regarding its safety, Haloperidol should remain the first line treatment option in delirium since the chance of developing VT remains low, even though the odds are significantly increased. Additional QT prolonging drugs do not increase this further and this combination in patients whom it is clinically appropriate appears to be safe. However, alternatives including atypical antipsychotics should be considered in patients with concomitant risk factors such as IHD and previous arrhythmias.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000334

INTRODUCTION. The presence of hypothermia is an independent predictor of outcome in traumatic shock. Nevertheless, hypothermia may be an effective therapeutic approach for otherwise lethal traumatic hemorrhage.
OBJECTIVES. To characterize the effects of hypothermia on microcirculation in normal conditions and in hemorrhagic shock.
METHODS. We studied 24 anesthetized and mechanically ventilated sheep. We measured cardiac output (CO, mL/min/kg) by thermodilution, renal (RBF, mL/min/100g) and intestinal (IBF, mL/min/100g) blood flow by ultrasonic probes, and systemic O_2 consumption (VO_2, mL/min/kg) by a metabolic cart. Renal (rVO_2, mL/min/100g) and intestinal (rVO_2, mL/min/100g) O_2 consumption were calculated from RBF and IBF and the respective arteriovenous O_2 content difference. Cortical renal, intestinal villi and sublingual microcirculation were assessed by IDF-videomicroscopy. After basal measurement, sheep were assigned to normothermia (N, n=12) and hypothermia (H, n=12) groups. In the former, central temperature (Temp, °C) was maintained at basal values and in the latter, it was reduced to ~34°C. Measurements were repeated after 1 h of hemodynamic stable conditions and 1 h of hemorrhagic shock.
RESULTS. During hemodynamic stability, hypothermia decreased CO, RBF, and systemic and regional VO_2. Renal, villi and sublingual red blood cell velocity (RBCV, µm/s) decreased while perfused vascular density (PVD, mm/mm^2) remained unchanged. In normothermia group, all these variables were unchanged.
During hemorrhagic shock, systemic and regional flow and VO_2, and RBCV and PVD were similarly reduced in normo- and hypothermia groups. The microcirculatory derangements were higher in the renal cortex than in the villi and the sublingual mucosa: PVD was reduced to 25±28, 67±29, 82±21% from basal values, in renal, villi and sublingual microcirculation; and RBCV to 37±28, 56±15, and 54±9% (P<0.001 for both, renal vs. villi and sublingual microcirculation).
CONCLUSION. 1) In stable hemodynamic conditions, hypothermia decreased peritubular, villi and sublingual RBCV but PVD was unaffected. 2) In hemorrhagic shock, hypothermia showed neither beneficial nor detrimental effects on microcirculation. 3) Renal microcirculation was more sensitive than villi and sublingual microcirculation to hemorrhagic shock.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000374

INTRODUCTION. Patients suffering from acute intoxication, whether voluntarily for autolytic or accidental purposes, often require life support in intensive care units.
METHODS. Retrospective observational study of all patients admitted for acute intoxication who required admission to the ICU of the Regional Hospital of Malaga between January 2012 and August 2016, older than 14 years with admission to the ICU for intoxication of any kind. We study patient characteristics in terms of age, sex and medical history, type of toxicity, severity and evolution in our unit.
RESULTS. We found 70 cases of patients who required admission to the ICU due to acute intoxication, of which 55.6% were women. The average age was 47.36 (standard deviation 18.22). The average stay in ICU was 5.04 (standard deviation 8.09). 54.2% of patients had a psychiatric history. As other background highlights, 19.4% were addicted to illegal drugs and 25% were hipertensive. Most patients took more than one toxic 83.3% and intoxication was voluntary in 84.7% versus accidental in 12.5% of cases. The toxic was known in 68%. The most used benzodiazepines in 26.4% of the total. The main cause of admission to the ICU was due to neurological deterioration in 49 of the cases registered and mechanical ventilation was necessary in 44 patients. The maximum time in mechanical ventilation was 34 days. The infection occurred in 24.3%, with the majority being respiratory infection. The 4.7% died in ICU. The hospital stay presented an average of 9.3 days.
CONCLUSION. The profile of patient admitted to the ICU due to acute intoxication is a woman of middle age and psychiatric history, with voluntary intoxication of several toxic substances and requiring

mechanical ventilation for a low level of consciousness for an average of 3 days. The survival is very high it would be necesary to analyze the possible relapses of these patients

000376

Acute drug intoxication in adult patients admitted to ICU: Analysis of the complications and prognostic value

MC. Martínez González[1], MP. Benitez Moreno[1], S. Jimenez Jimenez[1], A. Barroso González[2]
[1]INTENSIVE CARE, HOSPITAL CARLOS HAYA, MALAGA, Spain; [2]Anesthesia, HOSPITAL CARLOS HAYA, MALAGA, Spain
Correspondence: M.C. Martínez González
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000376

INTRODUCTION. Only some of the cases of exposure to toxic substances entails a serious poisoning that requires admission to the ICU. The initial instability in need of supportive treatment, alteration of the internal environment, or the appearance of sequelae differs widely depending on the degree, etiology and characteristics of the intoxication.
OBJECTIVES. To analyze the possible complications of the poisoning admitted in the ICU, as well as make a prognostic assessment of cases through the use of some analytical markers such as pH, lactate levels and the clearance of this one (obtained by the difference between the level of the first and the second day)
METHODS. We performed a retrospective observational study of all patients admitted for acute intoxication that required admission to the intensive care unit of the Regional Hospital of Malaga between January 2012 and August 2016. The inclusion criteria were age above14 years admitted to the ICU due to poisoning of any kind. We used the t-test or chi 2 for the univariate analysis according to need with an alpha error of 5%.
RESULTS. We recorded 70 patients, in which a 68% the poison was known, being 83.3% of the total caused by multiple toxics. The 21.7% of the patients underwent early gastric lavage or activated charcoal was administered, not finding significant differences with the group that did not receive treatment when compared to alterations in the internal environment (pH, lactate in the blood). The mortality of patients admitted for poisoning was 4.7%. There was a tendency, although not statistically significant between patients with worse pH and less of lactate clearance in the first 6 hours with mortality (p=0.09). No significant relationship between the patients who have neurological sequelae at discharge with those blood levels studied.
A 7.1% of the patients required dialysis during the stay in the ICU. There is a association of this fact with the finding of an average value of lactate in the early hours (p=0.038).
CONCLUSION. The mortality of the intoxicated patient is not negligible in our environment. The profile is of a middle-aged male patient, with
voluntary intoxication with several medications that requires VMI or dialysis in a variable percentage. The highest levels of lactate to income or in the early hours were associated with greater need of CRRT. Perhaps the concordance of these values with other complications can be demonstrated continuing the study and increasing the sample.

Low Meropenem Concentration in Brain-Dead Organ Donors: A Single-Center Pharmacokinetic Study and Simulation

JM. Lee
[1]Acute care surgery, Korea University Anam Hospital, Seoul, Republic of Korea
Correspondence: J.M. Lee
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000432

INTRODUCTION. Meropenem is an ultrabroad-spectrum antibiotic of carbapenem family. In brain-dead organ donors, administration of standard meropenem dosages does not reach therapeutic levels.
OBJECTIVES. Our objectives were to determine the plasma concentration of meropenem after administration of standard meropenem dose and to estimate an improved dosage regimen for these patients.
METHODS. One gram of meropenem was administered as 1-h infusion every 8 h for 1–3 days, and blood samples were collected. The plasma concentration of meropenem was measured and subjected to pharmacokinetic analysis. Simcyp simulation was performed to predict the optimum plasma levels and dosage based on the patients' individual pharmacokinetic parameters.
RESULTS. The maximum plasma concentration of meropenem was 3.29 μg/ml, which was lower than four times the minimum inhibitory concentration of 8 μg/ml. Although mean creatinine clearance of patients was moderately low (67.5 ml/min), apparent volume of distribution at steady state (*Vss*) and time-averaged total body clearance (CL) of meropenem were markedly elevated (4.97 l/kg and 2.06 l/h/kg, respectively) owing to massive fluid loading to decrease the high sodium levels and to treat shock or dehydration. The simulation revealed that dose and infusion time of meropenem should be increased based on patients' *Vss* and CL and loading dose is recommended to reach rapidly the target concentration.
CONCLUSION. In conclusion, standard meropenem regimen is insufficient to achieve optimal drug levels in brain-dead patients and increase in dose and extended or continuous infusion with intravenous bolus administration of loading dose are recommended for these patients.

Point-of-care 24/7 "load & go" flow cytometry to assess the innate immune responses in trauma patients: the start of a new era

R. Spijkerman[1], L. Hesselink[1], F. Hietbrink[1], L. Koenderman[2], L. Leenen[1]
[1]Traumasurgery, University Medical Center Utrecht, Utrecht, Netherlands; [2]Laboratory of translational immunology, University Medical Center Utrecht, Utrecht, Netherlands
Correspondence: R. Spijkerman
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000458

INTRODUCTION. Trauma patients are at risk for severe infections after trauma. The risk of developing these infections is associated with the severity of tissue damage and the amplitude of the following immune response. Neutrophils act as important effector cells in the immune response to trauma. Previous studies showed that shifts in neutrophil phenotypes directly after trauma are a promising predictor for inflammatory complications. Unfortunately, technical and logistical difficulties preclude application of such a test in the clinical setting. However, recently a fully automated point-of-care 24/7 "load & go" flow cytometry system became available, that can possibly overcome these challenges.
OBJECTIVES. The aim of this study was to assess the feasibility of implementing a point-of-care 24/7 "load & go" flow cytometry test in the shock room.
METHODS. A prospective mono-center cohort study was performed in our level one trauma center from November 2018 until February 2019. All trauma patients >18y initially presented at the shock room were included by the trauma team. An extra tube of blood was obtained during standard diagnostic workup and was placed in the 24/7 available "load & go" flowcytometer, AQUIOS CL©, co-located in the shock room by the trauma team. The markers CD35, CD16, CD62L, CD11b, active CD11b, CD10, CD66b and CD11c were immediately measured with and without the bacterial stimulus fMLF. All patient characteristics and follow-up data were collected from the electronic medical record.
RESULTS. A total of 235 patients were presented in the shock room during the inclusion period, of whom 166 patients were eligible for inclusion. Only in 3 patients the trauma team failed to start the analysis. This resulted in a total of 163 successfully placed tubes in the machine. Technical difficulties resulted in the exclusion of 4 samples, resulting in a total of 159 successfully analyzed patients. A total of 38 patients were marked as multi trauma (ISS ≥16) patients. Patients without any significant tissue damage had one clear

population of mature (CD16high/CD62Lhigh) neutrophils. Multi trauma patients with significant tissue damage always developed two new neutrophil subsets, CD16dim/CD62Lhigh and CD16high/CD62Ldim neutrophils. The amount of CD16dim neutrophils (5-50%) was related to the extent of tissue damage after trauma. All trauma patients that are admitted to the ICU showed CD16dim cells, however the amount of CD16dim cell differed between patients. Moreover some patients showed about 50% progenitor cells and all of them died <48h after admission.
CONCLUSION. Implementation of routine neutrophil analysis by point-of-care 24/7 "load & go" flow cytometry in the shock room is applicable. The percentage of CD16dim neutrophils is associated with the amount of tissue damage that can result in immune dysregulation and immune related complications after trauma. This quick analysis of CD16dim neutrophils as read out for tissue damage might proof a valuable tool to predict immune related complications in the ICU. A large prognostic study should be deployed.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000522

Correspondence: L. Hesselink
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000522

INTRODUCTION. More and more severely injured patients survive the critical first phase after trauma. A substantial portion of these patients require long-term critical care support and suffer from recurrent infections. This clinical condition fits in a syndrome also referred to as "Persistent inflammation, immunosuppression and catabolism syndrome" (PICS).
OBJECTIVES. The aim of this study was to investigate the incidence of PICS and clinical outcomes of these trauma patients with PICS in a level one trauma center.
METHODS. All trauma patients ≥ 16 years who were admitted to the intensive care unit (ICU) for ≥ 14 days between 2007 and 2017, were included. Patients with isolated neurological injuries were excluded. PICS patients were identified by ICU stay ≥ 14 days, ≥ 3 infectious complications and increased catabolism. Infectious complications included infections during hospitalization and readmissions due to an infection. Increased catabolism was defined as weight loss >10%, a body mass index <18 or persistent albumin levels <30g/L. Long term clinical outcomes of PICS patients were analyzed.
RESULTS. Of the 3859 polytrauma patients, only 194 patients had an ICU stay ≥ 14 days. After exclusion of patients with isolated neurological injuries, 78 patients were included. Of these patients, 18 developed PICS. PICS patients sustained 5 infectious complications on average (compared to 1 in the non-PICS group, p<0.001) and 72.2% of the PICS patients developed sepsis. There were no significant differences in Injury Severity Score and in-hospital mortality between PICS patients and the other patients with an ICU stay ≥ 14 days. However, these PICS patients had a longer hospital stay (mean of 90 days versus 50 days, p<0.001) and sustained more surgical procedures (mean of 13 versus 4 per patient, p<0.001). Infectious readmissions occurred until 5 years after the initial trauma.
CONCLUSION. Patients who develop PICS experience long-term inflammatory complications that lead to frequent readmissions and surgical procedures. Therefore, this clinical condition forms a burden on patients and a substantial financial burden on society, despite its low incidence.

INTRODUCTION. Patients often develop life-threatening infections after severe trauma. Neutrophils are the main immune cells to combat these infections by phagocytosis and killing of pathogens. However, severe injuries can induce malfunction of neutrophil killing. Analysis of this dysfunction is laborious and can therefore not be applied in routine diagnostics. Neutrophil phagosomal acidification, however, one of the last steps in the killing process, can nowadays be measured within an hour. Hence, we developed a quick and automated method to assess phagosomal acidification.
OBJECTIVES. The aim of this study was to investigate the relation between neutrophil phagosomal acidification and infectious complications in critically ill trauma patients.
METHODS. Multitrauma patients aged 18-80 years with an expected stay in the intensive care unit of ≥ 2 days, were prospectively included. Blood samples were obtained <12 hours after trauma, after 3 days, 6 days, 10 days and 15 days. Phagosomal acidification was analyzed using the fully automated "Load & Go" AQUIOS CL© flow cytometer after incubation of whole blood with double labeled (promofluor[PF]/pH insensitive and pHrodo/pH sensitive) Staphylococcus Aureus bioparticles for 60 minutes. Data are presented as mean ratio pHrodo/PF after 60 minutes ± standard error (SE).
RESULTS. Ten patients were included. Of these patients, 5 developed an infection between day 6 and 10 after trauma. Neutrophil phagosomal acidification remained stable and within reference values (0.83 – 1.05) in patients who did not develop an infection. In patients with infectious complications however, phagosomal acidificiation was slightly elevated on day 0 and day 3 (1.10±0.11 and 1.16±0.12 respectively), after which phagosomal acification decreased to below reference values (day 10: 0.78±0.11 and day 14: 0.74±0.07).
CONCLUSION. Flow cytometry analysis of neutrophil phagosomal acidification is a fast and clinical applicable method to assess neutrophil function. This method can be used to detect changes in neutrophil function in critically ill trauma patients and could therefore potentially be a useful method to identify patients at risk for infectious complications.

INTRODUCTION. Implementing the biological knowledge on the pathophysiology of ARDS and on different coagulative and inflammatory pathways activated by ECMO may improve patient's survival.
OBJECTIVES. Explore miRNAs expression changes in ARDS patients during ECMO treatment, as predictive markers of survival and monitoring of the disease.
METHODS. 754 human miRNAs were screened in whole blood before cannulation and on day 7 and 14 of ECMO support in ARDS patients weaned from ECMO. The miRNAs were analyzed by PCR using TaqMan™ Array Human MicroRNA A+B Cards Set v3.0 (Applied Biosystems).
RESULTS. From September 2018 to March 2019, 9 patients were supported with VV-ECMO for ARDS and n=7 survived (77.8%): age 53 (44-57) years, male gender n=6 (86%), BMI 26.5 (24.7-27.8), SAPS II at admission 37 (34.5-43.5), PaO2/FiO2 preECMO 60.5 (56.3-64.8), Preserve score 3.5 (2.3-5), Respscore 3 (-2.5-4.7), duration of ECMO support 19 days (9-31).
After quality control screening (amplification score > 1.1, Cq confidence > 0.8, high expression (Ct < 33), and detectable expression in more than half of the samples), 318 miRNAs were selected. Volcano plot analysis ($p < 0,05$ and fold change > 2) identified 12 miRNAs deregulated on day 7 and 27 miRNAs on day 14. In particular, we identified 6 upregulated miRNAs (figure 1A) and 6 downregulated miRNAs (figure 1B) on day 7, whereas 27 upregulated miRNAs on day 14
(figure 1C). Hierarchical clustering analysis showed systematic variations in the miRNAs expression among the different groups.
To correlate deregulated miRNAs and ARDS, we considered, through DIANA-miRPath v3.0, representative pathways for ARDS in which deregulated miRNAs are involved, reducing to 7 the miRNA deregulated on day 7, and to 20 the miRNA on day 14. The clustering of this new list of miRNAs leads to a complete cluster separation after 7 days of treatment, and an almost complete separation after 14 days of treatment.
These miRNAs are correlated to the pathways tissue remodeling cellular stress and apoptosis, regulation of immune system and regulation of coagulation process.
CONCLUSION. Up- and down-regulated miRNAs, tend to cluster in ARDS and ECMO support. MiRNAs from the whole blood are promising biomolecular markers to monitor ARDS evolution and the impact of ECMO on inflammation/coagulation system.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000388

INTRODUCTION. Prone positioning in severe ARDS patients improves oxygenation, reduces ventilator-induced lung injury and is associated with mortality reduction[1]. A strong physiologic rationale supports prone positioning (PP) in ARDS patients receiving ECMO therapy. However, the fear of complications historically limited its use during ECMO. To date, despite an increase in utilization of this procedure in ECMO patients[1], only few monocentric retrospective studies have been published on this topic.
OBJECTIVES. We conducted a multicentric retrospective study to evaluate safety, efficacy of PP during ECMO support. Secondly, we aim to compare outcomes between patients who underwent PP during ECMO (PP-ECMO group) with a matched population of patients treated with extracorporeal support (supine-ECMO group).
METHODS. A multicenter, retrospective trial including patients admitted to 6 ECMO referral centers between 2014 and 2018 and treated with veno-venous ECMO for respiratory failure: patients in the PP-ECMO group are enrolled in 4 ECMO centers where PP is a standard procedure during extracorporeal support, whereas patients in the supine-ECMO group are enrolled in 2 ECMO centers where PP is not performed during ECMO. In the PP-ECMO group, respiratory and hemodynamic parameters were recorded at four different steps: 1 - Supine; 2 - Start PP; 3 - End PP; 4 - Return to supine position We plan to include about 130 patients in the PP-ECMO group and 100 patients in the supine-ECMO group. Outcomes (survival, icu LOS, duration of ECMO support) will be compared between groups after individual and propensity-score matching.
RESULTS. We report preliminary data from 2 of 6 centers. During the study period 37 patient were included in the PP-ECMO group and 69 patients in the supine-ECMO group. In the PP-ECMO group the number of PP cycles was 3 [2-4] per patient and the duration was 12 [8-17] hours per cycle.
No major complication related to the procedure (extubation, cannula displacement, uncontrolled bleeding) was recorded.
Prone positioning was associated with an improvement of oxygenation and respiratory mechanics (see Figure 1 below). Lung Injury Score, SOFA and SAPS II did not differ between PP-ECMO and supine-ECMO group. ICU mortality did not differ (35% and 41% respectively, p=0.58).
CONCLUSION. Prone positioning during ECMO was safe and effective. The impact of this procedure on outcome during ECMO has still to be assessed.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000391

INTRODUCTION. Diaphragmatic atrophy starts within 12-18 hours after initiation of mechanical ventilation[1] and reaches a peak by 69-72 hours[2]. Both the duration and mode of ventilation are significant factors in determining the magnitude of atrophy[3, 4] Assist Control Mechanical Ventilation (ACMV) and Synchronized Intermittent Mandatory Ventilation with Pressure Support (SIMV+PS) are commonly used in ICUs. In ACMV the ventilator delivers the set tidal volume in both mandatory and spontaneous breaths. In SIMV+PS the inspiratory pressure support is tailored to the patient's effort and the mechanical properties of the lungs.
OBJECTIVES. We compared the decrease in diaphragmatic thickness (DT) measured ultrasonically between patients on ACMV and SIMV+PS.
METHODS. Ethical clearance and informed consent from the next of kin were obtained. 42 patients were randomly allocated to two equal groups (Group A: ACMV, Group B: SIMV+PS) within 6 hours of ICU admission. Tidal volume was set to 6-7 ml/kg. PS level was adjusted to deliver ~80% of the set tidal volume. DT was measured using a straight probe at the zone of transition on the mid-axillary line at the liver and spleen windows on the right and left sides (Sonosite Fuzifilm M-Turbo) within 6 hrs of initiation of mechanical ventilation and after 72 hours. Three repeat measurements were done separately for each hemidiaphragm and averaged. The quadriceps muscle thickness was also measured at each time point. Enteral feeding (1500-1600 Kcal/day) was started within 24 hours of ICU admission and serum procalcitonin was measured at 72 hours in all patients.
RESULTS. The decrease in DT was significantly greater in ACMV compared to SIMV+PS (7.2 vs 5.1 mm; Difference between groups: mean 1.9 mm, 95% CI: 0.9-3.8 mm, p=0.002, Welch's T-test). Quadriceps thickness and serum procalcitonin did not significantly change after 72 hours in either group. (Figure 1)
CONCLUSION. Using SIMV+PS reduces the magnitude of diaphragmatic atrophy compared to ACMV in critically ill patients on mchanical ventilation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000412

INTRODUCTION. Microaspiration of gastric and oropharyngeal contaminated secretions occurs frequently in intubated critically-ill patients, and plays a major role in the pathogenesis of ventilator-associated pneumonia (VAP). At steady state, patients with chronic obstructive pulmonary disease (COPD) have an increased risk of microaspiration (due to gastro-esophageal reflux disease, pharyngo-laryngeal dysfunction…), this risk may even be more important under mechanical ventilation.
OBJECTIVES. The purpose of this study is to determine if COPD is a risk factor for global abundant microaspiration (GAM) and its complications (ventilator-associated tracheobronchitis (VAT), VAP, death) in intubated critically-ill patients.
METHODS. We gathered data from three prospective randomized trials (1–3) focused on enteral nutrition or microaspiration in intubated patients. In all included patients, pepsin and salivary amylase were prospectively measured in all tracheal aspirates for 48h. Data on COPD were retrospectively collected. GAM was defined as the presence at significant level of pepsin (>200 ng/ml) and/or salivary amylase (>1685UI/L) in at least 30 % of the tracheal aspirates during the first 48 hours after intubation.
RESULTS. 540 patients were included among which 121 had COPD (70 with spirometric-proven COPD). GAM was present in 102 COPD patients and in 349 non-COPD patients (84.3% vs 83.3%, p=0,79). Abundant gastric microaspiration was found in 59 COPD patients and in 194 non-COPD patients (48.7% vs 46.3%, p=0.63). Abundant oropharyngeal microaspiration was found in 86 COPD patients and

in 304 non-COPD patients (71% vs 75.5%, p=0.83). Neither spirometric-proven COPD nor COPD severity were found as risk factors for GAM. There was no statistical difference between COPD and no-COPD groups for the rates of VAT (2.4% vs 2.1%, p=0.82), VAP (18% vs 22%, p=0.34), or ICU mortality (27% vs 27%, p=0.97). Similar outcomes were found in no-COPD and spirometric-proven COPD groups.

CONCLUSION. COPD is not associated with increased risk for GAM or VAP.

High-flow nasal cannula versus non-invasive ventilation on re-intubaion in patients with established post-extubation respiratory failure

M. Park[1], J. Kim[1], K. M.[1], HL. Lee[2], SM. Kwak[2], JS. Ryu[2], HS. Nam[2]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000425

INTRODUCTION. Post-extubation respiratory failure (PERF) is a common complication in electively extubated patients, it is unclear whether high-flow nasal cannula (HFNC) and non-invasive ventilation (NIV) decrease rates of re-intubation in patients with established post-extubation respiratory failure. As high-flow oxygen therapy delivered through nasal cannula could improve oxygenation, secretions management and reduce work of breathing, we assessed whether HFNC could reduce the rate of re-intubation in patients with established PERF compared with NIV by helmet or oronasal mask.

METHODS. Between March 1, 2017 and December 31, 2018, eighty-nine patients had established respiratory failure after elective extubation and were applied HFNC or NIV. The data of these 89 patients were collected prospectively in a medical intensive care unit (ICU), academic, tertiary care hospital and retrospectively analyzed.

RESULTS. The data of 89 patients were collected. HFNC was administered to 46 and NIV by helmet or oronasal mask was administered to 43. There were no differences between baseline characteristics in the two groups. A comparison of the HFNC and NIV groups showed no differences between rates of re-intubation, ICU or hospital mortalities in patients with established post-extubation respiratory failure. pH, PaO2/FiO2 in the NIV group were significantly lower and PaCO2 was higher than in the HFNC group before HFNC or NIV application.

CONCLUSION. In previous study, among high-risk patients who have undergone extubation, there was no difference in preventing re-intubation between HFNC and NIV. Similar to previous study, in patients with established pos-extubation respiratory failure, the effectiveness of HFNC was not significantly inferior to NIV in our study. A prospective study that takes into account patient selection and HFNC or ventilator settings is required to determine the clinical efficacy of HFNC or NIV.

Correspondence: R. Persichini

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000431

INTRODUCTION. Acute severe asthma (ASA) is a common cause of admission in intensive care units (ICU). In some rare cases, it can lead to invasive mechanical ventilation. There is currently few recent data in the literature about this specific subtype of patient.

OBJECTIVES. The aim of this retrospective and bicentric study was to investigate the factors associated with mortality of ASA requiring invasive mechanical ventilation.

METHODS. All ASA requiring invasive mechanical ventilation between 2008 and 2017 were analyzed.

Patients' characteristics and laboratory tests were tested in bivariate analysis for association with 28-day mortality. Factors achieving $p < 0.20$ were introduced into a multivariable model.

RESULTS. The main strength of this study is its completeness: it concerns the Reunion Island, a French overseas territory with only 2 ICU, both having participated in this study. Therefore, all ASA requiring invasive mechanical ventilation during the study period were analyzed without exception.

Eighty-one patients were evaluated in this study, among whom 52 (64%) were women. All patients were known to have asthma. The median age was 49 years old [interquartile range, 42-60] with a median Simplified Acute Physiology Score II (SAPS II) of 40 [30–54]. About a quarter of the patients (n=20) had experienced a previous ASA that required invasive mechanical ventilation. No decompensation risk factor was found in almost half of the cases (49% - n=40). The other decompensation risk factors found were cessation of asthma treatment (12% - n=10), allergenic exposure (10% - n=8), extra-respiratory sepsis (11% - n=9), bacterial or viral pneumonia (15% - n=12) and acute bronchitis (14% - n=11). Seven patients underwent salvage therapy, sometime in combinaison: ECMO for 6 patients, hallogenated gaz for 1 patient and anti-IL5 antibody (mepolizumab) for 2 patients.

The mortality rate was 14% (n = 11). In bivariate analysis, the occurrence of a cardiac arrest prior to admission, a cardiac arrest as the reason for intubation, the absence of a decompensating risk factor found and an intubation in prehospital setting were significantly associated with a poorer outcome. In non-survivor, SAPS II, creatinine level and lactatemia at admission were significantly higher whereas pH and HCO3 at admission were significantly lower. Multivariable analyses retained a positive fluid balance at day 1 (OR 6 [1-11] for 1L, $p = 0.02$) and the occurrence of a cardiac arrest prior to admission (OR 36.6 [3.6-374.9], $p < 0.01$) as being independently associated with 28-day mortality.

CONCLUSION. Nowadays, ASA requiring invasive mechanical ventilation is still responsible of high 28-day mortality. The prognostis is mainly related to multiorgan failure with the occurrence of a

cardiac arrest prior to admission as the worst risk factor. A positive fluid balance at day 1 is also associated with poor outcome, challenging the usual dogma that recommends a liberal hydratation in such patients.

INTRODUCTION. Predisposing conditions and risk modifiers have been recently used to identify patients at risk for acute respiratory distress syndrome (ARDS) instead of causes and risk factors. Risk modifiers of ARDS caused by sepsis due to pneumonia which is one of the most common predisposing conditions are well known. However, little is known about risk modifiers of ARDS especially among patients with non-pulmonary sepsis.
OBJECTIVES. Our aim was to evaluate risk modifiers associated with ARDS among patients with non-pulmonary sepsis.
METHODS. This is a secondary analysis of the sepsis cohort in the Focused Outcomes Research in Emergency Care in Acute Respiratory Distress Syndrome, Sepsis and Trauma (FORECAST) study. [1] This was a multicenter, prospective cohort study conducted in 59 intensive care units (ICUs) in Japan from January 2016 to March 2017.We included adult patients with severe sepsis and septic shock caused by non-pulmonary infection, who admitted to ICUs. The primary outcome was having ARDS defined as meeting the Berlin definition [2] at the first or the fourth day of ARDS screening. The secondary outcome was developing ARDS defined as both of (1) absence of ARDS at the first day of ARDS screening and (2) presence of ARDS at the fourth day of ARDS screening. The explanatory variables were prespecified a priori based on clinical experience and prior studies, such as age, gender, admission source, body mass index, smoking status, congestive heart failure, chronic obstructive pulmonary disease, diabetes mellitus, steroids, statin, site of infection, septic shock, and APACHE II score. After carefully checking collinearity, to identify risk modifiers associated with having ARDS and developing ARDS, we developed multivariate logistic regression models.
RESULTS. 594 patients with non-pulmonary sepsis met the inclusion and exclusion criteria of the study. 85 patients had ARDS at the first or the fourth day of ARDS screening, and 16 patients developed ARDS at the fourth day of ARDS screening.
There was no significant difference between patients with and without ARDS regarding baseline characteristics such as age, body mass index, coexisting conditions, smoking, and sites of infection. 80% of patients with ARDS and 66% of patients without ARDS had septic shock (P = 0.01). APACHE II scores were higher in patients with ARDS than those without ARDS (26.0 vs 21.0, P < 0.01). In the multivariate logistic regression model, ICU admission from other wards compared with emergency departments (odds ratio (OR) [95% confidence interval (CI)], 0.53 [0.294–0.947]), smoking status (current smoking compared with never having smoked: OR [95%CI], 0.18 [0.056–0.587]), soft tissue infection compared with abdominal infection (OR [95% CI], 2.39 [1.040–5.400]), and higher APACHE II score (OR [95% CI], 1.08 [1.050–1.120]) were independently associated with having ARDS. No risk modifiers were independently associated with developing ARDS in our cohort.
CONCLUSION. Soft tissue infection, ICU admission from hospital wards, and higher APACHE II score may be risk modifiers of ARDS in patients with non-pulmonary sepsis.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000443

INTRODUCTION. Tracheomalacia (TM) is defined as diffuse or segmental weakness of the trachea. Acquired TM, is more common than the congenital form and more frequent in male gender. The most important diagnostic method is observation of airway collapse via bronchoscopy.
OBJECTIVES. Aim of this study is to identify development frequency of and factors affecting TM in critically ill patients with prolonged intubation.
METHODS. This study was performed in Intensive Care Unit. Intubation time longer than 7 day patients were included into the study. A chest disease specialist examined the bronchoscopy video records and the study included patients who had a bronchoscopy video record on the first day of intubation and at least one bronchoscopy video record in the period between seventh day of intubation and extubation.
RESULTS. The study included 40 patients. Mean age of the patients was 59.9±13.2 years. Mean body mass index (BMI) of the patients was 26.4±4.9 kg/m2. Patients' median APACHE II and SOFA scores were 18 (range: 9-35) and 6 (range: 3-13), respectively. TM was identified in 4 patients (%10) among all the patients included in the study. When we checked risk factors for TM development, two patients had history of COPD. One patient had history of intubation. No risk factor was identified in the other patient. During follow-up weaning failure, requirement of re-intubation and fatal progress were identified in patients with TM. Gender distribution was equal in patients with TM.
CONCLUSION. We identified weaning failures, re-intubation requirements and fatal progress in all patients with tracheomalacia. TM is an important condition that increases morbidity and mortality in the

settings of intensive care units and suspected patients in terms of TM should undergo bronchoscopy.

Use of Extracorporeal Membrane Oxygenation in Patients with Acute High-risk Pulmonary Embolism: A Case Series with Literature Review

O. You Na[1], O. Dong Kyu[1], K. Younsuck[1], L. Chae-Man[1], H. Jin-Won[1]; L. Jae Seung[1], J. Sung-Ho[2], K. Pil-Je[2], H. Sang-Bum[1]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000449

INTRODUCTION. Acute pulmonary embolism (PE) is the most serious clinical presentation of venous thromboembolism and causes obstructive shock and hemodynamic instability [1-3]. It is stratified on the basis of the early PE-related mortality risk, and the high-risk group is defined as patients who have shock or systemic hypotension [2,3]. Unfortunately, despite the expedited lifesaving treatments such as systemic thrombolysis and surgical embolectomy, acute high-risk PE is associated with significant morbidity and mortality [2-5].
OBJECTIVES. Although extracorporeal membrane oxygenation (ECMO) has been used for the treatment of acute high-risk pulmonary embolism (PE), reports focusing on this approach are limited. We describe our experience with ECMO for acute high-risk PE.
METHODS. We retrospectively reviewed the medical records of patients treated for acute high-risk PE with ECMO between January 2014 and December 2018.
RESULTS. Among the 16 patients included, 6 (37.5%) were men. The median age was 51 years (interquartile range [IQR], 38–71 years). Cardiac arrest occurred in 12 patients (75.0%), including 2 with out-of-hospital arrest. All the patients underwent venoarterial ECMO for a median duration of 1.5 days (IQR, 0.0–4.5 days). Seven (43.8%) and 9 patients (56.3%) underwent systemic thrombolysis and surgical embolectomy, respectively, including 3 (18.8%) who received both treatments. The overall 30-day mortality rate was 43.8% (95% confidence interval, 23.1%–66.8%) and showed no significant difference among the treatment groups (thrombolysis vs. non-thrombolysis: 42.9% [n=3/7] vs. 44.4% [n=4/9], p=0.870 and embolectomy vs. non-embolectomy: 44.4% [n=4/9] vs. 42.9% [n=3/7], p=0.870).
CONCLUSION. Despite treatment efforts, the patients with acute high-risk PE had substantial morbidity and mortality. ECMO may be considered in these patients in conjunction with either systemic thrombolysis or surgical embolectomy.

The use of ward based high flow nasal oxygenation in patients with single organ respiratory failure reduces critical care admission

E. Hubbard[1], J. walton[2]
[1]Outreach nursing service, Newcastle Freeman Hospital, High Heaton, UK; [2]Intensive care medicine, Freeman Hospital, Newcastle upon Tyne, UK
Correspondence: J. walton
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000456

INTRODUCTION. 25% of critical care admissions in our hospital are for respiratory failure. High flow nasal oxygenation (HFNO) in respiratory failure has been shown to be safe and effective (1) and has been used at the Freeman Hospital since 2009. By introducing a formalized outreach nursing service led, ward based HFNO service for patients with single organ respiratory failure we aimed to reduce unnecessary critical care admissions without compromising patient safety.
OBJECTIVES. 2 prospective audits were conducted assessing the outcome of patients requiring critical care ventilatory support for single organ respiratory failure but managed with HFNO in a ward setting under outreach nursing team care.
METHODS. In a pilot audit 53 patients referred by the ward team to critical care for single organ respiratory failure via an early warning scoring system (NEWS) were reviewed by the critical care outreach team over a 12 month period.
If assessed as suitable for ward management, the patients were commenced on HFNO (Airvo 2 Fisher & Paykel) on the ward. The prescription was determined clinically to maintain patient comfort with targeted SpO2 and arterial blood gas monitoring as necessary. A medical decision was taken daily to either: escalate to critical care, continue HFNO or move to palliative care.
Triggering of the NEWS score or an admitting team request led to an urgent medical critical care review in accordance with hospital policy. Patient demographics and ultimate outcomes were recorded on every patient.
The second audit was of 200 patients using the same referral and assessment system over another 12 month period in 2016-17.
RESULTS. In the pilot audit of 53 patients, 43% remained on the ward and survived to discontinuation of HFNO. 42% were admitted to critical care and 15% received palliative care. In the follow up audit of 200 patients, 57.5% remained on the ward, 23.5% were admitted to critical care with 19% receiving palliative care.
No difference was seen in mortality rates between those managed on the ward and those admitted directly to critical care.
CONCLUSION. In our 2 prospective audits, ward based HFNO for respiratory failure significantly reduced critical care admissions without affecting patient outcomes, saving 582 bed days and potentially a net cost saving of £459,174(2).

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000462

INTRODUCTION. Percutaneous dilatational tracheostomy (PDT) is commonly performed in intensive care unit (ICU). Although it is safe and easily performed at bedside, it always needs endotracheal guidance such as bronchoscopy or light wand.
OBJECTIVES. We sought to the feasibility of PDT without endotracheal guidance.
METHODS. In the presenting ICU, PDT has been routinely performed without endotracheal guidance by single medical intensivist using Griggs technique PDT kit (Portex percutaneous tracheostomy kit, Smith Medical, England). We retrospectively reviewed the outcome of PDT without endotracheal guidance.
RESULTS. From January 2018 to December 2018, 78 cases of PDT were performed in medical ICU and coronary care unit. Mean age was 71.9 ± 11.5 years and 29 patients (37.2%) were female. Most patients were admitted to pulmonology (46 patients, 59.0%) and followed by cardiology (7 patients, 9.0%). PDT was successful in 76 patients (97.4%). Two patients were converted to surgical tracheostomy because of failure of guidewire passage. One patient were re-intubated for the surgical tracheostomy and in the other patient, supraglottic airway device (i-gel, Intersurgical, Wokingham, UK) were inserted during tracheostomy. No significant procedure related complication was observed in both patients. Another patient was re-intubated due to guidewire passage failure, however PDT was successfully performed.
Procedure related complication was observed in 5 patients (6.4%) and all of them were observed with 24 hours after PDT and controlled with simple local compression. In-hospital mortality was 33.3% (26 of 78 patients) and mean time from PDT to death was 41.7 ± 43.2 days.
CONCLUSION. PDT without endotracheal guidance is safe and feasible.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000464

INTRODUCTION. The invasive mechanical ventilation weaning protocol aims at the progressive removal of ventilatory support, after presenting acute respiratory insufficiency or not, and having overcome it totally or partially, this process is relayed after a standardized evaluation with international guidelines. Several authors have explored risk factors and prediction rates that are associated with failure in the release of ventilation.
OBJECTIVES. Evaluate if there is an association between the use of release failure rates in our population and the initial evaluation with Tobin's mandatory criteria.
METHODS. A retrospective study was conducted, which included 65 patients, in the intensive therapy unit of the "Hospital San Ángel Inn Universidad", in the period from May 2015 to July 2018, the included patients, were in mechanical ventilation for any cause with more than 24 hours of intubation, the included patients were over 18 years old; patients with incomplete records of the ventilation withdrawal protocol, diagnosis of failed extubation in the current hospitalization, pregnant or puerperal patients were excluded; criteria for elimination were voluntary discharge and signature of advance will. The patients were analyzed in two groups: success, 58 patients, or failure to withdraw, 7 patients. The data were analyzed by Student's t and sum ranges of Wilcoxón or Man-Whitney U as the case may be. A ROC curve was performed to describe the effect on the release of the different ventilation withdrawal rates.
RESULTS. There was no significant difference in the variables collected between the groups. Later in the analysis of ROC curves the variables Tobin 1, Tobin 2, p.01 and IWI did not show significant performance in the detection of failure in the extubation of this sample (p> 0.05 against Area under the Curve of 0.5), so that is not continued with subsequent corresponding analyzes.
CONCLUSION. In patients who undergo removal of invasive mechanical ventilation, using a protocol that evaluates the mandatory criteria cited by Tobin, it is not relevant to measure predictors of success as index of superficial respiration, at 1and 30 minutes, as well as the index of IWI.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000476

INTRODUCTION. While controlled mechanical ventilation (MV) still represents the standard of care in acute respiratory distress syndrome (ARDS), assisted MV has gained interest in recent years because of its recognized beneficial effects (e.g. more homogeneous ventilation, prevention of diaphragmatic atrophy, reduction in sedative requirements). Nevertheless, maintaining some degree of spontaneous ventilation also has a potential for harm (e.g. occult increase in transpulmonary pressure, Pendelluft phenomenon, loss of control of tidal volume). No clinical studies have compared spontaneous breathing to controlled MV during acute respiratory failure, and none has been conducted in the context of moderate to severe ARDS. Moreover, guidelines recommend limiting tidal volume (TV) to 4-8 ml/kg of predicted body weight (PBW), but the usefulness of TV limitation during *assisted* MV remains unproven.
OBJECTIVES. We aimed to evaluate the impact of spontaneous breathing on TV during the initial phase of moderate and severe ARDS, and to assess the association between high tidal volume (HTV) and outcome in spontaneously breathing patients.
METHODS. We conducted a retrospective analysis including all moderate to severe ARDS patients mechanically ventilated in pressure support mode for at least 72 hours between 2012 and 2018, within a 22-bed mixed ICU of a tertiary medical center. All data were retrieved from electronic medical recordings. Patients were divided into a HTV group and a low tidal volume (LTV) group based on the mean TV relative to PBW, patients with a mean TV > 8 ml/kg PBW being classified in the HTV group. LTV and HTV groups were compared in terms of demographics, comorbidities, MV and respiratory parameters, hemodynamics, adjuvant therapies and outcomes. In a subgroup analysis, we compared patients' characteristics and outcomes of the HTV group with the LTV group, stratified by ARDS severity.
RESULTS. Among 100 patients who fulfilled inclusion criteria, forty-six (46%) had a mean TV > 8 ml/kg PBW and were classified in the HTV group. The 90-day mortality rate was not significantly different between the LTV and the HTV group (44.4 vs 56.5%; p=0.25), despite higher severity in the HTV group. Median number of Ventilator-Free days at day 28 (9.5 days vs 11 days, p=0.89) and length of stay in the ICU (15.5 days vs 14 days, p=0.48) did not differ between LTV and HTV group. In the most severe patients (PaO2/FiO2 < 100, n=31), HTV was associated with a trend towards higher 90-day mortality (43 vs 73%, p=0.09), whereas in moderate ARDS patients (n=69), no difference between groups was shown, despite patients in the HTV group being significantly older.
CONCLUSION. In this retrospective analysis of patients spontaneously breathing during the first 72 hours of moderate-to-severe ARDS, TV > 8 ml/kg PBW was frequent and was not associated with adverse outcomes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000479

INTRODUCTION. The WHO defines drowning as " the process of experiencing respiratory impairment from submersion/immersion in liquid". It is a mayor public health problem that causes 7% of deaths from unintentional injury worldwide
OBJECTIVES. To know the epidemiologic and clinical characteristics (by organs), as well as therapeutic measures and evolution of drowning patients admitted to a medical ICU in a second-level hospital in a six-year period (from January 2013 to December 2018).
METHODS. Retrospective and descriptive study of drowning patients admitted to a medical ICU. The following parameters were analyzed: gender, mean age by group, location of drowning, causes of drowning, period of the year, source of admission, Simcock classification on hospital admission, alterations: respiratory, neurological, cardiac, renal and temperature, as well as therapeutic measures in terms of ventilatory support, inotropic support and rewarming. Time spent under mechanical ventilation and mortality were also analyzed. Statistical analysis: quantitative variables are expressed as mean and standard deviation (SD) and qualitative variables as percentages (%). The difference between qualitative variables are expressed using Chi-square test and quantitative using an ANOVA analysis.
RESULTS. 19 drowning patients admitted to our ICU were analyzed: 11 female (8 male), mean age by group: <30 years old: 1, 30-50 years old: 3, 51-70 years old: 8 (42%) and >70 years old: 7 (37%). Location of drowning: ocean 14 (73,5%), river 3 and swimming pool 2. Period of the year: between May - September: 12 (63%), between October - April: 7. Causes of drowning: unintentional l 8 (42%) , trauma 4 (21%), syncope 4 (21%), suicide attempt 2, seizures 1. Source of admission: paramedics 12 (63%), hospital A&E 4 , other hospital 3. Simcock classification: group II 1, group III 11 (58%), group IV (cardiac arrest) 7 (37%), shockable rhythm 5 (71%) non-shockable rhythm 2. Respiratory alterations: noncardiogenic pulmonary edema 12 (63%), single alveolar pulmonary infiltrate 4, barotrauma 1 and no alterations 2. Neurological alterations: category A (awake) 9 (47%), category B (blunted) 4 and category C (comatose) 6 (31,5%): C1 (decorticate) 1, C2 (decerebrate) 3 and C3 (flaccid) 2. Renal alterations: acute kidney injury (AKI) 2, rhabdomyolysis 1. Hypothernia: >32ºC 12 (67%) and between 32-28ºC 7 (33%), Ventilatory support: NIV 6 (31,5%): BiPAP 4 and CPAP 2, High Flow nasal cannula (HFNC) 1, low flow oxygen therapy (Venturi face mask) 2, intubation + mechanical ventilation 10 (52,6%), lung protective mechanical ventilaton (ARDS) 3; inotropic support 6 (31,5%) and rewarming 7 (37%) (4 active external and 3 active internal). In patients who required intubation (10), 8 (80%) were extubated, 5 within 72 hours (50%) and >72 hours 3 (20%). 2 patients (10,5%) died.
CONCLUSION. In our series, the drowning patient is a female between 51-70 years old, who suffered an unintentional drowning in the ocean, Simcock type III who required intubation and mechanical ventilation (52,6%), was extubated within 72 hours (50%) and required inotropic support (31,5%) and rewarming (37%) with a mortality rate of 10,5%.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000492

INTRODUCTION. In Asian countries, critical care delivery systems are underdeveloped compared to Western countries: there would be distinct characteristics regarding tracheostomy in patients with translaryngeal intubation
OBJECTIVES. Our study aimed to compare effect of early versus late or no tracheostomy on clinical outcomes in patients with prolonged acute mechanical ventilation (ventilator care ≥ 96 hrs).

METHODS. Data were obtained from 592 patients [median age 68 yrs (range, 17-93 yrs), 69.4% were male] at a medical intensive care unit (ICU) of a university-affiliated tertiary care hospital during 9 years. Early tracheostomy was defined as ≤ 10 days after translaryngeal intubation.
RESULTS. Of total patients, 271 (45.8%) patients underwent early tracheostomy. Early tracheostomy group showed significantly lower Acute Physiology and Chronic Health Evaluation II [median 18, (range 3-41) vs 22 (6-35), p<0.001] and Sequential Organ Failure Assessment [5 (1-18) vs 8 (2-17), p<0.001] scores, and Charlson's Comorbidity Index [2 (0-14) vs 4 (0-15), p<0.001)] as well as shorter ICU and hospital length of stay [15 (1-776) vs 22 (4-219) and 24 (6-745) vs 36 (6-374) days, (all p<0.001, respectively)] than late or no tracheostomy group. Also, they had lower healthcare-associated costs [19155.8 (2482.4–240960.5) vs 26677.9 (5711.4-206636.3) USD, p<0.001] and higher successful decannulation (41.0 vs 24.5%, p=0.004) during hospital stay. However, there were no significant differences between the both groups for in-hospital, 6-months, and 1-year mortality (38.4 vs 42.1%, 55.0 vs 55.5%, and 62 vs 62%, respectively).
CONCLUSION. The patients who underwent early tracheostomy were associated with lower severity-of-illness, comorbidities on ICU admission, lower total medical cost, and more success of decannulation. However, there was no significant difference in mortality.

Pleth variability index predicts fluid responsiveness in acute respiratory failure patients supported by nasal high-flow

M. García de Acilu, A. Pacheco, M. Santafé, F. Ramos, J. Ruíz-Rodríguez, R. Ferrer Roca, O. Roca
[1]Critical care department, Vall d´Hebron University Hospital, Vall d´Hebron Research Institute, Barcelona, Spain
Correspondence: M. García de Acilu
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000496

INTRODUCTION. The pleth variability index (PVi) has been shown to be a predictor of fluid responsiveness (FR) in mechanically ventilated (MV) patients(1). Patients treated with nasal high-flow (NHF) show similar haemodynamic changes to those observed in MV patients(2). However, the usefulness of PVi for predicting FR in NHF patients has not been evaluated.
OBJECTIVES. To analyze whether PVi can predict FR in acute respiratory failure (ARF) patients supported by NHF.
METHODS. Proof of concept study that included ARF patients ≥18 y treated with NHF (≥40lpm) showing signs of inadequate tissue perfusion. At baseline, they were all in Fowler position (head of the bed at 45º angle). Stroke volume (SV) was measured by transthoracic echocardiography and PVi was monitored using a pulse oximeter (Masimo Radical-7® Pulse CO-Oximeter®, Irvine, CA). Fluid-response was defined as an increase ≥10% in SV after passive leg raising (PLR). Responders then received a 250ml fluid challenge for 10 minutes. After PLR and fluid challenge, SV and PVi were reassessed. Results are expressed as mean (95% CI) or frequency (%).
RESULTS. Twenty patients were included, with a mean age of 63 years (56-59). They were treated with a mean flow of 48 (40-57) lpm and FIO2 of 0.6 (0.5-0.7). Mean SOFA at the moment of inclusion was 9 (7-10) and SAPS-II 48 (40-51), with a PaO2/FIO2 of 141 (112-171). Eleven (55%) patients required noradrenaline, with a mean lactate level of 3.7 (2.7-4.7) mmol/L. Twelve patients (60%) responded to fluid administration. Responders showed higher baseline values of PVi (24 [20-28]% vs 13 [8-18]%;p=0.001) and higher PVi variation (ΔPVi) after PLR (6.8 [5.0-8.5]% vs -1.7 [-4.8-1.4]%;p<0.001). Moreover, ΔPVi after PLR was similar to ΔPVi after fluid challenge (6.8 [5.0 – 8.5] vs 7.4 [5.3 – 9.4];p=0.237); both values were strongly correlated (r= 0.84;p<0.001). PVi and ΔPVi after PLR showed excellent diagnostic accuracy (AUROC 0.92 [0.77-1.00];p< 0.001 and AUROC 1.00 [1.00-1.00];p<0.001 respectively). The best cut-off points using the Youden index were baseline PVi ≥16 and ΔPVi after PLR ≥2 (Sensitivity, Specificity, PPV and NPV are presented in Table 1).
CONCLUSION. PVi may predict fluid responsiveness in ARF patients treated with NHF.

INTRODUCTION. Acute respiratory distress syndrome (ARDS) is an inflammatory syndrome of the lungs and associated with significant morbidity and mortality. Mechanical power is an estimation of the energy delivered to a patient during mechanical ventilation and is associated with both ventilator-induced lung injury and survival outcomes. Respiratory rate is one of the determinants of mechanical power; however, its influence on outcomes remains unclear.
OBJECTIVES.

1. Determine the association between respiratory rate and 28-day ventilator free days (VFDs), 28-day hospital survival and 3-year survival in patients with ARDS
2. Determine patient factors associated with an increased respiratory rate
3. Determine the optimal respiratory rate threshold for mortality

METHODS. A prospective standardized screening program for ARDS (4 intensive care units (ICUs) within Calgary Alberta from 2010 to 2012) was conducted. Demographics and outcomes of this cohort have previously been reported. An ancillary analysis of this database was performed. Outcomes included 28-day hospital survival, 3-year survival as well as 28-day VFDs. Adjusted logistic and linear regression were used to model the association between respiratory rate and these outcomes; models were adjusted for sex, age, height, weight, admission APACHE, pH, PF ratio, and PaCO2. Multivariable linear regression was also used to determine patient factors associated with increased respiratory rate. Youden's J statistic and area

under the receiver operating curve analysis was used to determine the optimal respiratory rate threshold for 28-day and 3-year mortality.
RESULTS. During the study period 7944 patients were screened and 633 patients (7.9%) met criteria for sustained ARDS. The median respiratory rate was higher in hospital non-survivors vs survivors (24, interquartile range [IQR] 20-28 vs 21, IQR 18-24 respectively, p< 0.001). Adjusted models showed that respiratory rate was associated with an increase in 28-day hospital mortality (odds ratio [OR]1.11, 95% confidence interval 1.06-1.17, p<0.001), 3-year mortality (OR 1.11, 95% CI 1.06-1.16, p<0.001), and reduced VFDs (mean difference -0.75, 95% CI -0.91 to -0.58, p<0.001). Patient factors associated with increased respiratory rate in a multivariable model included age, pneumonia or sepsis as ARDS etiology, admission pH, and initial mechanical ventilation on spontaneous mode. The respiratory rate threshold associated with an increase in 28-day hospital mortality and 3-year mortality was 22 for both.
CONCLUSION. Increased respiratory rate is associated with increase mortality and reduced 28-day VFDs. Further study will be required to determine if interventions targeted at reducing the respiratory rate can modify outcomes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001167

INTRODUCTION. Personalized positive end-expiratory pressure (PEEP) might attenuate lung injury and improve patient's outcome in acute respiratory distress syndrome (ARDS). However, how to set the optimal PEEP level remains controversial. Electrical impedance tomography (EIT), which monitors ventilation distribution, and esophageal pressure, which allows measure of transpulmonary pressure (PL), have been proposed as guide for personalized PEEP setting.
OBJECTIVES. To test if PEEP-EIT and PEEP-PL differs in terms of values,gas exchange and lung mechanics.
METHODS. After obtaining consent, an esophageal catheter (Nutrivent, SIDAM, Mirandola, Italy) and a 32-electrodes EIT monitor (Swisstom BB2, Swisstom, Landquart, Switzerland) were positioned in 20 ARDS patients . Each patient underwent, in random order, two PEEP titration trials to find the levels of PEEP associated with 1) positive end-expiratory PL based on a PL/FiO2 table (PEEP-PL) [1] and 2) the lowest PEEP providing silent spaces ≤15% (PEEP-EIT). FiO2 was set to obtain SpO2=88-95%, Vt was 6 ml/kg/PBW and RR to maintain normocapnia. After identifying the 2 PEEP levels, each was maintained for 20 minutes in a random order. Lung mechanics, gas exchange, hemodynamics and EIT data were recorded at the end of each step. Regional respiratory system compliance was calculated in 4 cranio-caudal regions of interest (ROI1=ventral;ROI4=dorsal). Wilcoxon signed-rank test was used to evaluate if the difference between variables during the two steps was significant.
RESULTS. Baseline P/F was 149 [108-210], RR 19 [16-24] bpm and Vt 380[358-440] ml. Median values of PEEP-EIT and PEEP-PL were 14 [8-17] cmH2O and 13 [11-14] cmH2O, with a median difference within patient of 1.5 [(-)7-5.8] cmH2O (p=0.95). No patient was assigned the same PEEP and correlation between the levels of PEEP was not significant (Rs=0.25; p=0.29). PEEP-EIT and PEEP-PL resulted in no statistically significant differences in gas exchange, but airway driving pressure (DP) was significantly higher and regional ventral lung compliance was lower at PEEP-EIT. On the other hand, PEEP-PL was associated with higher total and dependent hypoventilated regions (table 1).
CONCLUSION. Personalized PEEP levels assigned by EIT and PL were not correlated at the individual patient-level. PEEP-PL might be associated with lower risk of dynamic lung stress and overdistension while PEEP-EIT might be more protective from excessive lung inhomogeneity.

INTRODUCTION. Airway pressure release ventilation(APRV) is a type of inverse-ratio, pressure-controlled,
mode.In addition to being used in patients with acute respiratory distress syndrome(ARDS), lung protective effects have recently become prominent (1).The aim of this study is to investigate whether the use of early airway pressure release ventilation(APRV) mode as a lung protective strategy is superior to conventional methods in ARDS development.
METHODS. The study was planned as, randomized controlled study between 2016-2018 in an 18-bed general intensive care unit(ICU).Patients with invasive mechanical ventilation but who were not diagnosed with ARDS at baseline, had LIPS(Lung Injury Prediction Score) >7 and intensive care hospitalization for more than 24 hours were

included in the study.The patients were evaluated as APRV and P-SIMV groups.
RESULTS. 65 patients who met the eligibility criteria were included in the study.Thirty-three patients (50.8%) underwent P-SIMV mode and 32(49.2%) patients underwent APRV mode.P/F ratio values were higher in APRV group.This difference was statistically significant on day 3(p=0.032).The FiO2 value was lower in the APRV group.There was a statistically significant difference between the groups at day 7(p=0.011).Patients who needed sedation in the groups were statistically lower in the APRV group(p=0.048).The duration of mechanical ventilation was 9(3-65) days in the P-SIMV group and 7.5(2-29) days in the APRV group.No difference was found between the groups(p = 0.171).Duration of ICU stay was 8(2-11) days in the APRV group and 13(8-81) days in the P-SIMV group(p=0.019). (Table 1)
CONCLUSION. The goal of ventilation with APRV is to remain on the steep portion of the compliance curve between the lower and upper inflection points to prevent atelectrauma/barotraumas.Our study contributed to the results of a few preemptive studies in the literature.The same positive effects were also demonstrated in healthy lungs.Follow-up period, duration of ICU stay, sedation requirement and oxygenation parameters improved significantly.

Safety and Tolerability of Mechanical Insufflation-Exsufflation (MIE) and Hypertonic Saline with Hyaluronic Acid (HS-HA) for Respiratory Secretion Suctioning (RSS) in Intubated Patients

M. Sanchez Garcia, M. Alvarez, S. Domingo, A. Del Pino, F. Martínez, P. González, C. Cardenal, E. Velasco, MJ. Jimenez, A. Núñez
[1]Critical care, Hospital Clínico San Carlos, Madrid, Spain

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001178

INTRODUCTION. Conventional catheter RSS causes pain and injuries to the tracheobronchial mucosa, and other complications. MIE generates high expiratory air flow, simulating spontaneous cough, and is used extensively in debilitated non-intubated patients for airway clearance. HS-HA is nebulized to fluidify secretions and facilitate RSS.
OBJECTIVES. Safety and tolerability of both interventions in intubated critically ill patients.
METHODS. Randomised controlled trial of the effect of a single RSS manoeuvre on respiratory and cardiovascular (CV) parameters and pain, sedation-agitation scores in 120 consecutive patients, assigned to 1) catheter RSS, 2) catheter RSS after HS-HA, 3) MIE, and 4) MIE with HS-HA. Patients with an artificial airway (AAW) with cuff, on mechanical ventilation (MV) or spontaneous breathing (SB), without bronchospasm or haemoptysis were included after obtaining informed consent. Catheter RSS was done according to local protocol (-120 to -150 mBar), MIE was programmed at +50/-50 cmH2O and a jet nebulizer administered 5 ml of HS-HA placed at the AAW (group 2) or MIE tubing (group 4). Data were collected before, during and 5 and 60 minutes after the intervention, and occurrence of adverse events (predefined respiratory and CV and other) was monitored from inclusion to ICU discharge. We used chi2, one-way Anova and Bonferroni post hoc test.
RESULTS. 19 eligible subjects met exclusion criteria and 30 per group were enrolled and completed the study protocol. There were no differences in baseline characteristics and total, respiratory and CV adverse events (Table). Pain Scale (Behavior Indicators of Pain, "ESCID") rose significantly during RSS in groups 1 and 2 and were significantly higher during RSS in groups 1 and 2 for all comparisons. No difference in ESCID was observed at 5 and 60 minutes after RSS. Richmond Agitation-Sedation Scale did not differ between time-points or study groups. Chest x-rays within 24 hours after RSS did not disclose AEs.
CONCLUSION. MIE and HS-HA are save and better tolerated than conventional catheter RSS in critically ill patients with AAW. Future studies should address the efficacy of both measures.

INTRODUCTION. Esophageal balloon pressure calibration (Ebc) is a 2-steps procedure that was proven to increase accuracy of esophageal

pressure (Pes) measure in patients undergoing invasive volume-controlled mechanical ventilation (VCV) in the intensive care unit 1 (ICU) and the operating room 2.

OBJECTIVES. Aim of present study was to compare Pes measures after Ebc during VCV, pressure support (PSV), and PSV+Sigh with those obtained with conventional inflating at volume of 4 ml as manufacturer-recommended (V4).

METHODS. In 11 adult patients admitted in ICU, after esophageal balloon catheter was inserted, Ebc was performed to obtain optimal filling volume (Vbest) and to correct for pressure generated by esophageal wall and balloon during VCV, PSV and PSV+Sigh, applied in random order. The expiratory and inspiratory calibrated Pes values (Pescal), those obtained at Vbest (PesVbest) and at V4 (PesV4) were recorded.

RESULTS. PesV4 and PesVbest were higher than Pescal at end-expiration (13.1 ± 3.2 cmH2O vs 8.4 ± 3.1 cmH2O, $P<0.0001$; 11.1 ± 4.6 cmH2O vs 8.4 ± 3.1 cmH2O, $P=0.0427$) and end-inspiration (15.6 ± 3.1 cmH2O vs 11.7 ± 3.3 cmH2O, $P<0.0001$; 14.3 ± 5.1 cmH2O vs 11.7 ± 3.3 cmH2O, $P=0.0427$), respectively, during VCV. During PSV, expiratory and inspiratory PesV4 was greater than Pescal (14.1 ± 4 cmH2O vs 9.6 ± 3.9 cmH2O, $P=0.0020$; 17.2 ± 4 cmH2O vs 13.8 ± 4.4 cmH2O, $P=0.0020$). During Sigh, expiratory and inspiratory Pescal was lower compared to PesVbest (9.3 ± 3.9 cmH2O vs 14.9 ± 5 cmH2O, $P=0.0002$; 16.9 ± 4 cmH2O vs 22.4 ± 5.2 cmH2O, $P=0.0002$) and PesV4 (9.3 ± 3.9 cmH2O vs 13.4 ± 3.7 cmH2O, $P=0.0060$; 16.9 ± 4 cmH2O vs 20.1 ± 3.5 cmH2O, $P=0.0232$), respectively.

Vbest for Sigh was greater compared to that computed at VCV (5 ± 1.6 cmH2O vs 2.4 ± 1.9 cmH2O, $P=0.0086$) and PSV (5 ± 1.6 cmH2O vs 2.5 ± 1.8 cmH2O, $P=0.0168$), respectively. Esophageal wall pressure at Vbest increased moving from VCV and PSV to Sigh (2.6 ± 2.9 cmH2O vs 5.6 ± 2.7 cmH2O, $P= 0.0086$; 2.6 ± 2.6 cmH2O vs vs 5.6 ± 2.7 cmH2O, $P= 0.0168$), whereas no modifications were noted at V4 over the trials. Esophageal wall pressure was higher at V4 in VCV (5 ± 1.2 cmH2O vs 2.6 ± 2.9 cmH2O, $P=0.0371$) and PSV (5.1 ± 1 cmH2O vs 2.6 ± 2.6 cmH2O, $P=0.0195$) compared to Vbest.

CONCLUSION. Ebc improved Pes assessment during VCV, PSV and sigh. Average Vbest at VCV and PSV never achieved V4 and Vbest at Sigh. Balloon filling volume and esophageal wall artifacts were the only factors that negatively affected conventional Pes assessment in our series.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001185

INTRODUCTION. Ventilator-Induced Diaphragm Dysfunction (VIDD) is considered a major determinant of the ability to successfully wean patients from mechanical ventilation (1). Maintaining diaphragm work using electrical stimulation during mechanical ventilation (MV) has been proposed to attenuate VIDD (2).

OBJECTIVES. This first-in-human study assessed the safety and feasibility of temporary Percutaneous Electrical Phrenic Nerve Stimulation (PEPNS) on user-specified inspiratory breaths while on MV. Primary endpoints included the ability to synchronize electrical stimulation with inspiration to mobilize the diaphragm and to maintain work of breathing (WOB) within defined limits. Secondary endpoints included the percentage of patients with successful pdSTIM multipolar lead placement via ultrasound guidance and serious device/procedure-related adverse events.

METHODS. This prospective, multi-center, single-arm trial enrolled ICU patients on MV. PEPNS was used for 6 two-hour sessions at eight-hour intervals over 48 hours. Electrical stimulation was used to activate the diaphragm in synchrony with inspiration while on MV. Data collected included lead deployment success, nerve integrity, ventilation parameters, blood gasses, vital signs, WOB, electrical stimulation parameters, stimulation-breath synchrony and diaphragm thickness measured by ultrasound at 0, 24 and 48 hours.

RESULTS. Twelve patients were enrolled with 2 initial pilot patients having leads inserted on the left side only. Lead insertion was successful in 21 of 22 attempts (95.5%). An analysis of 36,059 stimulated breaths from the 10 non-pilot patients in whom the pdSTIM leads were placed bilaterally demonstrated phrenic nerve stimulation had a mean inspiratory lag of 23.66 msec ($p<0.001$ vs. null hypothesis of <88msec). WOB was maintained between 0.2 and 2.0 joules/L for 96.77% of the time, exceeding the 80% target. No serious device/procedure-related adverse events were reported. Diaphragm thickness increased for both stimulated and unstimulated diaphragm hemispheres.

CONCLUSION. Our results demonstrate the ability to safely and successfully place PEPNS leads in MV patients and the feasibility of using this approach to synchronize electrical stimulation with inspiration while also maintaining WOB between defined limits.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001196

INTRODUCTION. Several trials have reported promising clinical effects of high flow nasal oxygen therapy (HFOT) as compared to standard oxygen therapy or noninvasive ventilation in various settings. However, factors associated with successful HFOT weaning have never been assessed. As HFOT continuation might lead to unnecessarily prolonged ICU stay, we aimed at identifying predictors of successful HFOT weaning.

METHODS. This is a retrospective monocenter study over a 2-year period including all patients treated with HFOT for acute respiratory failure. Patients who died or were intubated without prior HFOT weaning attempt, those who were treated with noninvasive ventilation at the time of HFOT weaning, and those who received HFOT as a preventive treatment during the post-extubation period were excluded. HFOT weaning was driven by the attending physician. HFOT weaning failure was defined as a respiratory failure requiring HFOT resumption, noninvasive ventilation initiation, intubation, or death within the first 48 hours after HFOT weaning. Demographic data, ventilatory settings, and vital parameters under HFOT were collected before each weaning attempt. The pulse oximetry to fraction of inspired oxygen ratio (SpO2/FiO2) and the ROX index (SpO2/FiO2 to respiratory rate) were calculated under HFOT before each weaning attempt (1).

RESULTS. Among the 190 patients retained in the analysis, maximal gas flow and FiO2 set under HFOT were 50 ± 3 L/min and 75 ± 21 %, respectively. The main reason for HFOT initiation was pneumonia in 46% of cases. The first HFOT weaning attempt was successful in 168 patients (88%). Their baseline characteristics were not different from those who failed. They required lower FiO2 under HFOT than those who failed (39 ± 7% vs. 48 ± 16%, respectively, p= 0.02). A FiO2 ≤ 40% was a predictor of successful HFOT weaning with a sensitivity of 85%, a specificity of 41%, a positive predictive value of 92%, a negative predictive value of 26% and an accuracy of 80%. Likewise, the ROX index was higher in patients who were successfully weaned from HFOT than in those who failed (12.7 ± 1.2 vs. 10.2 ± 3.0, p = 0.002). A ROX index > 9.2 was a predictor of successful HFOT weaning with a sensitivity of 84%, a specificity of 50%, a positive predictive value of 93%, a negative predictive value of 30% and an accuracy of 80%.
ICU length of stay was longer in patients who failed the first HFOT weaning attempt than in those who succeeded: 10 (7-12) vs. 5 days (4-8) respectively (p < 0.0001). The main reason for failure was hypoxemia in 95% of cases (21 out of 22) and required HFOT resumption after 13 (5-26) hours under standard oxygen. After the first HFOT weaning failure, 86% of patients (19 out of 22) were eventually weaned successfully from HFOT. Their ROX index before the weaning success was higher than before their prior weaning failure (12.4 ± 3.8 vs. 10.1 ± 3.1, respectively, p = 0.04).
CONCLUSION. In this retrospective monocenter study, a FiO2 ≤ 40% and a ROX index > 9.2 were the best predictors of successful HFOT weaning at the bedside. A multicenter prospective study is mandatory to confirm the usefulness of these two easy-to-assess parameters to predict the successful HFOT weaning.

INTRODUCTION. Acute respiratory failure with respiratory acidosis is characterized by hyperinflation and insufficient, inappropriate muscle function with usually high muscle energy expenditure. Non-invasive assisted ventilation (NIV) via face mask can be used to facilitate gas exchange in the lungs but also to assist the distressed respiratory muscle function and diminish dyspnea levels. Indirect calorimetry uses gas exchange at the level of the lungs to calculate energy expenditure (EE) by incorporating O2consumption and CO2production in the Weir equation.
OBJECTIVES. The aim was to investigate the influence of NIV on indirect calorimetry and its correlation with respiratory effort.
METHODS. In 5 healthy subjects NIV (V60, Philips, Eindhoven, The Netherlands) was administered at a level of positive end expiratory pressure (PEEP) around 4 cmH2O and without additional inspiratory support. Inspiratory support was then increased by 2 cmH2O every 2 minutes until 8 cmH2O was achieved for 2 minutes. The EE was measured using indirect calorimetry (Q-NRG, Cosmed, Italy). To measure respiratory effort, the combined reversed RPE-scale was created for the purpose of the study. It uses the validated "rate of perceived exertion" scale (RPE-scale) which was altered by adding a reversed part. This could result in a score of -10 (no respiratory effort) until +10 (maximal respiratory effort) where 0 represents the basal respiratory condition.
RESULTS. The application of NIV without inspiratory support resulted in a mean EE of 1080 ±267 Kcal/day and a combined reversed RPE-score of 1.8 ±1.1. After incremental increase of inspiratory support to 8 cmH2O, mean EE changed to 1138 ±397 Kcal/day (p=0.46)and the combined reversed RPE-score to -4.6 ±2.1 (p=0.004). From the inspiratory support, EE could be predicted as 16.91* X + 1037 (R2= 0.74) and combined reversed RPE-score as -0.845*X + 1.12 (R2= 0.91) using linear regression. Pearson r test showed a correlation coefficient of -0,828 (p=0.083).
CONCLUSION. NIV seems to induce a minimal metabolic burden in healthy subjects. Surprisingly a reversed relationship was observed between respiratory relieve by NIV and energy expenditure in healthy subjects. This suggests that in healthy subjects, respiratory relieve is not due to altered muscle energy expenditure.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001215

INTRODUCTION. Tracheotomy (TT) is a frequent procedure in critically ill patients. Its risks and benefits are matter of an ongoing debate. At least in theory there are some advantages including lower airway resistance due to the shorter tube length and less dead space. However, data on improved outcome are conflicting, and there is consensus about early and late complications as well as a substantial procedural mortality of up to 0.6%.
Little is known about short term haemodynamic effects.
OBJECTIVES. Therefore, we compared pre- and post TT hamodynamics and respiratory effects in 30 ICU-patients with transpulmonary thermodilution (TPTD) and pulse contour analysis (PCA) monitoring with the PiCCO-device (Pulsion; Germany).
METHODS. Analysis of a prospectively maintained database on haemodynamic monitoring with the PiCCO device. Comparison of the last values before and the first values after TT (primary endpoint).
RESULTS. 30 patients undergoing surgical tracheotomy for prolonged mechanical ventilation, 17 male; 13 female. APACHE-II 26± 8; age 72±10 years; height 170±10cm; weight 75±15kg.
Haemodynamics: SVRI was higher before compared to after TT: 1552±524 vs. 1361±437dyn*s/cm5/m^2; p=0.020.
All other haemodynamic parameters were comparable before and after TT: Heart rate 89±15 vs. 93±18/min; p=0.156. MAP 87±18 vs. 83±13mmHg; p=0.304; CVP 13±5 vs. 13±6mmHg; p=0.775. dPmax 1447±522 vs. 1469±553 mmHg/s; p=0.516; global enddiastolic volume index GEDVI 799±244 vs. 830±231mL/m^2; p=0.897; extravascular lung water index EVLWI 9.6±3.0 vs. 9.8±3.1mL/kg; p= 0.894; stroke volume index SVI 46±14 vs. 46±14mL/min; p=0.869;

Cardiac index CI 4.11±1.44 vs. 4.13±1.11L/min/m²; p=0.674; global ejection fraction GEF 24±7% vs. 24±8%; p=0.418.
Respiratory parameters: Tracheotomy resulted in an increase in the number of patients with controlled compared to assisted or spontaneous ventilation (8/30 vs. 2/30; p=0.038). All other respiratory parameters were comparable before and after TT: Respiratory rate 22±8 vs. 22±8/min; p=0.920; tidal volume 488±167 vs. 493±158mL; p=0.728; PEEP 7.6±1.9 vs. 7.9±1.9cmH2O; p=0.382; P_peak 24±6 vs. 23±6cmH2O; p=0.305; P_mean 12±4 vs. 12±3cmH2O; p=0.972; FiO2 0.42±0.11 vs. 0.42±0.10; p=0.859. P/F-ratio 240±77 vs. 234±84mmHg; p=0.349; Oxygenation index 6.2±3.9 vs. 6.6±4.0cmH2O/mmHg; p= 0.313; compliance 35±15 vs. 42±29mL/cmH2O; p=0.241.
CONCLUSION. 1.) TT did not result in haemodynamic impairment.
2.) TT induced a slight short-term increase in the rate of patients under controlled mechanical ventilation, but did not improve any respiratory parameter.

INTRODUCTION. Esophageal balloon calibration (Ebc) has been proposed in intensive care unit 1 (ICU) and the operating room 2 to improve accuracy of esophageal pressure (Pes) measure in patients undergoing invasive mechanical ventilation. Ebc is a 2-step procedure and consists in 1) identifying optimal balloon filling volume (Vbest) and 2) subtracting esophageal wall recoil pressure to Pes measured at Vbest (PesVbest) to obtain calibrated Pes (Pescal).
OBJECTIVES. The present study aimed to evaluate Ebc and Pescal in intubated patients undergoing pressure support ventilation (PSV) compared to the technique recommended by the manufacturer (i.e., standard filling volume of 4 ml (V4)).
METHODS. In intubated and mechanically ventilated adult patients, admitted to the ICU for acute hypoxemic respiratory failure, a naso-gastric tube equipped with esophageal balloon was inserted (Nutrivent, Sidam, Mirandola, Italy). After correct insertion depth was assured, Ebc was carried out while patients were ventilated on PSV. Briefly, the balloon was progressively inflated with volume ranging between 0 and 8 ml. Aiming to construct the end-expiratory and inspiratory balloon pressure-volume curve, a series of short end-inspiratory and end-expiratory holds were applied at each filling volume, assuring patient's relaxation during occlusions and interval of 15-30 breaths between each occlusion 3 - 5. Vbest, was identified as the filling volume associated with the maximal tidal Pes swing (Pesswing) on tidal volume (Vt) ratio (Pesswing/Vt). Then, on the end-expiratory pressure-volume curve, esophageal wall elastance was quantified to quantify esophageal recoil pressure at Vbest and, finally, Pes measured at Vbest (PesVbest) was corrected for esophageal wall pressure to obtain Pescal. Raw Pes at V4 values (PesV4) were recorded, too. Finally, the Baydur occlusion calibration test was performed to compare accuracy of the two methods. Finally, pressure generated by esophageal balloon pressure was computed.
RESULTS. Ebc was performed in 11 patients. Occlusion test was accurate (0.8-1.2 ratio) in 11/11 (100%) at Vbest and 5/11 (45.5%) patients at V4 (P = 0.0124), being 0.87 ± 0.07 with Vbest and 0.79 ± 0.1 with V4 (P = 0.0098), respectively. Vbest and Vmin was lower than Vmax (2.5 ± 1.8 vs 6.3 ± 1.3 ml, P = 0.0316; 0.6 ± 0.2 vs 6.3 ± 1.3 ml, P < 0.0001). Pesswing/Vt at Vbest was higher than that computed at V4 (8.5 ± 3.1 vs 5.9 ± 3.5 cmH2O/l, P = 0.0010). Esophageal wall pressure computed at Vbest was lower than at V4 (2.6 ± 2.6 vs 5.1 ± 1 cmH2O, P = 0.0195). Esophageal balloon pressure was negligible at Vbest and V4. Expiratory and inspiratory Pescal was lower than PesV4 (9.6 ± 3.9 vs 14.1 ± 4 cmH2O, P = 0.0020; 13.8 ± 4.4 cmH2O, P 0.0020).
CONCLUSION. Ebc is feasible in patients undergoing PSV and it might be associate with more accurate assessment of the esophageal pressure swings, which are a critical component of the risk of lung and diaphragm injury during assisted ventilation.

INTRODUCTION. Application of Sigh in patients with the acute respiratory distress syndrome undergoing invasive assisted mechanical ventilation has been shown to improve oxygenation and lung recruitment 1.
OBJECTIVES. Aim of present study was to compare, in patients undergoing pressure support ventilation (PSV) + Sigh, the pressure applied to the lung (PI) during Sigh breaths, measured at optimal esophageal balloon filling volume (Vbest) versus at recommended filling volume of 4 ml (V4).
METHODS. In intubated ICU adult patients with hypoxic acute respiratory failure of various etiologies, mechanically ventilated in PSV, a naso-gastric catheter equipped with esophageal balloon (Nutrivent, Sidam, Mirandola, Italy) was inserted. During PSV, inspiratory 4 sec-long PCV mode Sigh at a pressure of 35 cmH2O was set at a rate of 1 per minute. After the correct position of esophageal balloon was reached, esophageal balloon calibration was performed to obtain calibrated esophageal pressure at Vbest during Sigh. Hence, expiratory and inspiratory PI for dependent (PId) and non-dependent (PInd) lung regions was calculated at Vbest and V4 2.
RESULTS. In 11 patients we performed esophageal balloon calibration during Sigh. Vbest was similar to V4 (5 ± 1.6 vs 4 ± 0 ml, P = 0.0859). Expiratory PId at Vbest was 0.1 ± 4.2 cmH2O vs -4 ± 4.2 cmH2O at V4 (P = 0.0010). Expiratory PInd was slightly lower at Vbest compared to V4 (6.4 ± 2.5 vs 6.8 ± 2.5 cmH2O, P = 0.0020).

Inspiratory Pld was 18.2 ± 4 cmH2O at Vbest vs 14.9 ± 3.5 at V4 (P = 0.0049) whereas Inspiratory Plnd at Vbest was 24.5 ± 4.5 cmH2O vs 25.9 ± 4.5 cmH2O at V4 (P = 0.0020). Lung, chest wall, and respiratory system elastances at sigh pressure were 23.8 ± 25.2 cmH2O/l, 7.5 ± 6.6 cmH2O/l, and 31.35 ± 28.5 cmH2O/l, respectively. Tidal volume during sigh was 1,371 ± 0.841 l (tidal volume - predicted body weight ratio 21.3 ± 11. 04 ml/Kg). Lung and respiratory system driving pressure was 18.1 ± 4.9 cmH2O and 25.6 ± 3.8 cmH2O, respectively. Inspiratory Plnd was directly correlated with lung driving pressure (Spearman r = 0.8091, confidence interval 0.3891 – 0.9506, P = 0.0039).

CONCLUSION. In patients undergoing mechanical ventilation under PSV + Sigh, Pl assessment was more accurate applying Vbest compared to V4. Noteworthy, when Sigh is delivered at 35 cmH2O, inspiratory Plnd exceeded the safety threshold of 20-22 cmH2O, suggesting that setting sigh at lower pressure might be safer.

INTRODUCTION. Major suegery and taruma patients are important subset of patients who are liable to acute respiratory distress syndrome (ARDS).

OBJECTIVES. We intended to validate a previously derived lung injury prediction scores (LIPS) in predicting ARDS and in-hospital mortality in high risk major trauma and surgical ICU patients.

METHODS. 79 patients with APACHE-II score≥15 admitted to the ICU by major trauma and/or major surgery were included in our prospective observational study. LIPS was calculated within six hours of admission using two previously derived formulas by Cartin-Ceba et al, 2009 and Trillo-Alvarez et al, 2011. We measured C-reactive protein on admission (CRP-0) and 48-hours later (CRP-48). Our endpoints included ARDS development and in-hospital mortality.

RESULTS. 33 patients (41.8%) developed ARDS after median(Q1-Q3) of 4(2-7) days. The LIPS of Cartin-Ceba et al and Trillo-Alvarez et al were 5(4-6) and 4.5(3-6.3) in ARDS patients compared to 3(1.8-4.3) and 3(1.5-4.6) in non-ARDS patients (P=0.000 & 0.001 for them respectively). CRP-48 was 96(57-192)mg/L and 48(24-96)mg/L in both groups respectively (P=0.000). The AUC was 0.741 and 0.712 for Cartin-Ceba et al and Trillo-Alvarez et al respectively. LIPS of Cartin-Ceba et al of 3.5 was 79% sensitive and 59% specific while LIPS of Trillo-Alvarez et al of 2.25 was 91% sensitive and 41% specific for ARDS prediction. CRP-48 was the only variable which was significantly higher in non-survivors (P=0.000). CRP-48 of 94 mg/L was 73% sensitive and 69% specific in predicting in-hospital mortality.

CONCLUSION. We concluded that despite both LIPS scores are equally effective in predicting ARDS in ICU trauma and major surgery patients, they were less accurate than in general ICU population.

Acute Respiratory Distress Syndrome in patients with severe P. falciparum Malaria admitted to an Intensive Care Unit of a Tertiary Teaching Hospital from Portugal

L. Graça[1], I. Abreu[1], L. Graça[2], A. Ferreira[1], S. Xerinda[1], AS. Faustino[1], P. Figueiredo[1], L. Santos[1]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001689

INTRODUCTION. ARDS (Acute Respiratory Distress Syndrome) is a common (up to 25%) and serious complication of malaria. Factors associated with its development and prognosis are poorly understood.

OBJECTIVES. This study aims to identify risk factors for ARDS and related prognosis.

METHODS. We retrospectively evaluated the clinical records of 99 patients with severe malaria due to P. falciparum who were admitted to an Intensive Care Unit (ICU) of a Tertiary Care Hospital from January 2009 to December 2018. We defined severe malaria according to World Health Organization (WHO) 2015 guidelines and used the Berlin criteria for ARDS. Continuous variables were compared among groups using the t test or Mann-Whitney test and categorical variables using the chi-square test.

RESULTS. We identified 33 ARDS cases (33%). The mean age was 44.7 ± 11.3 years and 87.9% were males. Patients developed ARDS 7.4 ± 3.5 days after the onset of symptoms. At the time of the admission to the ICU, 36.4% of patients already had ARDS. Three patients were managed with non-invasive ventilation (NIV) only, 30 patients required invasive ventilation (IMV), 10 of which had failed NIV trial. The ventilator parameters were available for 30 patients: none had mild ARDS, 43.3% had moderate ARDS and 56.7% had severe ARDS. The mean time between ICU admission and intubation was 1.9 days (minimum 0, maximum 5 days) and the mean duration of IMV was 8.95 days (min 1, max 52 days). Thirteen patients required curarization, 3 prone positioning and 3 Extra Corporeal Membrane Oxygenation (ECMO), for 7, 15 and 45 days, respectively. Cough was the only factor significantly associated with ARDS (OR 2.7; 95% CI 1.1 - 6.7). Time to endotracheal intubation was not associated with duration of IMV, need for curarization, prone positioning or ECMO. The overall fatality rate was 4% and the fatality rate in those with ARDS was 6.4%, with no deaths directly attributed to ARDS. Patients with ARDS had longer ICU stay (16.6 ± 11.3 vs 4.4 ± 4.4), longer hospital stay (24.7 ± 14.9 vs 9.5 ± 7.7) and a higher risk of nosocomial infection (OR 2.1; 95% CI 1.4-3.2), namely ventilator-associated pneumonia (OR 1.4; 95% CI 1.1 – 1.8).

CONCLUSION. Cough, a clinical parameter, was the best predictor of development of ARDS in our study which highlights the need to evaluate these patients thoroughly and monitor for the development of respiratory failure. NIV trial, although with a high failure rate, did not worsen the prognosis of these patients and might be an adequate therapy for some patients. The treatment of malaria ARDS by specialized teams with access to advanced techniques dramatically improves the chance of survival.

Right and Left Ventricular Functions during Proportional Assist Ventilation and During Weaning from Mechanical Ventilation

M. Elansary, YS. Nassar, R. Soliman, H. Mowafy
[1]Critical care medicine, Kasr El Aini Teaching Hospital, Cairo, Egypt
Correspondence: M. Elansary
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001702

INTRODUCTION. Mechanical ventilation (MV) induces changes in lung volumes and intrathoracic pressures which are transmitted to the heart, great arteries and veins and therefore independently affect the key determinants of cardiovascular performance and consequently Heart rate (HR) and myocardial contractility. New ventilatory modes as Proportional assist Ventilation (PAV+) with more patient synchrony may have better hemodynamic effects.
OBJECTIVES. To evaluate the changes in hemodynamics , left & right ventricular functions during weaning from MV & to document the hemodynamic impact of MV in patients with normal & impaired left ventricular systolic function.
METHODS. 100 patients who received MV using pressure control mode were recruited in the study after fulfilling all the criteria for a spontaneous breathing trial. Every patient underwent 4 phases of ventilation with 2 hours apart and each phase lasted for 3 hours which were Pressure control – Assisted control ventilation (PC-ACV) with a preset pressure sufficient to maintain tidal volume of 4-6ml/kg & preset respiratory rate (RR) which is sufficient to eliminate CO2 in arterial blood gases, spontaneous breathing trial (SBT) with Pressure Support (PS) 10 , Positive end Expiratory pressure (PEEP) 5 , PAV+ mode with 20-30% assist and finally after discontinuation of MV. During each phase, the changes in change in HR, RR, systolic and diastolic blood pressures (SBP & DBP) were followed. Thoracic electrical bioempedance was used to measure stroke index (SI), cardiac index (CI) and systemic vascular resistance (SVR) in each phase of ventilation. Echocardiography and tissue Doppler imaging (TDI) were used to assess the changes in Left and right ventricular systolic and diastolic functions during each phase of ventilation. Patients with atrial fibrillation (AF), receiving vasopressors and inotropes and patients who failed weaning trial within less than 24 hours post extubation were excluded.
RESULTS. SBP, DBP, SI, CI & SVR did not show any significant changes between all phases of ventilation in all groups **(P: Non significant). HR & E/A** were higher during spontanous breathing in all patient groups **(P<0.001 & P<0.012 respectively). EF** was highest during PAV+ in all patient groups **(P<0.018). Left ventricular "S" wave** was higher during PAV+ & PC-ACV in Normal & Impaired systolic function groups **(P 0.024). E/E'** was lower during PC-ACV in Normal systolic function group **(P 0.037).**
TAPSE was higher during PAV+ & PC-ACV in Normal systolic function group **(P<0.008). Right ventricular "S" wave** was higher in PAV+ in impaired systolic function group **(P 0.024). Tricuspid E/E'** was higher during Spontanous breathing in all patient groups **(P 0.002). Pulmonary artery systolic pressure (PASP)** was lower during PC-ACV in impaired systolic function group **(P 0.04).**
CONCLUSION. PAV+ may have favourable effects on hemodynamics, left & right ventricular functions in patients ready for weaning.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001704

INTRODUCTION. Extravascular lung water (EVLW) and pulmonary vascular permeability index (PVPI) measured by transpulmonary thermodilution (TPTD) add objectivity to ARDS diagnosis. Paradoxically, up to a third of patients who meet ARDS criteria have near-normal EVLW. In addition, ARDS can be classified as focal or non-focal according to computed tomography (CT) lung attenuation pattern.
OBJECTIVES. To assess the association between EVLW or PVPI and CT lung attenuation pattern in patients with acute respiratory failure (ARF).
METHODS. Retrospective observational study. Inclusion criteria were invasive mechanical ventilation, PaO_2:FiO_2 ratio <300, hemodynamic monitoring with TPTD (PiCCO®, Pulsion Medical System) and CT of the chest performed <8 hours apart form a TPTD measurement. Patients with cardiogenic pulmonary edema or chronic lung diseases were excluded. Measurement of EVLW indexed by predicted body weight (EVLWi), PVPI (EVLW/pulmonary blood volume), PaO_2:FiO_2 and oxygenation index (mean airway pressure/PaO_2:FiO_2*100) closest to the CT acquisition were recorded. Patients were classified according to CT attenuation distribution as non-focal ARDS (bilateral diffuse), focal ARDS (bilateral dependent) and non-ARDS (unilateral). Data are expressed as median [IQR]; variables were compared according to morphologic categories using the Kruskal-Wallis test and $p<0.05$ was considered significant.
RESULTS. 36 patients were included, 29 fulfilled the Berlin definition for ARDS. Age 65 [51-71] years, APACHE II 18 [13-26], PaO_2:FiO_2 176 [107-252], oxygenation index 7.6 [3.7-13.2]. Oxygenation and TDTP variables according to morphologic categories are presented in table 1. There were no differences in oxygenation between groups. EVLWi was significantly higher in patients with non-focal ARDS (n=20) than in those with focal ARDS (n=9) or non-ARDS (n=7). PVPI was also higher in non-focal than in focal ARDS. EVLWi and PVPI were not different between focal ARDS and non-ARDS patients. Among the 29 patients with ARDS, 10 (34%) had EVLWi <10 ml/Kg; 7 of these (70%) were focal.
CONCLUSION. Patients who meet conventional ARDS criteria with EVLWi <10 ml/Kg are likely to have focal morphology. Conversely, ARDS with EVLWi >10 ml/Kg is likely non-focal. Focal ARDS has an oxygenation and TPTD profile similar to ARF with unilateral lung opacities. Non focal or difuse ARDS may represent true permeability pulmonary edema.

An Initial Study of Delivery of Nebulised Drugs During High Flow Nasal Cannula Oxygenation

M. McCullagh[1], T. Young[2], J. Martin-Lazaro[2]
[1]Newham University Hospital, London, France; [2]Icu, Newham University Hospital, London, France
Correspondence: M. McCullagh
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001734

INTRODUCTION. High flow nasal cannula (HFNC) oxygenation is an emerging therapy for hypoxic respiratory failure(1,2,3). Frequently patients receiving HFNC therapy also require nebulised drug delivery; in particular, bronchodilators such as salbutamol. Some of these patients are unable to tolerate even brief periods of time without HFNC oxygen and desaturate if the HFNC is swapped to a face mask with a nebuliser attached. Therefore, nebulised drugs should ideally be delivered simultaneously to HFNC therapy. The optimal method to achieve this simultaneous delivery is not yet established. Studies exist on HFNC therapy combined with nebuliser therapy - showing optimal aerosol particle sizes in vitro in nebuliser delivered through HFNC compared to via face mask with jet nebulisation(4); and looking at identification of optimal settings for the implementation of nebulisation within HFNC circuits(5) - but comparison of nebuliser delivery method with ongoing HFNC has not been widely studied.
OBJECTIVES. To compare effects of nebulisation therapy in conjunction with HFNC therapy between delivery with face mask plus nebuliser attachment, and delivery with nebuliser attachment in-line with HFNC tubing.
METHODS. A retrospective observational study on critical care patients with respiratory failure requiring HFNC therapy and bronchodilators (n=20). Group 1 (n=9) received nebuliser therapy via a face mask fitted with a jet nebulisation chamber which was placed over the nose and mouth, with the HFNC still in place.Group 2 (n= 11) received nebuliser therapy via a nebulisation chamber which was attached upstream of the HFNC in-line with the HFNC tubing. Clinical and biochemical parameters were compared in each patient within 1 hour before and within 1 hour after nebuliser therapy with 2.5 mg salbutamol. Heart rate (HR), respiratory rate (RR) and peripheral capillary oxygen saturation (SpO2) were measured as the clinical parameters. Arterial blood gas sampling was used to assess biochemical parameters: pH, PaCO2, PaO2 and HCO3-.
Data collection and analysis was carried out using Excel.
RESULTS. Twenty patients were included in the study with an average age of 59 +/- 15 years.
An initial direct comparison of means showed a generally favourable outcome in parameters post nebuliser therapy delivered via tubing compared with delivery via face mask. Using t-test analysis (significance set a p value of <0.05), we observed a statistically significant reduction (p=0.037) in heart rate with nebuliser therapy delivered through tubing compared to delivery via face mask. Changes in other parameters were statistically comparable between the two groups (RR: p = 0.107; SpO2: p = 0.316; pH p = 0.238; PaCO2 p = 0.313; PaO2: p = 0.298, HCO3-: p = 0.298).
CONCLUSION. Current statistical analysis suggests that nebuliser therapy delivered in conjunction with HFNC via tubing is at least as effective as nebuliser therapy delivered in conjunction with HFNC via face mask, with a statistically significant improvement in heart rate in the tubing group. The improvement in mean parameters for nebuliser delivered via tubing compared to face mask is promising, although not statistically significant. However, it is possible that the small population size could lead to a Type II error (failure to reject a false null hypothesis), and it would certainly be of value to extend this initial study to a prospective study over a larger timescale with a greater sample population.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001736

INTRODUCTION. Enzymatic debridement has supposed a great advance in the treatment of critically burned patients, reducing time until debridement and therefore ICU stay. There is a great amount of systemic implications that hasn't been fully studied about these topic treatments, including those in patients with Inhalation injury.
OBJECTIVES. To describe our experience using enzymatic debridement in critically burn patients with inhalation injury and determine possible complications of its use in this set of patients.
METHODS. We performed a Retrospective observational study in the Critical Burn Unit of the La Paz Hospital in Madrid Spain from January 2017 until February 2019. All critically burned patients over 18 years old with a high suspicion or confirmed Inhalation Injury were included. Mean and standard deviation were used for normal quantitative variables and median and interquartile range in the opposite case. Qualitative variables were presented by absolute and relative frequencies.
RESULTS. We studied 152 patients admitted in our Critical Burn Unit. 16 patients (10.5%) had high suspicion or compatible criteria with Inhalation Injury, with initial carboxyhemoglobin over 4% at admission. Mean age was 59 (+- 24.5), Median TBSA was 17% (RI 6-42%), APACHE II was 15 (RI 10-19), ABSI score was 7 (RI 5-9). The median initial levels of Carboxyhemoglobin at admission in the ICU was 13 (RI 5-22), mean Lactate at admission was 4.2. Out of the 16 patients studied, 5 patients (31%) underwent enzymatic debridement in the first 12 hours of admission. 3 out of 5 patients (60%) in whom enzymatic debridement was performed presented a prolongation of corrected QT interval, two of them developed Ventricular Tachycardia followed by cardiac arrest in the first 24 hours.
CONCLUSION. Inhalation of toxic gas in critically burn patients might worsen the systemic response typical of these patients. 60% of the patients that received enzymatic debridement presented abnormalities in the electrocardiogram, 2 of them resulting in fatal Ventricular Tachycardia. Although more studies are needed, we suggest close monitoring and follow-up of patients with inhalation injury who undergo early enzymatic debridement because it can increase the inflammatory response or potentiate the effects of inhaled toxins.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001753

INTRODUCTION. Since the definition of "subjective experience of breathing discomfort" provided in 1999 by the ATS consensus statement, the concept of dyspnea has been widened covering not only a sensory-perceptual domain (i.e., dyspnea due to increased work of breathing) but also a behavioral-emotional area. Hence, the relief of dyspnea may not be strictly linked to the improvement of gas exchange, but also to the reduction of psychological suffering. Do-not-intubate (DNI) patients with acute hypoxemic respiratory failure (AHRF) are usually treated with noninvasive respiratory supports, mainly aimed at improving patients' comfort. High flow oxygen therapy (HFOT) seems to have a significant impact on dyspnea Limited literature data are available about the treatment of AHRF in DNI patients, included the relief of dyspnea
OBJECTIVES. To assess the effects of HFOT in DNI patients affected by AHRF, hospitalized in general wards
METHODS. We selected a subset of patients included in a larger trial evaluating the use of HFOT outside the ICU under the constant supervision of an Intensivist. 9 wards of Ospedale Policlinico (Milan, Italy) were equipped with HFOT devices; in each ward, educational meetings were given by an ICU physician and an ICU nurse. HFOT was started in patients with AHRF (PaO2/FiO2 ≥150 and <300). The ICU Outreach team followed the patients daily. Arterial blood gases, respiratory rate (RR), dyspnea (assessed by Borg scale) and comfort (assessed through a visual analogic scale) were collected just before the beginning of HFOT, after 2 hours and then every 24. Data are presented as median and interquartile range.
RESULTS. From November 2017 to April 2019, the ICU Outreach Team followed 118 patients. 50 patients (42%) were classified as DNI; 18 (36%) were terminally ill (End-Of-Life). Median age was 76 [66.75-85] years. Hospital mortality was 68%. Twenty-four patients (48%) had oncologic comorbidities and 16 (32%) had COPD. Median PaO2/FiO2 was 156 [116-191]. The duration of HFOT was 10 [4-15] days. After 2 hours from the beginning of HFOT, we observed a significant reduction of RR from 28 [24-31] to 23 [20-28] breaths/min ($p < 0.05$), a reduction of Borg scale value from 3 [2-5] to 2 [1-3] points ($p < 0.05$) and an increase in comfort scale from 3 [2-3] to 3.5 [3-4] points ($p < 0.05$). Gas exchange did not improve
CONCLUSION. HFOT is effective inalleviating dyspnea and improving comfort in DNI patients with AHRF hospitalized in general wards. The effect on dyspnea is not explained by an improvement of PaO2/FiO2 ratio

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000347

INTRODUCTION. Exosomes have been studied extensively in several diseases including cancers and cardiovascular diseases as an inflammatory marker, however, little is known about their role and behavior in sepsis. Sepsis is a dysregulated inflammatory response syndrome that leads to multiple organ failure. Current sepsis biomarkers may be helpful in determining organ failure and evaluating the patients' clinical course, but there are no direct molecular biomarkers to predict subsequent organ failure. Exosome play an important role in the inflammatory response, coagulation process, and cardiac dysfunction in sepsis.
OBJECTIVES. The objective of this study was to evaluate the association of plasma exosome with severity of sepsis and mortality in critically ill patients with sepsis.
METHODS. Plasma exosome levels were measured in 80 patients prospectively enrolled in ongoing ICU cohort in Korea between April 2014 and January 2019, in comparison to healthy controls (n = 4). The levels of plasma exosomes expressing CD9 among groups of healthy donor, sepsis and septic shock were compared. To detect and quantify exosomes in plasma, we used a CD9 expression based enzyme-linked immunosorbent assay (ELISA) kit according to the manufacturer's protocol (Novusbio, Littleton, CO, USA).
RESULTS. A total of 80 patients admitted to the medical ICU and diagnosed sepsis or septic shock at our institution were recruited, among which 36.5% presented with septic shock. The median age of patients was 68 (IQR; 61–75) years and 73% were male. Patient with septic shock had higher exosome levels in the plasma compared with healthy controls and patients without shock (median(IQR);

200(158–242) μg vs. 490(468–473) μg vs. 928(899–946) μg, $p < 0.001$). Serum levels of lactic acid and procalcitonin were also higher among patients with septic shock ($p < 0.001$) compared to sepsis patients. We also performed ROC analysis and Delong's test to demonstrate and compare the predictive value of exosomes as a prognostic predictor of 28-day all-cause mortality. The area under the ROC curve (AUC) was 0.68 (95% CI; 0.44–0.92) for plasma exosomes, while the AUC of serum lactic acid and procalcitonin were 0.50 (95% CI; 0.30–0.69) and 0.65 (95% CI; 0.38–0.92), respectively. Pairwise comparisons of ROC curves showed that there was no difference to predict 28-day mortality between exosome and either lactic acid ($p = 0.11$) or procalcitonin ($p = 0.86$) in this study.
CONCLUSION. Our findings suggest that the elevated levels of plasma exosomes in patients admitted to the ICU are associated with septic shock and organ failure. Further studies involving molecular characterization of exosomes are required to fully understand their role in the pathophysiology of sepsis.

000381

A risk scoring model predicting ICU mortality in severe septic shock patients treated with combined vitamin C, hydrocortisone, and thiamine therapy

H. Kim, WY. Kim
[1]Internal medicine, Chung ang University Hospital, Seoul, Republic of Korea
Correspondence: W.Y. Kim
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000381

INTRODUCTION. Recent observational studies demonstrated that septic patients who received the combination of vitamin C, hydrocortisone, and thiamine had a substantial mortality benefit [1, 2]. Several randomized controlled trials are ongoing to assess the effect of this combination therapy on clinically important outcomes in sepsis. Better prediction of mortality in these patients may help clinicians to target patients most likely to benefit from vitamin C protocol.
OBJECTIVES. To develop a model for predicting ICU mortality at initiation of vitamin C protocol for septic shock.
METHODS. Data were obtained from severe septic shock patients (requiring high-dose vasopressors such as norepinephrine ≥0.2 ug/kg/min ± vasopressin) treated with the vitamin C protocol between September 2018 and February 2019 at a university-affiliated tertiary care hospital in Korea. Binary logistic regression was used to identify pre-treatment variables predicting ICU mortality. The Vitamin for Sepsis (VITASEP) score was calculated as the sum of simplified regression weights (SRW).
RESULTS. Data from 55 patients were reviewed. A total of 22 patients (40%) died during ICU admission. On the basis of multivariate analysis, the following factors were included in the VITASEP score: non-urosepsis (SRW 1), body temperature <37.1°C (SRW 1), white blood cell <14,000/mm3 (SRW 1), and C-reactive protein <200 mg/L (SRW 2). The area under the receiver operating characteristic curve of the VITASEP score predicting ICU mortality was 0.77 (95% confidence interval, 0.64–0.89). For VITASEP scores 0–1, 2, 3, and 4–5, the 28-day mortality rates were 17%, 27%, 35%, and 71%, respectively (log-rank test, $P = 0.02$). For VITASEP scores 0–1, 2, 3, and 4–5, the mean number of vasopressor-free days at day 28 were 24.7, 17.1, 13.6, and 9.0, respectively (Kruskal-Wallis test, $P = 0.02$).
CONCLUSION. Our results suggest that VITASEP score may predict ICU mortality among septic patients treated with combined vitamin C, hydrocortisone, and thiamine therapy. Vitamin C protocol may benefit septic patients with a "hyperinflammatory" subphenotype. Further validation in a larger sample is required.

INTRODUCTION. Sepsis may result in life-threatening organ dysfunction, which is caused by various infections and dysregulated immune responses of host. Phosphorus is an important substance that plays various roles in the body such as intracellular energy exchange and mineral metabolism. Several studies reported that the phosphate concentration is associated with prognosis in diseases which cause ischemic injury of tissues such as intestinal ischemia, coronary heart disease, critical limb ischemia, and cardiac arrest. In sepsis, tissue hypoperfusion induces cytopathic hypoxia at the cellular level and it results in ischemic tissue injury and organ dysfunction. Therefore, we hypothesized that the phosphate concentration, which was a marker of ischemic tissue injury, could be used to predict prognosis in patients with sepsis.
OBJECTIVES. Ischemic injury caused by tissue hypoperfusion is one of the major mechanisms of sepsis, and phosphate concentration is elevated in ischemic tissue injury. This study was performed to investigate the association of the phosphate concentration with the mortality of patients with sepsis.
METHODS. This was a retrospective cohort study of patients with sepsis. The patients were divided into three groups according to the phosphate concentration: hypophosphatemia ($P < 2.5$ mg/dl), normophosphatemia ($2.5 \leq P \leq 4.5$ mg/dl), and hyperphosphatemia ($P > 4.5$ mg/dl). Multivariable Cox proportional hazard regression analysis was performed to evaluate the independent association of phosphate concentration with 28-day mortality.
RESULTS. A total of 3,034 patients were included in the study and the overall mortality rate was 21.9%. The 28-day mortality rates of the hypophosphatemia, normophosphatemia, and hyperphosphatemia group were 14.8%, 19.8%, and 38.1%, respectively ($p < 0.001$). In the multivariable Cox proportional hazards regression analysis, hyperphosphatemia was independently associated with 28-day mortality compared with normophosphatemia (hazard ratio, 1.27; 95% confidential interval, 1.05-1.54).
CONCLUSION. Hyperphosphatemia was associated with 28-day mortality in patients with sepsis and could be used as a prognostic factor in sepsis.

INTRODUCTION. The surviving sepsis campaign guidelines recommend empirical broad-spectrum therapy within earlier time from triage such as one hour for both sepsis and septic shock.
OBJECTIVES. To describethe association timing of antibiotic administration and outcomes among patients with severe sepsis and septic shock in real-world clinical setting in Japan.
METHODS. We included adult patients (≥16 years) with severe sepsis based on the sepsis-2 criteria published in 2003 [1], who were admitted to the ICU in the Focused Outcomes Research in Emergency Care in Acute Respiratory Distress Syndrome, Sepsis and Trauma (FORECAST) study [2]. It used a sample of 59 ICUs in Japan from January 1, 2016 to March 31, 2017. The primary outcome was in-hospital mortality. We compared characteristics and outcomes among patients initiating antibiotics at different timing (0-60, 61-120, 121-180, 181-240, 241-360, and 361-1440 minutes after the time of sepsis recognition), with analysis of variance, Kruskal-Wallis test, or chi-square tests. We estimated the impact of antibiotic timing on risk-adjusted hospital mortality using the generalized estimating equation (GEE) model with an exchangeable within-group correlation matrix where hospital was the panel or grouping variable. The covariates were prespecified a priori based on clinical experience and prior studies, such as patient age; gender; admission source (emergency department (ED), ward, or in intensive care unit (ICU)); CCI; antibiotic use before arrival; site of infection (e.g., lung, abdomen, urinary tract, soft tissue, central nerve system, blood stream-related, or others); and SOFA score.
RESULTS. 1124 patients met criteria in 54 hospitals. Of these patients,30.5% of patients received antibiotics within one hour and 73.9% of patients received antibiotics within three hours. The median time to antibiotic administration was 102 min (IQR, 55–189 min). Patients in ED or those diagnosed sepsis in ICU received antibiotics earlier than those in ward. The earlier antibiotic use group was likely to achieve the 3-hour bundle. Overall crude mortality was 23.4% in the study population. Patients who received antibiotic within 60 minutes had highest mortality (28.0%). Patients received antibiotics within the first 60 min had also highest adjusted mortality rate (28.5% [23.1–33.9]), whereas that of patients administered antibiotics between 61 and 120 min was the lowest (21.6% [16.5–26.6]). Differences in mortality were noted only between the 0–60 min and the 61–120 min groups. There was not significant difference among patients initiating antibiotics at different timing in ICU-free days, ventilator free days, and length of hospital stay. Similar results were observed even if patients from ED were stratified.
CONCLUSION. This prospective observational study failed to show the association between earlier antibiotic administration and reduction of in-hospital mortality among patients with severe sepsis.

INTRODUCTION. Extracorporeal blood purification techniques aim to ameliorate the excessive host response to sepsis and/or remove circulating endotoxin. Various devices have been evaluated in randomised clinical trials (RCTs) (1-3) although not in routine use.
OBJECTIVES. We conducted a meta-analysis and trial sequential analysis (4) of RCTs to determine the potential mortality benefit of extracorporeal blood purification techniques in sepsis.
METHODS. A systematic search of MEDLINE, Embase, clinicaltrials.gov, and the Cochrane Central Register of Controlled Trials for RCTs was conducted. Mortality was assessed using Mantel-Haenszel models and *I2* used for heterogeneity. Data are presented ad odds ratios (confidence intervals); p-values; *I2*).
RESULTS. We identified 28 RCTs including 2,194 patients, with 1,115 (51%) in the treatment arm. Eight studies used haemofiltration, 15 endotoxin absorption devices, four non-specific cytokine removal devices, and one used plasma exchange. An improvement in mortality was associated with the use of endotoxin removal devices (0.47 (0.28-0.79); p=0.004; *I2*=68%), but not haemofiltration (0.74 (0.49-1.13); p=0.17; *I2*=0%) nor non-specific cytokine removal (0.81 (0.33-2.00); p=0.65; *I2*=72%). Subgroup analyses revealed that mortality benefit was limited to the use of endotoxin removal devices in Asian (0.23 (0.12-0.47); p<0.001; *I2*=47%) but not Western countries (1.10 (0.82-1.48); p=0.54; *I2*=5%). The use of endotoxin removal devices (0.21 (0.12-0.34); p<0.001; *I2*=0%) and cytokine removal devices (0.43(0.20-0.94); p=0.02; *I2*=51%) was associated with an improvement in mortality only among patients with a high risk of death (control arm mortality >50%). Patients with documented Gram-negative sepsis were most likely to benefit from endotoxin removal devices (0.22 (0.12-0.42); p<0.001; *I2*=0%).
CONCLUSION. The use of endotoxin removal devices in sepsis is associated with mortality benefit, particularly in patients with high mortality risk and with documented Gram-negative sepsis.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000401

INTRODUCTION. Although small animal sepsis model is well established, longitudinal assessment of hemodynamic variables, laboratory values, and blood culture in a single living sepsis model is limited.
OBJECTIVES. Therefore, we aimed to comprehensively characterize the fecal peritonitis-induced sepsis in the porcine model.
METHODS. Autologous feces (1g/kg) were administered into the peritoneum of eleven male pigs (49 ± 8 kg). The pigs were monitored up to 12 hours with the full support of fluid and vasopressors to maintain over 65mmHg of the MAP. Longitudinal blood culture and laboratory values were obtained every one or two hours. The cytokine levels in plasma were analyzed. Moreover, clinical registry of sepsis patients in single emergency department was utilized to compare the SOFA score with those of the porcine model.
RESULTS. The hyperdynamic phase of increasing cardiac output with decreasing systemic vascular resistance was maintained until 2 hours, followed by the reverse hypodynamic phase. With the escalating requirement of fluid and vasopressor, the lactate level was progressively increased while platelet counts, urine output, and serum albumin level were consistently decreased. Bacteremia was developed at 7 hours after administration of feces and the *Escherichia coli* was the most common pathogen. The pattern of SOFA score with prominent cardiovascular failure was comparable to clinical data.
CONCLUSION. We implemented the porcine fecal peritonitis-induced sepsis model which demonstrates culture-proven bacteremia and multiple organ failure, particularly the cardiovascular system. This model could be utilized in the development of early diagnostic technology of bacterial pathogens in the blood.

Effect of recombinant human soluble thrombomodulin on coagulation and inflammatory markers in patients with sepsis-induced disseminated intravascular coagulation: a retrospective observational study

C. Mitaka, I. Kawagoe, D. Satoh, E. Inada
[1]Anesthesiology and pain medicine, Juntendo University, Hongo Tokyo, Japan

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000402

INTRODUCTION. Thrombomodulin (TM) on vascular endothelium binds to thrombin and acts as anticoagulant. In addition, the thrombin-TM complex activates protein C to produce activated protein C, which inactivates factors Va and VIIIa, thereby inhibiting thrombin formation. Furthermore, TM has anti-inflammatory and cytoprotective activities [1]. In Japan, recombinant human soluble TM (rhTM) has been used for treatment of disseminated intravascular coagulation (DIC) since 2008.
OBJECTIVES. The objectives of this study are to evaluate the effectiveness of rhTM on platelet count, fibrin/fibrinogen degradation products (FDP), prothrombin time (PT) ratio, and C-reactive protein (CRP) levels in patients with sepsis-induced DIC.
METHODS. We retrospectively searched patients with sepsis who were admitted to ICU between April 2015 and January 2019, and investigated patients who are diagnosed as sepsis-induced DIC and received rhTM. Sepsis was defined according to Sepsis-3. DIC was diagnosed based on DIC score ≥ 4 on the Japanese Association for Acute Medicine (JAAM) DIC scoring system [2]. Platelet count, FDP, PT ratio, DIC score, and CRP levels were collected. Dose and duration of rhTM was also collected. DIC resolution was defined as DIC score ≤ 3 by the day after the last rhTM.
RESULTS. Total 137 patients with sepsis were admitted to ICU and 34 patients (25%, 66 ± 15 years) out of them were diagnosed as sepsis-induced DIC and received rhTM. Sources of sepsis are abdomen (n =19), urine (n = 5), lungs (n = 3), skin (n = 2), blood (n = 2), and unknown (n = 3). The mean ± SD values of dose and the duration of rhTM were 292 ± 121 U/kg/day and 5 ± 2 days, respectively. The platelet count (median, IQR) increased significantly ($p < 0.001$) from 99 [41-99] to 147 [87-379] (×1000/μL) after rhTM administration. The PT ratio and FDP level (median, IQR) significantly ($p < 0.001$) decreased from 1.49 [1.27-1.66] to 1.13 [1.06-1.27] and from 30.75 [21.15-51.25] to 14.05 [6.7-17.8] (μg/mL), respectively. The DIC score (median, IQR) significantly ($p < 0.001$) decreased from 5[4.25-7] to 2[1-4] and 23 patients (68 %) were recovered from DIC after rhTM administration. The CRP levels (median, IQR) significantly ($p < 0.001$) decreased from 21.1 [14.4-28.0] to 8.2 [5.3-11.5] (mg/dL). Twenty eight-day mortality was 20.6%.
CONCLUSION. This study showed that rhTM significantly increased platelets counts and significantly reduced PT ratio, FDP level, DIC score and CRP levels, resulting in improvement of DIC in patients with sepsis-induced DIC. Further studies are needed to verify the effectiveness of TM-α on these patients.

Description of hemodynamic patterns of pediatric patients with septic shock during admission and after 48 hours in the ICU of IPPMG-UFRJ

C. cury, E. Gomes, R. Belmino
[1]PICU, Instituto de Puericultura e Pediatria Martagão Gesteira - IPPMG, Rio de Janeiro, Brazil

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000404

INTRODUCTION. Severe sepsis and septic shock are important issues of public health worldwide and persist as the leading causes of death in children under 5 years-old (with mortality rates around 25%).
We classified shock under two different patterns during clinical evaluation: hypodynamic shock, most frequent in patients who present with low cardiac output, and hyperdynamic shock, most frequent in patients who present with high cardiac output. Hypodynamic shock has been reported as the predominant type of shock in children. However, diagnosis made by clinical findings alone

has its limitations and we propose that, with adequate hemodynamic monitoring, we can find a change in the initial patterns of shock, often changing from the most prevalent hypodynamic shock to a hyperdynamic shock pattern 48 hours after admission.
It is of utmost importance identifying the hemodynamic type of shock to improve our clinical approach and treatment plans, both relevant to the outcome of patients
METHODS. This was a retrospective observational study aimed to classify and identify the hemodynamic profiles of patients admitted in the Pediatric Intensive Care Unit of Martagão Gesteira Pediatric Childcare Institute – Rio de Janeiro Federal University (IPPMG-UFRJ), between November 2016 and December 2018, as well as assess if there was any change, 48 hours after PICU admission, in the pattern initially identified.
RESULTS. 44 patients were included in the study, with median age 13.5 months, 75% presenting comorbidities, 40.9% with primary respiratory disease, and death occurring in 20.5% of patients. The shock pattern was observed at admission and 48 hours later for us to classify patients with hypodynamic or hyperdynamic shock. At admission, 9 patients (20.5%) had hyperdynamic shock and 35 patients (79.5%) presented with hypodynamic shock, with those numbers changing after 48 hours post admission, with 19 patients (43.2%) presenting with hyperdynamic and 25 patients (56.8%) presenting with hypodynamic shock. Within the patients who modified the shock pattern, 85.7% were from the hypodynamic group at admission, with statistical significance in the associations observed ($p < 0.05$ – Fisher's test). Clinical/Non-invasive criteria (97%) were predominant for the definition and initial approach of shock in the first evaluation at admission, followed by lactate (75%), central venous saturation and oxygen extraction rate (40.9%). Monitoring with invasive blood pressure (45%) and central venous pressure (34%) were less utilized as a primary tool.
CONCLUSION. Our results were compatible with recent researches, meaning that we observed a considerable percentual change in the hemodynamic profiles, mostly from a hypodynamic to a hyperdynamic type of shock, between ICU admission and the following 48 hours. Patients' evaluation was mostly through clinical evaluation, with only 40-45% of patients receiving invasive monitoring, which may have contributed to our findings. However, even within our limitations, it was indeed observed a clear pattern that seems to occur somewhat frequently, as described in similar studies on the subject.

INTRODUCTION. Bacteremia is common in severely ill patients. However, little research has been done on clinical characteristics and outcomes of bacteremia among patients with sepsis.
OBJECTIVES. We aimed 1) to compare the clinical characteristics and outcomes of severe sepsis patients with and without bacteremia, and 2) to assess the relationship between procalcitonin (PCT) and bacteremia, including different pathogen species.
METHODS. This is a secondary analysis of the sepsis cohort of the Focused Outcomes Research in Emergency Care in Acute Respiratory Distress Syndrome, Sepsis and Trauma (FORECAST) study, a multicenter, prospective cohort study of patients with severe sepsis which was conducted in 59 ICUs in Japan over 15 months [1]. Adult patients (≥16 years) with severe sepsis or septic shock admitted to a participating ICU were included. We compared characteristics and outcomes of patients with and without bacteremia. To know a characteristic of bacteremia of each pathogen in details, we also assessed the prognostic utility of PCT for bacteremia of each pathogen by drawing a receiver operating characteristics (ROC) curve.
RESULTS. One thousand one hundred sixty-seven patients from the FORECAST database met the study criteria. Among those, 636 patients (54.5%) with bacteremia were identified. Patients with bacteremia had significantly higher rates of septic shock than those without (422 [66.4%] vs. 313 [58.9%], $p<0.01$). There was no significant difference in the comorbidities of the groups. Sepsis severity scores such as APACHE II and SOFA were higher for patients with bacteremia than patients without bacteremia (median [interquartile (IQR)] 23 [18–30] vs. 22 [16–29], $p=0.02$ and 9 [6–12] vs. 8 [5–11], $p< 0.01$, respectively). Regarding the laboratory data, white blood cell count and platelet count were lower in patients with bacteremia

than in patients without bacteremia (median [IQR] 10,600 [4,760–17,300]/µL vs. 12,440 [6,620–18,430]/µL, p=0.02 and 12.4 [7.5–18.6] ×104/µL vs. 17.5 [11.1–24.5] ×104/µL, p<0.01, respectively). PCT concentration was significantly higher in patients with bacteremia than in patients without bacteremia (median [IQR] 21.3 [3.5–75.6] ng/mL vs. 5.2 [1.1–34.4] ng/mL, p<0.01). In-hospital mortality was 158/614 (25.6%) for patients with bacteremia and 108/515 (21.0%) for those without (p=0.08). Length of hospital stay was 23 (IQR 12–44) days for patients with bacteremia and 24 (IQR 13–50) days for those without (p=0.10). The area under the ROC of PCT for predicting bacteremia was 0.631. The optimal cutoff value of PCT for predicting bacteremia was 3.84 ng/mL. The highest PCT level was found in *Klebsiella* (median [IQR] 60.8 [20.8–130.1] ng/mL), followed by *E. coli* (30.0 [5.5–100] ng/mL) and *Pseudomonas* (24.7 [5.6–49.1] ng/mL). The lowest PCT level was found in *Staphylococcus* (7.7 [2.0–25.4] ng/mL).

CONCLUSION. Severe sepsis patients with bacteremia had more shock and higher severity scores than those without. However, there was not much difference between the two groups in outcomes such as in-hospital mortality. PCT levels were different among patients with bacteremia of different pathogen species.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000445

INTRODUCTION. Despite a decrease in the mortality rate of septic shock, morbidity remains high due to the sequelae of sepsis and prolonged stay in intensive care unit. Among the different sequelae included in the post-Intensive Care syndrome, Intensive Care Unit - associated weakness (ICU-AW) plays a particular role. This generalized muscle weakness affects 30 to 50% of septic shock patients and is associated with an increased duration of both mechanical ventilation and hospitalization. In addition, one-third of patients will suffer severe sequelae such as the inability to walk or breathe on their own. The pathophysiology of this syndrome appears to be multifactorial but is largely based on pre-clinical data: sodium channel inactivation, oxidative stress, proteolysis, mitochondrial dysfunction and muscle stem cell dysfunction.

OBJECTIVES. The objective of this study was to characterize in a multimodal way the early muscle dysfunction in patients with septic shock or severe sepsis compared to control patients.

METHODS. Three patient populations were included in the DISCUSS study: a septic patient population requiring surgery; an inflammatory non-septic patient population in brain death or cardiogenic shock; and a non-inflammatory non-septic patient population operated on scheduled visceral surgery. After obtaining the consent or non-opposition of the relatives (brain-dead state), patients were sampled when they went to the operating room or when they were placed on the ECMO with 2 cm3 of muscle and 5 ml of blood. This research has been approved by the Comité de Protection des Personnes Ile de France V (06/10/2015, N°15051). The samples were processed at the Institut Pasteur for mitochondrial morphological analysis by Transmission Electron Microscopy (TEM), proteomic analysis and analysis of mitochondrial parameters of muscle stem cells and serum.

RESULTS. Sixty-seven patients were included between June 2016 and April 2018. Eighteen septic patients, eighteen brain-dead patients, twelve cardiogenic shock patients and nine controls. The TEM analysis showed a difference in mitochondrial ultrastructure and a significantly different morphotype distribution: more type 2 morphotypes were found in the control group while there were more type 3 morphotypes (mitochondrial suffering with swelling and loss of peaks) in septic patients. Compared to the other conditions, proteomic analysis of septic patients showed significant differences in protein expression related to acetyl-CoA metabolism pathways, Krebs cycle, propanoate metabolism, amino acid biosynthesis and pyruvate metabolism. Serum analysis showed a significant difference between groups regarding the amounts of reactive oxygen species, of acetyl-CoA and of ATP but no differences were found regarding reactive nitrogen species and SOD activity.

CONCLUSION. In the acute phase of sepsis in humans, we therefore show an early muscle dysfunction secondary to mitochondrial damage and to a structural impairment of the proteins involved in muscle synthesis and proteolysis. Yet, we did not find any evidence for specific damage to satellite cells.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000447

INTRODUCTION. Sepsis is a life-threatening multi-organ dysfunction caused by dysregulated host response to infection with unmet clinical needs. In the context of adults, patients who survive sepsis can develop long-term immune dysfunction, with an expansion of the IL-33/M2 macrophages/regulatory T (Treg) cell axis (1). However, these findings were reported in humans and adult mice; however, there is no evidence of these alterations in the pediatric sepsis.

OBJECTIVES. To investigate the role of age in the genesis of immunosuppression following sepsis

METHODS. C57BL/6 mice (infant and adults) were submitted to sepsis and treated with antibiotic for three days. On day 15 after infection, Treg cells frequency and the activation of IL-33/Th2 profile cytokines/ILC2 cells/M2 macrophages axis were evaluated. To assess the immunosuppression, surviving sepsis mice were inoculated intranasally with *Pseudomonas aeruginosa* or by subcutaneous inoculation of B16LucF10 Melanoma cell line. Finally, blood samples from pediatric and adult surviving sepsis patients were collected and the Treg cells and Th2 profile cytokines were evaluated

RESULTS. Here we showed that sepsis surviving-infant mice, in contrast with the adult mice, were resistant to secondary infection and controlled the tumoral growth suggesting the non-development of immunosuppression. Mechanistically, the "resistance" was related to the decrease in *Foxp3* expression, lower phosphorylation of SMAD2/3

on TCD4+ cells and reduction in Tregs cell expansion and FOXP3 stability. Furthermore, infant mice presented lower production of IL-33 as well as a lower expansion of ILC2 cells and production of Th2 profile cytokines (IL-4 and IL10), leading to a progressive decrease in the M2 macrophages population and Tregs cell expansion. Importantly, in a translational manner, we demonstrated that sepsis-surviving pediatric patients, in contrast to adult patients, did not exhibit an increase in Treg cell, IL-33 and IL-10 in their peripheral blood, indicating that "resistance" to the development of immunosuppression observed in infants could be associated with the impairment of the IL-33/cytokines of the Th2 profile/ILC2 cells/M2 macrophages/Tregs cells axis

CONCLUSION. These findings demonstrate for the first time that the immunosuppression post-sepsis is related to the age of host. Thus, a better understanding of the process could lead to differential therapeutic treatments of adult and pediatric sepsis.

INTRODUCTION. Cardiac function is known to be negatively impacted by sepsis. Stroke volume (SV) change in response to Passive Leg Raise (PLR) is an effective method to predict fluid responsiveness (FR) or cardiac response to preload expansion. Preload functional status and trends in cardiac output may identify patient phenotypes with varying cardiac reserve, dysfunction and outcome.

OBJECTIVES. The goal of this study is to identify resuscitation phenotypes based on fluid responsiveness and evidence of cardiac dysfunction, and assess outcome differences between them

METHODS. FRESH is randomized controlled study, evaluating the incidence of FR in critically ill patients with sepsis or septic shock (NCT02837731). Patients randomized to PLR guided resuscitation were classified as FR if SV increased ≥ 10% when measured with non-invasive bioreactance (Starling SV, Cheetah Medical). Patients were characterized asNon FR if SV increased <10%. Patients were grouped into 6 different sextets based on the percentage of FR PLRs. Patients in Group 1 (N=11) exhibited 100% FR PLRs, where Group 2 (N=5) exhibited between 80-90% FR PLRs. Groups 3-5 (N= 19, N=26, and N=20) exhibited FR rates between 5-75%, with Group 6 (N=15) exhibiting 0% incidence of FR PLRs.

RESULTS. A total of 670 PLR assessments were performed in 96 patients over a 72 hour monitoring period. 60 % were female, and the average age was 61 years. Overall, 40% of assessments demonstrated a FR positive response after receiving initial resuscitation fluid of 2.3 (+/- 0.6) L. There were no differences among the 6 groups with respect to age, gender, or QSOFA score. Fluid responsiveness was dynamic changing over the 72 hours of the study. When Groups 1-3 (54%-100% incidence FR PLRs) were compared to Groups 4-6 (50%-0% incidence FR PLRS) there were differences in patient outcome. Patients in Groups 1-3 exhibited a significant reduction in need for new onset dialysis (0%) compared to groups 4-6 (18%), p=0.012, and a decreased incidence of MACE (0% compared to 11.7%, p=0.04). Patients in Groups 1-3 also exhibited a notable trend toward decreased mortality (8.6%) compared to Groups 3-6 (25%) p=0.059. Patients in Group 6 exhibited the highest incidence of mortality during the 30 day follow up period (40%).

CONCLUSION. Short-term sepsis resuscitation phenotypes based on SV and responses to PLR identify discrete and significantly different patient sub-groups. Patients who were FR, and who augmented CO in response to the resuscitation experience decreased need for dialysis and a decreased incidence of MACE, as well as a trend towards decreased mortality. Periodic dynamic monitoring may predict patient outcome and guide treatment for sepsis-associated cardiac dysfunction.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000471

INTRODUCTION. In sepsis, blood hypo-flow into the splanchnic territory has been related to cytopathic hypoxia, microcirculatory dysfunction, gut bacterial overgrowth, gut barrier dysfunction, bacterial translocation, activation of lymphoid tissue associated with the intestine and exacerbation of systemic inflammation in the host, culminating with organic dysfunction and clinical worsening [1-3]. The main hypothesis for these events has been attributed to the selective reduction of physiological blood flow to the gut in order to preserve the nobler organs for the preservation of life. However, the dynamics of splanchnic blood flow distribution during sepsis and survivors remains relatively unknown.

OBJECTIVES. Evaluate the kinetics of blood flow distribution to splanchnic territory in the acute phase of sepsis and after recovery from sepsis.

METHODS. Following DL50 sepsis model induction (2mL E.coli 108 CFU/mL, iv) in adult Wistar female rats, the animals were monitored to macro (MAP, HR and abdominal aorta blood flow by Transonic, TS420 transit-time flowmeter), regional (mesenteric artery, celiac trunk artery and portal vein by Transonic, TS420 transit-time flowmeter), and micro hemodynamics (kidney cortical microcirculation by SDF videomicroscopy). Animals were monitored at before sepsis (T-0) and at 3 hours (T-3h), 6 hours (T-6h) and 1month (T-1m) post-sepsis periods. Naïve animals (N) were used as control. (n=4-5/period). All rats were euthanized at the end of experiments.

RESULTS. The results showed a significant fast fall of the aorta's blood flow until 6h after sepsis induction and partial recovery at 1 month, but not reaching T-0 value. The celiac trunk artery, mesenteric artery and portal vein showed a significant blood flow decrease up to 6h after sepsis induction and remained significantly low up to 1 month after sepsis (fig1). These observations were even more evident when verifying the delta-percent of their blood flow decay in relation to the naive group without sepsis (T-0h). (Fig.2). Following, when examined the proportion of blood flow of the same vessels in relation to of the aorta flux to evaluate the blood fraction distribution, we observed a similar pattern in all splanchnic vessels (fig.3). The percentage of flow from the aortic artery to the celiac trunk artery increased in the acute phase of sepsis (T-3h and T-6h)

suggestive of the hyperdynamic phase in this DL50 model of sepsis, and after 1-month survival presented a significant reduction of their distributive percentage compared to the other periods. The blood flow to the mesenteric artery and portal vein showed a similar pattern between T-0 and T-3h periods but was significantly decreasing in other periods. These data suggest that the blood flow of splanchnic vessels and of the abdominal aorta do not return to normal levels until 1 month after sepsis, and this hypovolemic feature may be associated with the chronic oxygen deficiency stress in splanchnic organs.

CONCLUSION. Splanchnic hemodynamics decays substantially since the early acute phase of sepsis and remains in a state of hypovolemic stress up to one month after recovery. Studies are evaluating if this hemodynamic dysfunction in post-sepsis is transitory or permanent.

INTRODUCTION. Bacterial CNS infections lead to high morbidity and mortality requiring early diagnosis and treatment. The aim of the study is to assess the utility of PCT and lactate levels in the cerebralspinal fluid (CSF) as biomarkers of bacterial infection in neurocritical patients.
METHODS. An observational study of a group of 65 patients admitted to an ICU of 18 beds between the period of July 2017 and December 2018. Patients who, due to admission to ICU, were included in the analysis of the CSF. Demographic variables, lactate and PCT in blood and lactate, PCT, Gram staining and CSF culture were collected. The CSF PCT/serum PCT and CSF lactate/serum lactate quotients were also analyzed. The patients were put into 2 groups and were classified according to the final diagnosis: bacterial infections of the CNS and other CNS affections.
RESULTS. In the sample analyzed (n = 65), 61.5% were men. The mean age was 54 ± 16. Mortality was 21.5%. The average APACHE II was 25.3 ± 6.4 and the average SOFA of 6.1 ± 3.2. With an average PCT in CSF of 0,5 ± 1,6 ng/mL and an average lactate in CSF of 36,4 ± 30,4 mg/dL. In the group of bacterial infections of the CNS, Gram staining was positive in 54.55% of the cases. The culture was positive in all of them. The isolated germs were: *S. Pneumoniae* (45.4%), *E. Coli* (18.2%), *L. Monocytogenes* (18.2%) and *M. Tuberculosis* (18.2%).
CONCLUSION. PCT in CSF is not a useful biomarker for the diagnosis of bacterial infections of the CNS. Lactate in CSF is elevated in different pathologies of the CNS, being significantly higher in bacterial infectious pathology. In addition, lactate index CFS/serum could be a good early marker of bacterial infection of the CNS.

Table 1 (abstract 000472). See text for description

	Bacterial infections CNS (n = 11)	Other affectations CNS (n = 54)	p
Serum PCT (ng/mL)	9.3 ± 13.6	7.1 ± 28.9	NS
Serum lactate (mg/dL)	15 ± 6.1	22.1 ± 25.1	NS
CSF PCT (ng/mL)	0.7 ± 1.5	0.4 ± 1.6	NS
CSF Lactate (mg/dL)	90.4 ± 38.2	25.4 ± 10.6	< 0,01
CSF PCT/serum PCT	9.2 ± 13.6	11.2 ± 29.1	NS
CSF lactate/Serum lactate	6.4 ± 2.5	1.9 ± 1.6	< 0,01

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000498

INTRODUCTION. Hyperchloremia is known to be associated with poor clinical outcomes in sepsis patients. However, the clinical significance of hypochloremia is not well studied.
OBJECTIVES. We investigated the association between hypochloremia and mortality in patients with septic shock.
METHODS. This is a retrospective analysis of prospectively collected multicenter registry including 11 emergency departments. The Outcome was defined as 28-day mortality. Patients were divided into three groups according to initial serum chloride level; hypochloremia (<98 mEq/L, 760/2037 [37.3%]), normochloremia (between 98 mEq/L and 110 mEq/L, 1182/2037 [58.0%]), and hyperchloremia (>110 mEq/L, 95/2037 [4.6%]). Multivariate logistic regression analysis was used to test the independent association between chloride categories and the 28-day mortality.
RESULTS. The 28-day mortality rates were 34.7% (33/95), 23.8% (181/760), and 19.2% (227/1182) (Chi square test, p <0.001) in

hyperchloremia, hypochloremia, and normochloremia groups, respectively. Multivariate logistic regression analysis showed that both hyperchloremia (adjusted odds ratio [OR], 1.65, 95% confidence intervals [CI], 1.00–2.70; p value, 0.048) and hypochloremia (adjusted OR, 1.30, 95% CI, 1.02–1.67; p value, 0.035) were independently associated with 28-day mortality.

CONCLUSION. Hypochloremia (37.3%) was more frequently observed than hyperchloremia (4.6%) and it was independently associated with 28-day mortality in patients with septic shock in the emergency departments.

Candidemia in intensive care unit patients, study from a tertiary care hospital in Dubai

A. Alsabbah[1], M. Salam[1], H. Celiloglu[2], S. Tausif[2], S. Al-Sabbah[3]
[1]Intensive care unit, Mediclinic City Hospital, Dubai, UAE; [2]Microbiology department, Mediclinic City Hospital, Dubai, UAE; [3]Department of statistics, Administration and Economics college, Kerbala University, Karbala, Iraq

Correspondence: A. Alsabbah

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000520

INTRODUCTION. · Candidemia remains a major cause of morbidity and mortality in the health care setting, and the epidemiology of Candida infection is changing.

· . Non-albicans Candida species have emerged as major causes of candidemia in many countries. Added to it is the problem of antifungal resistance in Candida isolates.

OBJECTIVES. · To find out the prevalence of candidemia in our intensive care unit (ICU), the ratio of candida albicans to non albicans and what are the difference in the outcome of each type along with the antifungal susceptibility pattern of Candida isolates and various risk factors associated with candidemia.

METHODS. · A single-center, retrospective analysis over 5 years covering the period from January 1, 2012 to December 31, 2017 was performed.

· The epidemiology, risk factors, demographic features, species distribution, and clinical outcome associated with candidemia in patients admitted to a single tertiary-care hospital in Dubai, were analyzed.

RESULTS. A total of 30 Candida isolates were isolated during the study period (overall incidence of 13.5 cases/1,000 ICU admission). Candida Non albicans were isolated more than Albicans in 63% (n= 19) vs 37% (n=11). Among Non albicans Candida parapsilosis was the most common isolate 58.8% (n=10) followed by Candida tropicalis 26.3% (n=5), Candida glabrata 11.8% (n=2) while only one case isolated of Candida kefyr and Candida auris. 26 Candida isolates (86.7%) were pansensitive while 4 isolates (13.3%) were resistant to fluconazole & amphotericine B.

· The most common medical problem associated with candidemia was cancer patient followed by Diabetes Mellitus, CVA and renal failure. The risk factors commonly associated with candidemia patients were use of central venous catheters, mechanical

ventilation, hemodialysis or CRRT, abdominal or pleural drain, Trans parenteral nutrition and post abdominal surgery.
· There was no significant difference in mortality between male and female 60% vs 55% while the mortality was significantly higher in old age group above 60 year old comparing to younger patient than 60 (58% vs 33%). The species distribution and outcome of candidemia showed significant difference in the crude mortality between patients infected with C. albicans and non-albicans 45% vs 63% while among non albicans candidemia both candida Tropicalis & candida Parapsilosis had the highest mortality rate around 60%.
CONCLUSION. Candidemia is emerging as a significant problem in hospitalized patients. Non-albicans Candida species are the major cause of candidemia as found in our study. The epidemiology and choice of therapy for candidemia are rapidly changing. Additional multicentric studies involving many hospitals are required to know the true prevalence of candidemia, differences in virulence among Candida species and to determine the best therapeutic regimen.

Time for antibiotics on sepsis: ¿How much earlier is the earliest? A propensity score analysis

J. Ascuntar[1], D. Mendoza[1], F. Jaimes[2]
[1]Internal medicine, Universidad de Antioquia, Medellin, Colombia; [2]Direccion de investigaciones, Hospital Universitario San Vicente Fundacion, Medellín, Colombia
Correspondence: F. Jaimes
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000546

INTRODUCTION. Early use of antibiotics is a critical point in the treatment of patients with sepsis. The exact time of initiation is controversial and may be a difficult intervention in crowded emergency services
OBJECTIVES. To estimate, using a matched propensity score, the effectiveness on hospital mortality of using antibiotics within one or three hours of diagnosis of sepsis, on patients hospitalized by emergency services (ES)
METHODS. Secondary data analysis of a prospective cohort conducted between 2014 and 2016 in three emergency services of university hospitals in Medellín, Colombia. A propensity score analysis for use of antibiotic, both within one and three hours of admission by the ES, was fitted with 28 variables related with clinical attention and physiological changes. As a sensitivity analysis, a logistic regression model was fitted for antibiotic use adjusted both by propensity score and confounding variables.
RESULTS. The study cohort was composed of 2,454 patients with a median age of 62 years (IQR=46-74). Among them, 32% (n=781) received antibiotics within three hours and 14% (n=340) within the first hour. The main diagnosis were urinary tract infection (28%, n=682) and pneumonia (27%, n=671). Blood cultures were requested in 87% (n=2140) and yielded positive in 29% (n=629), mainly with *Escherichia coli* (37%, n=230), *Staphylococcus aureus* (21%, n=132) and *Klebsiella pneumoniae* (102%, n=64). Hospital mortality rate was 11.5% (n=283). There were no significant differences in mortality using antibiotics either in the first hour (OR 1.09; 95% CI = 0.69; 1.72) or three hours (OR 0.98; 95% CI = 0.74; 1.32). There were no changes with different models for sensitivity analysis (Table).
CONCLUSION. Despite the obvious constraints given for sample size and residual confounding, our results suggest that we need a more comprehensive approach to sepsis treatment, considering multiple interventions and goals beyond the simple time-to-antibiotics

Table 1 (abstract 000546). Effectiveness of antibiotic prescription within one or three hours of admission by emergency services in patients with sepsis

Model	≤ 1 hour	≤ 3 hours
Matched by propensity score	OR (95%CI), n=680	OR (95%CI), n=1562
Without adjustment	1,09 (0,69-1.72)	0,98 (0,74-1,32)
Adjusted by propensity score	1,05 (0,66-1,77)	0,86 (0,63-1,17)
Adjusted by covariates*	1,07 (0,65-1,75)	0,93 (0,67-1,28)
Adjusted by PS and covariates*	1,03 (0,63-1,7)	0,85 (0,61-1,20)
Total Cohort (n=2454)		
Without adjustment	1,13 (0,8-1,6)	1,28 (0,99-1,66)
Adjusted by propensity score	0,94 (0,63-1,40)	0,89 (0,67-1,2)
Adjusted by covariates*	0,98 (0,66-1,45)	1,04 (0,77-1,4)
Adjusted by PS and covariates*	0,89 (0,58-1,37)	0,87 (0,63-1,22)

Associated factors to the presence of agitation in maxillofacial surgery postoperative

R. Padilla[1], M. Dalorzo[1], F. Moran[1], M. Sanchez Casado[1], R. Martin[2]
[1]Icu, Virgin Health Hospital, Toledo, Spain; [2]Maxillofacial surgery, Virgin Health Hospital, Toledo, Spain
Correspondence: R. Padilla
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000095

INTRODUCTION. Patients undergoing elective and major maxillofacial surgery are one of the groups of greater risk of psychomotor agitation. It is associated with a greater frequency of complications, longer stay in ICU and hospital stay.
OBJECTIVES. Evaluate the factor asociated to the presence of agitation in maxillofacial surgery postoperative.
METHODS. Retrospective revission in the clinical histories of the patients entered into ICU in the prospector of maxillofacial surgery higher in the last 6 years.
It was recorded basal variables, records, clinics and evolutive. To determinate the agitation it was used Riker scale and AgitatedBehaviorScales (ABS) scale. And we define psychomotor agitation as a ABC value bigger than or equal to 21. The cuantitative data are expressed like medium (interquartile range) and cathegorics like counting (percentage).
RESULTS. We get 60 patients, of wich 28 (46,7%) were agitated patients. We compare patients without agitation regarding patients with agitation. There are differences in males (78,1% vs 96,4%; p= 0,037); the most important history antecedent was to be an active drinker (43,8% vs 64,3%; p=0,112); SOFA (1(1-1) vs 1(1-2);p=0,022). Tracheostomy was present (78,1% vs 96,4%;p=0,037).
There are evolutionary differences in re-surgery (21,9% vs 50%;p= 0,023), infectious complications in ICU (12,5% vs 42,9%;p=0,008), rebleeding (9,4% vs 28,6%; p=0,055) and graft thrombosis (6,3% vs 21,4%;p=0,084); longer sedation time, (1 (1-1,5) vs 4 (2-7) days; p= 0,001); start weaning (1 (1-1) vs 2 (1-3) days; p<0,001); mechanical ventilation duration (1 (1-2) vs 4 (2,5-9,5) days; p<0,001); days in ICU (3 (2-5,5) vs 4 (1,5-6,5) days; p<0,001).
CONCLUSION. Know the factors asociated to psychomotor agitation in the maxillofacial surgery postoperative will help us to get better in knowledge and use prophylaxis of it in certain treatment groups

Another New Attempt of Combination of Sedative Agents in Repeated Treatment for Pediatric Patients with Hemato-Oncology Disease

H. Koh, J. Huh, L. Min Soo

[1]Anesthesiology and pain medicine, The Catholic University of Korea Seoul St. Mary's Hospital, Seoul, Republic of Korea

Correspondence: H. Koh

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000266

INTRODUCTION. Many procedures and tests have been performed for the diagnosis and treatment of children. Young patients feel anxious and fear for repeated tests and procedures irrespective of the occurrence of pain. Many hours and manpower are consumed throughout all these process.

OBJECTIVES. These were two cases about the deep sedation which was undergone daily radiation therapy (RT) due to malignant solid tumor. They were failed in previous sedation with other agents (chlroral hydrate and midazolam), so referred to our department to solve the problem.

METHODS. One is the case for a 5 year-old-child (weight 20.8~22.9 kg) who was diagnosed into anaplastic ependymoma. After suboccipital craniotomy with tumor removal, they were scheduled to 28 fractions tomotherapy 1.8 Gy/d (total of 50.4 Gy/28d) at two target sites; posterior cranial fossa and spine. The other is for a 34-month-old infant (weight: 12.7~12.9 kg) was diagnosed to neuroblastma in adrenal gland with metastasis. After liver wedge resection and Lt. adrealectomy, they were scheduled to 12 fractions tomotherapy 1.73 Gy/d (total of 20.76Cy/12d) at two target sites; Lt. adrenal area and Rt. Fibular. Before RT, the former, midazolam 0.05mg/kg was injected and the latter, dexmedetomidine (Dex) 1mcg/kg for 10minutes as premedication. In both cases, after premedications were applied, three times of 1mg/kg of 1% propofol at a time were administered and then 150mcg/kg/min were continuously infused during RT. Blood tests were performed the next days after radiotherapy.

RESULTS. In both of these cases, there were no abnormal findings other than mild decreased hemoglobin, platelet and ANC (absolute neutrophil count) by bone marrow suppression. They were done all RT cycles well and discharged without complications. there were no gradual increases in dose of sedatives and drug dependence which were resulted from repeated sedation. In addition, hemodynamic adverse reactions; severe hypo or hypertension and bradycardia except for slight hypotension (systolic blood pressure 85~95mmHg) during sedation were not observed and other vital signs; pulse rate, SpO2 (saturation of percutaneous oxygen), respiration rate were kept constant within normal range. In sedation status, the RSS (Ramsay sedation scale) was maintained satisfactorily at level 4~5 and the Bispectral Index for measuring anesthetic depth was also showed at 40~50.

CONCLUSION. Generally, midazolam and propofol are widely used in procedural sedation. Recently, various trials through Dex are applied. The use of Dex is increasing as the way to maintain a safe sedation in cases of respiratory problems or in ICU. However, Dex alone is not enough to maintain an effective anesthetic depth during procedures or clinical tests, and does not show the same effect as propofol with shorter duration and recovery. However, due to the side effects of benzodiazepine as a sedative, it has gradually been replaced by other stable sedative agents, one of which is Dex. Therefore, Dex instead of midazolam was used as an adjuvant agent based on propofol sedation. Through this case, we suggest that Dex was able to maintain the sedation reliably when it is used as only pretreatment loading and also strengthen the sedation state even though not a the continuous infusion of Dex.

The effect of polyolefin bag preservation with shaking on human platelet functions in hemodilutional autologous blood transfusion

Y. Murata, S. Kawamoto, K. Fukuda

[1]Department of Anesthesia, Kyoto University Hospital, Kyoto, Japan

Correspondence: Y. Murata

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000273

INTRODUCTION. In recent years, hemodilutional autologous blood transfusion (HAT) has attracted attention for its effects in reducing hospital stay days and postoperative complications in cardiovascular surgery. HAT is a blood conservation technique using polyvinyl chloride bag with CPDA fluid including citrate sodium, glucose, adenine and sodium dihydrogenphosphate at room temperature without shaking. But this is not suitable for maintaining platelet functions because of low pH of CPDA fluid, and low gas permeability of polyvinyl chloride bag. At present, HAT has not been implemented mainly for the purpose of hemostasis. Therefore, there is a need to develop new HAT that can preserve platelet functions and be used as an optimal hemostatic products in cardiovascular surgery.

OBJECTIVES. The aim of this study is to find storage conditions that can best maintain platelet functions. We used polyolefin bag with shaking to maintain platelet functions. Since polyolefin have high gas permeability, shaking storage can release carbon dioxide generated by the equilibrium reaction of lactic acid and bicarbonate, and maintain an appropriate pH.
METHODS. Informed consent was given and the protocol was approved by the ethical committee. Venous blood was taken from 3 healthy volunteers who had not taken any medication at least for two weeks before blood collection. 50 ml of whole blood were preserved in polyolefin bag with shaking at 50/min or polyvinyl chloride bag without shaking for 8 hours at 22 degrees Celsius. CPDA fluid was used as preservative solution. We performed blood gas analysis (PaO2, PaCO2, pH, BE, lactate, HCO3-), complete blood count (hematocrit, platelet count, mean platelet volume (MPV)) and platelet function tests including ADP-induced aggregability using light transmission method and P-selectin expression with or without ADP stimulation using flow cytometry at 0 and 8 hours after blood collection. Wilcoxon signed rank test was used to compare the two groups. P values less than 0.05 were considered to indicate statistical significance.
RESULTS. No statistically significant difference was found between the two groups in any of the items, but in the polyvinyl chloride group and the polyolefin group, the aggregability was reduced by 61.0% and 25.3%, non-ADP stimulated P-selectin expression was increased by 193.7% and 104.5%, after 8 hours, respectively. MPV and ADP-stimulated P-selectin expression were almost similar. The polyolefin group had tendency to keep PaO2 high, PaCO2 low, and pH high. P-selectin expressions with or without ADP stimulation represent potential platelet adhesivity and platelet activation level by HAT procedure itself, respectively. MPV indicates platelet activation. Further cases are needed to determine whether platelet functions are maintained in the polyolefin group due to the high oxygen permeability with shaking. 8 hours might be too short to detect the superiority of polyolefin storage in platelet aggregability and adhesivity. Other platelet function evaluations, including release ability, hypotonic shock recovery rate, intracellular Ca concentration, clot dynamics, and morphology are needed to clarify the effectiveness of polyolefin preservation with shaking.
CONCLUSION. Further evaluations are needed to confirm the usefulness of polyolefin preservation with shaking on maintaining platelet functions.

Use of parenteral iron in the perioperative resuscitation of hip fracture patients – a quality improvement project

JM. Dudziak, A. Ahsan, D. Factor
Anaesthetics, Queen Elizabeth Hospital, London, UK, UK
Correspondence: J.M. Dudziak
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000624

INTRODUCTION. Blood loss in hip fracture patients is common, resulting both from initial trauma and subsequent operative intervention. As UK national standards mandate operative fixation within 36h of presentation to hospital, rapid correction of anaemia is paramount to optimise postoperative mobility (*Lawrence 2003*). However, multi-centre trials have found no benefit from using a liberal (transfusion if Hb <100 g/L) over a restrictive strategy (Hb <80 g/L or patient symptomatic) (*Carson 2011*), indicating that adverse effects of red cell transfusion could offset the potential benefits of higher Hb levels. Parenteral iron replacement promises to increase Hb without transfusion-related morbidity (*Bernabeu-Wittel 2016*).
OBJECTIVES. To assess and optimise our use of parenteral iron to treat iron deficiency in anaemic hip fracture patients.
METHODS. Initial cohort of 43 consecutive hip fracture patients, median age 81, 63% female, admitted to our UK district general hospital over six weeks from November 2018 to January 2019. Forty patients survived to operative fixation and were included in the primary analysis. We deployed a care bundle to improve testing for and correction of perioperative iron deficiency in April 2019, will assess its impact in June and present our findings at the congress.
RESULTS. All but one (97%) patient were anaemic (Hb <130 g/L, from *Muñoz 2017*) during their inpatient episode. Thirty-seven (93%) patients had their serum iron levels measured, which was low in 29 (78%) cases. Only four patients (10%) had transferrin saturation (TSAT) measured, which were low in all cases (100%). Ferritin was measured in 21 (53%) patients, but only in three (13%) cases was less than 100 mcg/L (threshold in presence of inflammation, from *Muñoz 2017*). Twelve patients (30%) received ferric carboxymaltose (FCM), all with low serum iron levels. However, only two (50%) of the patients with low TSAT, and only one (33%) of the patients with low ferritin received FCM. Seventeen patients (59%) with low serum iron did not receive FCM, although four of those patients additionally had either low TSAT or low ferritin, see above.
CONCLUSION. Both anaemia and iron deficiency were extremely common. Serum iron was the most commonly used biomarker of iron deficiency and showed overwhelmingly low iron stores in our cohort. TSAT was underused, despite being the most sensitive marker for insufficient iron supply in the presence of trauma. Ferritin, despite still being the diagnostic mainstay (*Muñoz 2017*) was poorly sensitive in our cohort, likely due to false elevation as part of the acute phase response. Although most patients would likely have benefited from parenteral iron replacement, only a minority received it. We will intensify staff education, deploy a care bundle containing prompts for blood sampling as well as indications for parenteral iron replacement and will report the result of this intervention at the congress.

New recombinant antithrombin gamma may improve its activity and coagulation abnormality

H. Miyazaki, R. Furuya, K. Takada, R. Matsumura
Emergency and critical care medicine, National Health Organization Yokohama Medical Center, Yokohama, Japan
Correspondence: H. Miyazaki
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000852

INTRODUCTION. The coagulation system in human is extraordinarily fragile. Various stimuli may deteriorate the system, cause life-threatening events such as Disseminated intravascular coagulation (DIC). Replacement of decreased antithrombin may improve the coagulopathy caused by noxious stimuli such as sepsis or severe trauma.
Recently, recombinant antithrombin gamma (Kyouwa Hakkou Kirin Co.Ltd. Tokyo) has been introduced into Japan. This novel recombinant protein will reduce adverse effects related to the blood extracts, but also may diminish the problem of blood supply.
We investigated the efficacy of the newly introduced recombinant antithrombin. This study is a brief report of the administration of the antithrombin gamma for 54 patients who were diagnosed as DIC or decreased antithrombin activity.
METHODS. From December 2017 to November 2018, 54 patients who were diagnosed DIC and were administered the antithrombin

gamma were surveyed by retrospectively using medical records. The collected data were as follows, patients age, sex, body weight, the illness of patients, acute DIC scores (defined by the Japanese Society of Emergency and Critical Medicine), dose of study drug, other combination therapies and prognosis of the patient.

RESULTS. In 54 studied patients, 34 cases were diagnosed DIC; however, all patients showed antithrombin activities below 70% of normal. Twenty-eight in 54 patients had sepsis. The average dose of the antithrombin gamma was 1877±450U. The administration days were 1 day (1 to 14 days) in 65% of cases. Administration of the antithrombin gamma had increased antithrombin activities linearly. Average activity before administration and after were 47±12% and 72± 12%, respectively. Eleven in 34 patients recovered from DIC after administration. Also, 36 in 54 patients were survived at the time of discharge.

CONCLUSION. Various stimuli may cause abnormality of coagulation systems. Despite a long history of investigations, there have been no well-established therapies. However, antithrombin administration for the patients who were suffered by coagulopathy is a controversial issue; some guidelines mention about this therapy. Recently, recombinant antithrombin has been developed and introduced into clinical practice. Our result showed the recombinant antithrombin gamma restored the activity of antithrombin, and recover from DIC in one-third of the study group. This finding is compatible with the former studies of antithrombin administration which was extracted from the human blood. In the study group, we have not experienced any adverse events related to the antithrombin gamma. A phase I trial of the antithrombin gamma has been conducted in Europe from April 2018. Still, little literature revealed its feasibility and equivalency of AT gamma over conventional antithrombin. We will need to further investigations, especially a RCT, to assess the efficacy and safety of the recombinant antithrombin gamma.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000962

INTRODUCTION. Objective: Presenting clinical and epidemiological data of patients with a radical cystectomy with urinary diversion who required ICU admission.

METHODS. Retrospective, descriptive study of patients admitted in ICU from May 2018 to December 2018. Clinical, epidemiological and result-related variables were analyzed. Quantitative variables are expressed as mean and standard deviation, while qualitative variables are expressed as ratios and absolute value.

RESULTS. A total number of 15 patients took part in this study; mean age was 60.73 ± 9.49 years (73.3% were males). APACHE II at admission was 10.6 ± 1.35. SAPS3 52.6 ± 10.03. Between the comorbidities 40% of the patients presented high blood pressure, 26.7% had dyslipidemia, 20% were diabetics, 46.7% were smokers, 13.3% took alcohol, and 26.7% had others as obesity or COPD. 6.7% had no comorbidities. All of the patients had history of urological disease; the most frequent were prostatic hyperplasia (13.3%) and urinary tract infections (UTI) (13.3%). Previous abdominal surgery was performed in 26.7% of the patients. In 12 of the cases the radical cystectomy was necessary because of muscle-infiltrating urothelial bladder carcinoma. Two patients required the surgery because of obstructive problems, and one of them because of neurogenic bladder (multiple sclerosis). 66.7% patients received at first transurethral resection (TUR). 6.7% required chemotherapy before the procedure; braquitherapy was administered also in 6.7%. None of them had neoadjuvant radiotherapy. The most common urinary diversion was Bricker (only one was Nesbitt). At the ICU admission 53.5% of the patients presented creatinine values between 1 and 1.5mg/dl. 33.3% had light metabolic acidosis and none of them hydroelectrolyte imbalance.Peri and postoperative antimicrobial prophylaxis with Amoxicillin-Clavulanic was done in 80% of the patients; 13.3% were treated with Quinolones and only in 6.7% Piperacillin-Tazobactan was used. 26.7% (4) of our patients had complications, the most frequent was paralytic ileus (50%); 25% had acute renal failure, and only one (25%) had minor bleeding which didn't need surgery. A patient need re-entry en UCI due to Sepsis of unknown origin, dying after 7 days of intensive therapy. Average ICU stay was 1.26 ± 0.59 days. ICU mortality rate was 6.7% and one-year mortality after the cystectomy was 20%.

CONCLUSION. The profile of the patient admitted to the ICU after cystectomy is a 60 year old patient with comorbidities, muscle-infiltrating urothelial carcinoma and normal renal function, to those who underwent prophylactic treatment with Amoxicillyn-Calvulanic. A good postoperative progress and no re-entry en ICU was observed.

Preeclamsia patients who need ICU: A descriptive study

MP. Benítez Moreno[1], C. Joya Montosa[1], JF. Martínez Carmona[1], MJ. Delgado Amaya[1], MA. Barbancho Fernández[2]
[1]Intensive care unit, Regional Hospital of Malaga, Málaga, Spain; [2]Fisiology department, University of Malaga, Málaga, Spain
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000966

INTRODUCTION. We consider severe preeclampsia when the increase in blood pressure is associated with certain symptoms, analytical alterations, oligohydramnios or Intrauterine *growth restriction* (IUGR). Treatment sometimes requires admission to the ICU, depending on the severity of the episode, aimed at controlling blood pressure levels with maternal and fetal monitoring, maturing the fetus, if necessary, and avoiding possible complications.

METHODS. We conducted a descriptive retrospective study in which the patients who required admission to the gynecological ICU in our hospital were collected during 2018 with a diagnosis of gestosis to evaluate the type of preeclampsia, the treatment performed and the results obtained.

RESULTS. A total of 14 patients diagnosed with preeclampsia, who required admission to the ICU during 2018, were collected. The gestational age was between 22 and 39 weeks. Fetal maturation with betamethasone was performed in 64.3% of the cases, only 14.7% if the pregnancies were multiple. All patients who required admission to the ICU were diagnosed with severe preeclampsia. The most frequent symptoms that they presented were visual anomalies (85.7%), followed by edema and abdominal pain (71.4% each), headache (57.1%) and proteinuria (42.9%). No cases of acute pulmonary edema (APE) or oliguria were observed. Upon admission to the ICU, 71.4% had SBP ≥ 160 mmHg with a medium of 120.7 and a typical deviation of 14.16. 100% required more than one antihypertensive to control blood pressure and in all cases labetalol was used, followed by hydralazine (71.4%), alpha methyl dopa (42.9%), and nifedipine (21.4%) . Magnesium sulfate was used in

71.4% of the cases, with a mean dose of 6.28 g /day and a standard deviation of 4.87. End of the pregnancy for maternal or fetal benefit was needed in most of the cases, been early caesarean section performed in 85.7% of patients; only 1 case was delayed 9 days due to low gestational age. Maternal complications after ICU admission only appeared in 3 of the 14 cases and were: 1 post-cesarean bleeding, 1 urinary tract infection and 1 case of paralytic ileus. As far as the fetus IUGR was observed in 14.3% of the cases and only one presented oligohydramnios. Maternal survival was 100% meanwhile 87.5% was observe in newborns.
CONCLUSION. All patients admitted to the ICU due to gestosis present criteria of severe preeclampsia. The most frequent symptoms were visual alterations, abdominal pain and edema. A 71.4% on admission showed arterial hypertension. 100% of the cases required more than 1 antihypertensive for the control of blood pressure in the ICU, being labetalol the antihypertensive that was administered in all cases. It is a small sample but with full survival despite the severity of the case we continue with the collection of data to confirm that patients diagnosed with severe preeclampsia benefit from admission in ICU.

Andalusian Women preeclampsia: ICU epidemiology

MP. Benítez Moreno[1], C. Joya Montosa[2], E. Trujillo García[2], MJ. Delgado Amaya[2], MA. Barbancho Fernández[3]
[1]Intensive care, HOSPITAL CARLOS HAYA, MALAGA, Spain; [2]Intensive care unit, Regional Hospital of Malaga, Málaga, Spain; [3]Fisiology department, University of Malaga, Málaga, Spain
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000968

INTRODUCTION. The incidence of hypertensive disorders associated with pregnancy is increasing due to maternal age, obesity, assisted reproductive techniques, etc. Preeclampsia refers to a blood pressure ≥140/90 mmHg, with proteinuria in pregnant women over 20 weeks or up to 2 weeks after delivery. Risk factors are: maternal age, (<20 or > 35), personal or family history of preeclampsia, hypertension, diabetes, obesity, renal failure, primiparous or multiparity, multiple pregnancy, and coagulation disorders.
OBJECTIVES. We wanted to know the epidemiology of the patients who needs ICU admission due to gestosis, risk factors, mortality scores and survival of pregnant women and newborns.
METHODS. Retrospective, descriptive study of patients admitted in ICU from January 2018 to December 2018 . Clinical, epidemiological and result-related variables were analyzed. Quantitative variables are expressed as mean and standard deviation, while qualitative variables are expressed as ratios and absolute value.
RESULTS. During 2018, 14 patients with a diagnosis of gestosis required ICU admission. The patients had between 23 and 50 years, medium age of 35.14 years and standard deviation of 7.8. Gestational age at admission was between 22 and 39 weeks with a medium of 31.5. 100% of pregnant women had at least a risk factor (nuliparity was the most frequent (57.14%), 42.9% were older than 35 years, diabetes and coagulation disorders were observe in 28.6% of the patients, and hypertension, preeclampsia history and multiple pregnancy in 21.4%. Only 2 patients were in vitro fertilisation, in both cases were their first pregnancy. ICU stay was between 1 and 6 days with a medium of 2.6 days and standard deviation of 1.5. APACHE II at admission was 6.3 with a standard deviation of 3.6. All of our patients were alive when the results were taken. Two of the sixteen babies died: one of them was a twin who died in uterus a month before the admission; the second one had a gestational age of 22 weeks.
CONCLUSION. Our low incidence of preeclamsia, which need ICU admission, could be explained by primary prevention and treatment in healthcare centres. Patient admitted in our ICU with preeclamsia, is a 35 years old woman who at least has one risk factor, been nuliparity the most frequent, as well as age over 35 year, diabetes and coagulation disorders; and with a low mortality predicted by APACHE II at admission.

Scientific evidences as a policy for the optimization of beds in public ICUs in Brazil

G. Rossone Reis[1], W. Rodrigues[2], GJ. Von Glehn Dos Santos[3], E. Barbosa[4], SE. Bazzo Júnior[5]
[1]Physiotherapy, UnirG - Universidade de Gurupi, Gurupi, Brazil; [2]Economics, UFT - Universidade Federal do Tocantins, Palmas, Brazil; [3]Medicine, UnirG - Universidade de Gurupi, Gurupi, Brazil; [4]Critical care, HGP - Hospital Geral de Palmas, Palmas, Brazil; [5]Physiotherapy, HDT - Hospital de Doenças Tropicais da Universidade Federal do Tocantins, Araguaína, Brazil
Correspondence: G. Rossone Reis
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001079

INTRODUCTION. The availability of beds in intensive care units in Brazil has become a serious public health problem. Through the identification of studies and data collection that resulted from the analysis of variables that generated better indicators of quality in intensive care, such as the reduction of length of stay, costs of care and mortality rate.
OBJECTIVES. To analyze whether the implementation of public policies based on scientific evidence focused on ICU patient admission criteria and infection control can contribute to increase the availability of beds and reduce hospital costs in public ICUs in Brazil.
METHODS. The retrospective, quantitative and statistical documentary research through collection, correlation and comparison of data, aiming to analyze if the admission criteria and the incidence of nosocomial infection is related to length of stay, costs and mortality rate in patients hospitalized in Brazilian public ICUs. Data were analyzed of all hospitalizations of patients admitted to the three largest public ICUs in the State of Tocantins, in the north of Brazil, from January to December, 2018. The clinical data of the 1013 patients admitted to the ICUs in the year of 2018 were collected, based on the ICU vacancy request form sent to the Regulation Center, where they were allocated to the priority admission groups (Groups with priority 1, 2 and 3, and Group with priority 4). After the analysis of the patients' records at the respective hospitals, the length of stay, the infection index, the mortality rate and the cost estimate were collected. Regarding the statistical analysis, the correlation data between the quality indicators (length of stay, costs and mortality rate) on the presence or absence of hospital infection and the admission criteria, were analyzed by the coefficient of Pearson and Staverman in order to evaluate the degree of linear association.
RESULTS. A total of 1013 patients were collected, however, some patients did not present the necessary information to perform the study, and only 634 patients were considered to compose the sample. Through analysis of the pearson correlation, it can be observed that high infection rates (n=260 or 41%) and lack of admission criterion (criteria 4 with n=134 or 21%) corroborate for higher mortality ($p<0.001$), longer stay time ($p=0.0019$) and higher costs ($p<0.001$), reducing the quality indicators of public ICUs in Brazil.
CONCLUSION. Evidence shows that the adoption of continuous assessment measures based on technical knowledge and the application of evidence-based medicine in the management of public health policies, especially in the intensive care unit, can corroborate better quality indicators, with a greater supply of beds and, consequently lower waiting time for vacancy in ICU, lower mortality rate and lower costs, without investments in new units and/or opening of new beds.

INTRODUCTION. Medical Emergency Team (MET) is implemented in many hospitals all over the world and it seems associated with the prevention of cardiac arrests and unexpected deaths in wards, reduced rates of admissions to intensive care units and hospital mortality (1). Therefore, international bodies of quality certification, such as the Joint Commission and the Institute for Healthcare Improvement, support creation and implementation of MET in every hospital (2). Although its implementation is recommended, little is known about the presence of MET and its organization in Italian National Health Service hospitals (3).
OBJECTIVES. To investigate the presence of MET and its organization in Italian National Health Service hospitals.
METHODS. A national survey was conducted for two months in 2018. All public and private National Health Service associated hospitals with a service of intensive care were invited to participate. An online questionnaire was sent via e-mail to nursing coordinators or MET referents.
RESULTS. Among the 544 Italian hospitals identified, 197 (36.2%) answered the questionnaire. In every hospital there was a physician who answered the emergency calls, but a real MET (intensivist physician and critical care nurse) was present only in 59.9% of the hospitals, particularly in the north of Italy and in the community hospitals (61.5%). MET activity started about 10 years ago (51.7%) and in most hospitals the service is available 24/24 hours, 7/7 days (84.8%). The team members' minimal education was a specialization on intensive care medicine (100%) for physicians, while the most usual criteria for nurses were working experience in critical care (70.3%), besides specific internal courses were also performed (21.2%). The MET nurses belonged to the intensive care unit (83.1%) or to the emergency room (21.2%). Unfortunately, the intensivist physician and the critical care nurse weren't dedicated to MET (67.8% and 69.5% respectively), in particular in the community hospitals. The Modified Early Warning Score was used in 22.9%, while in 34.8% of hospitals no warning score was used.
CONCLUSION. This survey has shown that in Italian National Health Service hospitals MET appears structured and consolidated in some realities, while in others it is totally absent or lacking in some fundamental peculiarities of an intra-hospital emergency system.

Burnout experience in the ICU staff of the Regional University Hospital in Ukraine

M. Grynovska[1], A. Wong[2]
[1]Anesthesia and intensive care, Ivano-Frankivsk National Medical University and Regional University Teaching Hospital, Ivano-Frankivsk, Ukraine; [2]{street_address}, Guildford, UK
Correspondence: M. Grynovska
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001083

INTRODUCTION. Burnout (BO) is reaching epidemic levels in the medical population with prevalence reported around or over 50%.[1] Its presence is associated with poor patient safety outcomes.[2] Those working in ICM are disproportionately affected, rating higher on stress, BO and compassion fatigue indices.[3] In Ukraine, specifically, the concept of BO in ICM remains poorly understood and is largely under recognized, or dismissed. With paucity of literature addressing the issue, we decided to investigate the reality of BO experience in our country.
OBJECTIVES. To assess the BO experience and identify associated risk factors in the ICU of a university teaching hospital.
METHODS. The focus of the study was the frontline ICU staff nurses (n=40) and doctors (n=49). Data collection was performed with the help of the Maslach Burnout Inventory (MBI) survey. The BO rate was assessed across various ICU types, seniority, gender and age groups.
RESULTS. The overall prevalence of BO in ICU staff was 60.7 % (nurses 62.5% doctors 59.2%). There was no difference on BO subscales between doctors and nurses (95%CI,P>0,05).We also found no statistically significant difference in the incidence of BO between doctors and nurses (P>0,05). Our study showed no difference (P> 0,05) in the incidence of BO in doctors across ICU type, seniority level, gender or age group. In contrast, there was a difference in the incidence of BO in nurses across the ICU type (P < 0,05).
CONCLUSION. The response rate was 92%. BO prevalence was notably high in both ICU nurses and doctors. Our findings indicate that doctors and nurses are equally at risk of a BOexperience. The study showed no clear association between any of the risks and the incidence of BO in doctors. With regard to nurses,the ICU type proved to be a factor in the incidence of burnout. The nurses of general and neurosurgery ICUs were most affected by BO possibly due to demanding workload and severity of the patients in these units. Limitations of our study include a relatively small number of respondents that prevents from drawing conclusions in the context of a country/healthcare system. Further research across more hospitals in Ukraine is warranted to determine the BO rates and risk factors. In conclusion, we expect to raise awareness of the ICU staff BO in Ukraine and advocate for more research in this field. In a wider perspective, we hope that our study contributes to a better understanding of BO experience and promotes a broader discussion on the welfare and sustainability of the ICM workforce.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001089

INTRODUCTION. It has recently been shown that mitochondrial DNA (mtDNA) is associated with outcome in critically ill patients, however measurement of mtDNA is time consuming and cumbersome. Uric acid is a product of the metabolic breakdown of purine nucleotides and can be measured routinely.
OBJECTIVES. To analyze whether uric acid is associated with levels of mtDNA and predicts 30-day survival in ICU.
METHODS. In this prospective, observational cohort study, 222 consecutive patients admitted to a cardiac ICU at a tertiary care center were enrolled. Blood was taken at admission to the ICU and levels of circulating mtDNA were quantified by real-time.
RESULTS. Mean Apache II score was 19.6±8.3 and 30-day mortality was 26.1%. Uric acid correlated with circulating mtDNA plasma levels (R=0.21; p<0.002). Non-survivors showed significantly higher uric acid levels as compared to survivors (7.8±3.9 vs 6.2±2.5mg/dL). Patients with uric acid levels in the highest quartile (≥8.5mg/dL) showed a 2.8 (1.7 - 4.8)-fold risk of death as compared to patients in the lower quartiles (p<0.001). This increased risk of death was independent of age, gender, serum creatinine and APACHE II score.
CONCLUSION. Uric acid levels correlate with circulating mtDNA and predict mortality in critically ill patients.

INTRODUCTION. Critically ill patients have a decline in their muscle strength and in their functional capacity, which may occur after their hospital discharge.
OBJECTIVES. To evaluate the functionality and peripheral muscular strength of patients who were hospitalized in the ICU after three months of their discharge
METHODS. Retrospective study with data collected from January to December 2018, performed through the analysis of medical records of patients who were admitted to the ICU in the Hospital Universitário do Oeste do Paraná - Brazil, who returned for evaluation in the outpatient clinic three months after their discharge from the ICU. This study was approved by the Ethics Research Committee from the Western Parana State University, protocol number 436.770/2013. During ICU the patients were allocated into three groups: passive group (PG), Active-Assisted Group (AAG) Active Group (AG), according to their condition and clinical evolution. Peripheral muscle strength was assessed by the Medical Research Council (MRC), and functionality by the Functional Independence Measure scale (FIM) on discharge from the ICU and outpatient clinic. Variables with normal distribution were compared using the *Student's T-Test,* and the non-normally distributed variables were compared using the *Man Whitnney* tests. All analyzes were performed at 5% significance.
RESULTS. The sample had 54 patients, 18 in the passive group, 17 in the active-assisted, and 19 in the active, predominating the masculine gender, with age of 46.83 ± 21.37 vs 45.05 ± 19.24 vs 48.73 ± 15.56; p=0.91, with neurological (44%), non-neurological (35%) and neurological (31%) admission causes in PG vs AAG vs AG, respectively. The variables APACHE II (27.05 ± 5.47 vs 24.35 ± 8.50 vs 23.57 ± 8.19, p = 0.40), SOFA (11.16 ± 2.92 vs 7.23 ± 3.71 vs 8.11 ± 2.28, p = 0.002), sedation time in hours (93.17±76.80 *vs* 80.71±84.52 *vs* 20.17±31.27; p=0.008), mechanical ventilation in hours (224.16± 130.56 *vs* 162.31±154.86 *vs* 50.47±56.95; p=0.0009), ICU length of stay in days (14.72 ± 8.52 vs. 13.11 ± 11.27 vs 5.63 ± 4.33, p = 0.0004), Glasgow coma scale at discharge from the ICU (9.5 ± 3.11 vs 13.23 ± 2.01 vs. 14.38 ± 1.41; p <0.0001) in PG vs AAG vs AG respectively. Table 1 presents a comparison of the variables of the peripheral muscle strength and functionality in the ICU and in the outpatient clinic. In all three groups there were an increase in MIF and MRC, showing a recovery of the patient.
CONCLUSION. Functional and peripheral muscle strength improved in all groups three months after their discharge from the ICU.

INTRODUCTION. Depending on the definition and the method used for detecting, up to 34% of intensive care unit (ICU) patients have a history of an alcohol use disorder. (1-3) One study has reported high prevalence of risky alcohol use and its association with increased incidence of bacterial infection, and a recent systematic review found an increased risk for ARDS among patients with harmful alcohol use. (3,4) However, reports on its association with mortality are contradictory, partly because of the diagnostic methods used are variable (1-3).
OBJECTIVES. To study the prevalence of alcohol use disorders and their association with the length of stay (LOS), treatment intensity and outcome in ICU treated patients.
METHODS. Since the beginning of 2017, ICUs in Finland have collected AUDIT-C (Alcohol use disorder identification test-

consumption) data from ICU patients into the Finnish Intensive Care Consortium Database. AUDIT-C is based on the interview of the patient or a close relative. Risky drinking is defined as ≥5 points (of 12) for females and ≥6 for males. We used the registry data from January 1 to March 31 2018 to study the prevalence of risky alcohol use. Data from centres with an AUDIT-C recording rate less than 70% of admissions were excluded. We compared the disease severity scores, ICU LOS, Therapeutic Intervention Scoring Systems (TISS) and ICU-, hospital-, and one-year mortality in patients with and without risky drinking. Here, we report the results of the preliminary analyses.

RESULTS. Ten centres had a 70% or higher availability of AUDIT-C score. Of the 2186 admissions in these centres, AUDIT-C was available in 1660. AUDIT-C scores suggesting risky drinking were recorded in 22% of the patients. Patients with risky drinking were younger [median age 55 (IQR 42-65) vs 67 (IQR 57-74), (p>0.001)] and more often male, 78.1% vs 60.9% (p<0.001) than other patients. In unadjusted analyses we found no difference in disease severity scores, LOS, TISS, ICU or hospital mortality. According to preliminary analyses (data of 299 patients pending), the 1-year mortality curve according to AUDIT-C divided in subclasses is U-shaped with the highest mortality in the group of AUDIT-C 11 to 12 points (Figure). Final analyses will be performed after completing the mortality data.

CONCLUSION. Based on results obtained by using a validated self-report tool AUDIT-C, the prevalence of AUDs in Finnish ICU:s was 22%. We did not find an association of AUDs with patient outcomes in preliminary unadjusted analyses. However, one-year mortality appears highest in patients with very high AUDIT-C score as well as abstainers.

INTRODUCTION. Predictions of survival or functional outcome may influence clinical decision making in critically ill patients. One study investigating the discriminative accuracy of mortality estimations by physicians and nurses found that nurse's estimations of in-hospital mortality were most accurate. (1)

OBJECTIVES. To validate previous observations on forecasting in-hospital mortality. To study the accuracy of students' estimations and the association of combined estimations by physicians, nurses and students with in-hospital mortality.

METHODS. This is a substudy of the Simple Observational Critical Care Study (SOCCS, NCT0355306), by the SICS study group. (2) All patients acutely admitted to a tertiary centre Intensive Care Unit (ICU) were included. Within three hours of ICU admission a medical student, an ICU nurse and a physician independently predicted in-hospital mortality. Medical students had at least completed their first year of medical school and were trained to perform a structured one-time physical examination. Physicians and nurses received no additional training.

RESULTS. So far, 702 patients were included between May 12, 2018 and March 28, 2019. In 151 patients no estimations were made, due to absence of the researcher or interference with clinical care, leaving 551 patients for analysis. Estimations concerning in-hospital mortality were obtained from medical students in all cases, from the nurses in 486 cases (88%) and from the physicians in 331 cases (60%). Medical students predicted an in hospital-mortality of 11.4%, nurses 15.2%, and physicians 18.1%. Observed in-hospital mortality was 19.2%. Estimations by medical students, nurses and physicians all were correct in 81% with no differences between groups (p=0.6). The estimations of students, nurses and physicians were all associated with mortality (OR 5.8, CI 3.3-10.1, OR 6.8, CI 4.1-11.5 and OR 8.3, CI 4.5-15.2 respectively), and when more estimators forecasted non-survival, odds of non-survival increased (OR 2.7, CI 2.1-3.5 per additional estimate).

CONCLUSION. Physicians, nurses and students accurately estimate in-hospital mortality in 81% of cases. When more caregivers estimated non-survival, the risk of death increased. Future research should focus on investigating the conditional dependencies between the estimates and the variables obtained from clinical examination, ie using Bayesian networks, to assess how caregivers come to their predictions.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001192

INTRODUCTION. Early and proper management of multimorbid hospital patients have an important role in improving the quality of care. The aim of this study is to determine which pre-operative variables were significantly associated with mortality of patients before admission to the surgical intensive care units(SICU).
METHODS. 307 patients who admitted to SICU after emergency operation from 2013 to 2018 were recruited at the Department of General Surgery at Ajou university hospital. A total of 35 variables from database were extracted. Cox regression model and restricted cubic spline (RCS) were used to evaluated the association between preoperative variables and mortality.
RESULTS. In the final model, serum albumin level was the most important predictor of mortality (χ2-df=23.7, p<0.001). The respiratory rate(RR) was the 2nd most important predictor. (χ2-df= 17.7, p<0.001). The likelihood ratio χ2 test showed significant added value of RR (p=0.008). The bias corrected C-statistic was 0.788 with RR and 0.768 without RR.
CONCLUSION. Compared with a set of available clinical risk factors, increase of RR was a stronger predictor of preoperative mortality. In critically-ill patients who need emergency operation, increased RR could be a good surrogate marker for predicting a need for prompt management including surgery and careful intensive care.

Critical care consultants versus parent team: Predicting mortality on a Critical Care Unit in a tertiary oncology centre

BU. Adam, UU. Adam, P. Haji-Michael
Critical care, Christie Hospital, Manchester, UK
Correspondence: B.U. Adam
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001199

INTRODUCTION. The Christie Hospital is a tertiary cancer centre in northwest England. The Critical Care Unit (CCU) provides level 2 and 3 support to patients with cancer. Patients are referred by a patient's oncologist, haematologist or surgeon.
OBJECTIVES. To compare mortality of non-elective patients admitted to CCU at The Christie based on the opinion of the patient's oncologist and the admitting critical care consultant (CCC).
METHODS. Non-elective patients referred to CCU at The Christie are always reviewed by a CCC. Following initial review, the on-call CCC was asked what their opinion of the ceiling of care should be. This was either level 1, 2 or 3 care. The patient's parent consultant was also asked the same question. Where possible, the opinion of a second CCC was obtained and recorded. All consultants involved were blinded to the study.
The responses were recorded and compared against the maximum level of treatment the patient went onto receive during that episode and the subsequent outcome. Primary outcome was mortality on CCU.
RESULTS. 91 referrals to critical care led to 74 (81%) non-elective admissions. Medical oncology made up over half of referrals (56%), and others were from haematology (20.8%), clinical oncology (12.1%) and surgery (11%).
There was agreement between the CCC and the parent oncologist/ surgeon about the ceiling of care in 49.5% of cases. In 47.2% of cases the CCC recommended a lower level of care and in 3 patients (3.2%) the CCC recommended a higher level of care than the admitting oncologist.
When a second CCC reviewed the patient, there was agreement between CCC about the ceiling of care in 46/91 cases, disagreement in 28/91 cases and no data in 17 cases.
13 patients (14.3%) went on to receive a higher level of treatment than that recommended by a CCC. These patients had the highest mortality on the unit (table 1).
CONCLUSION. This study shows that while the parent team may know a patient well, the opinion of the CCC is more accurate in predicting mortality on a critical care environment. Mortality was 100% if a patient received level 3 support against the advice of the CCC.

Table 1 (abstract 001199). Mortality on CCU based on the opinion of the admitting CCU consultant and the levels of care given

CCU Consultant recommended ceiling of care	Actual maximal level of care received	Number of patients	Number of patients who died on CCU (mortality rate %)
Received care at a or below the level recommended by a CCC		61	16 (26.2%)
Level 1	Level 2	3	1 (33.3%)
Level 1	Level 3	3	3 (100%)
Level 2	Level 3	7	5 (71.4%)

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001203

INTRODUCTION. Prompt reperfusion treatment is important for the patients with ST elevation myocardial infarction (STEMI). However, patients often need interhospital transfer for percutaneous coronary intervention (PCI) because not all facilities are available for this procedure. The purpose of this study is to reduce the PCI delay through the regionalization protocol, in the patients with STEMI when they are transferred from the hospital where PCI not available.
METHODS. We established revascularization protocol named PREPARE (Preparing Revascularization Equipment before Patients Arrival as Regionalization Engagement) for the STEMI patients transferred from an outside regional hospital. The protocol included immediate referral acceptance by emergency physician, real-time electrocardiogram sharing via messenger service and early activation

of the PCI team. We analyzed the differences between PREPARE group with non-PREPARE group about time consumption for PCI, length of hospital stay and major adverse cardiac events within 4 weeks.
RESULTS. In PREPARE group, the median time from the visit of first hospital to the PCI in receiving facility (D1toB time) was 111 minutes, and it was significantly shorter than non-PREPARE group (147 minutes). Rate of D1toB time achieved within 120 minutes was 26.0% (13/50%) in Non-PREPARE and 60.0% (30/50) in PREPARE and showed meaningful differences between the two groups(p=0.000). There were no statistically significant differences in hospital length of stay and major adverse cardiac events within 4 weeks.
CONCLUSION. PREPARE protocol as a regionalization strategy was effective to reduce revascularization time in transferred STEMI patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001217

INTRODUCTION. Patients on the Intensive Care Unit (ICU) require high levels of nurse staffing. Critically ill patients have complex multiple diseases and are exposed to many diagnostic and therapeutic interventions. Therefore, they are at risk for Adverse Events (AEs). Many studies have looked at the association between nurse staffing and AEs with contradictory results. The omission of variables such as units, days of the week, shifts and nurse education are potential sources of bias.
OBJECTIVES. The aims of this study were, 1) to describe the shift variation of the patient-to-nurse ratio (PNR) of an ICU in the Swiss setting; 2) to describe, whether AEs vary by shifts and days of the week and 3) to investigate nurse staffing per shift and their association with AEs.
METHODS. Retrospective analysis of nurse staffing, routine patients and AE data was performed on one interdisciplinary ICU with eight units. Data were from January 1st, 2014 to January 31st, 2016. After merging the three data sources, PNR were calculated for each nurse educations (critical care nurse, critical care nurse in training, and registered nurse (RN)) and for every unit, day of the week and shift separately. To assess the association between nurse staffing per shift and AEs, two regression models were fitted: 1) model to predict nurse staffing with patient, units, days of the week, shifts and nurse educations variables; and 2) model to predict AEs with shifts and observed over expected (OE) estimator. The OE was obtained by dividing the observed (actual data) PNR through the expected (predicted data from staffing model) PNR. Three values were possible: 1) OE = 1 meant predicted staffing equals the actual staffing; 2) OE < 1 meant actual staffing higher than expected (unusually high staffing); and 3) OE > 1 meant actual staffing lower than expected (unusually low staffing).
RESULTS. A total of 6'938 shifts with 11'979 patients and 235 nurses (115 critical care nurses, 45 critical care nurses and 75 RN) were analysed. The PNR ranged from 0.93 to 1.01 for morning, from 0.98 to 1.10 for afternoon, and from 1.25 to 1.37 for the night shift. There was little to no PNR variation between units, days of the week, shifts and nurse education. No pattern could be seen between the occurrence of AEs and days of the week, but an increase of AEs from morning to afternoon to night shifts was observed. For the OE, the percentage of shifts with unusually low and high staffing were from 10.4% to 14.4% and from 13.0% to 17.1%, respectively. No association between the occurrence of AEs and shifts with unusually low or high nurse staffing could be established.
CONCLUSION. Although no association between PNR and AEs was identified with the current statistical approach and variables, the OE estimator allowed to describe the low and high staffing variability in the given ICU units on a shift basis. The OE estimator provided a new perspective to describe nurse staffing, which opens new possibilities for the future.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001232

INTRODUCTION. The prolonged mechanical ventilation (MV) causes deleterious effects to the patients, such as the decrease of muscle strength, interfering negatively in the weaning of the MV.
OBJECTIVES. To compare Maximal Inspiratory Pressure (MIP) and Glasgow Coma Scale (GCS) in extubated and tracheostomy patients for weaning from MV, evaluated in the ICU and in the outpatient clinic.
METHODS. Retrospective study with data collected from January to December 2018 of patients who were admitted to the ICU in the Hospital Universitário do Oeste do Paraná- in south of Brazil, and who returned for evaluation in the outpatient clinic three months after their discharge from the ICU. Variables with normal distribution were compared using the Student's T-Test, and the non-normally distributed variables were compared using the Man Whitnney and Kruskal-Wallis test. All analyzes were performed at 5% significance.
RESULTS. The sample consisted of 57 patients, 36 extubated and 21 requiring tracheostomy. The main causes of admission were, extubated group (EG): 33% clinical neurological condition, 19% clinical non-neurological condition, and 19% postoperative elective; tracheostomy group (TG): 66% clinical neurological and trauma with TBI and 29% clinical non-neurological. The variables comparing EG vs TG: age in years (47.33±16.81 vs 46.90±19.06; p=0.88), male gender (61% vs 52%); APACHE II (24.8±6.80 vs 26.5±6.38, p=0.39), SOFA (8.25± 3.07 vs 10.95±2.87, p=0.002), sedation time in hours (26.64± 44.73 vs 104.08±83.56, p=0.0007), time of MV (64.97±75.82 vs 256± 136, p=<0.0001), ICU *length of stay in days* (6.34±4.68 vs 17.14±10.15, p=<0.0001). GCS of EG on the day of extubating, on the day of discharge, and in the clinics (10.58±0.64 vs 14.05±1.09 vs 14.06±1.04, p=<0.001). GCS of TG on the day of tracheostomy, on day of discharge, and in the clinics (5.23±1.26 vs 9±1.92 vs 14.71±0.88, p=< 0.001). Both groups had gain MIP in the discharge vs clinics, EG (-38.05 vs -68.47, p=<0.0001) and TG (-28.23 vs -54.76; p=0.0003). Table 1 shows the EG and TG variables. TG had a lower level of consciousness on the day of the procedure and on discharge. In the outpatient clinic, there was no difference in GCS between the groups. The MIP of the TG on discharge from the ICU was low when compared to the EG.
CONCLUSION. Patients submitted to the TG, presented worse SOFA, and even with tracheostomy, had a longer time of sedation and MV. This may be related to the cause of admission, with a prevalence of

neurological patients. The TG also demonstrated lower MIP, and lower level of consciousness compared to extubated patients.

Table 1 (abstract 001232). See text for description

Variables	Tracheostomy Group	Extubation Group	p-value
GCS on the day of the procedure	5.23 ± 1.26	10.58 ± 0.64	p< 0.0001
GCS discharge ICU	9 ± 1.92	14.5 ±1.09	p< 0.0001
GCS clinics	14.71 ± 0.88	14.6 ± 1.04	0.86
MIP discharge ICU	-28.23 ± 12.37	-38.05 ± 19.23	0.06
MIP clinics	-54.76 ± 23.01	-68.47 ± 25.97	0.04

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001234

INTRODUCTION. The Doppler-based renal resistive index (RRI) [(peak systolic velocity – end-diastolic velocity)/peak systolic velocity] is a newly recognized non-invasive technique to detect earlier patients with renal tissue hypoxia and imminent acute kidney injury [1]. Moreover, the ratio of veno-arterial PCO2 difference to arterio-venous O2 content difference (ΔPCO2/ C(a-v)O2), has been recognized as a reliable marker of global anaerobic metabolism [2].
OBJECTIVES. The objective of our study was to evaluate whether the combination of both RRI and ΔPCO2/ C(a-v) O2 ratio is better associated with the presence of shock and clinical outcome in intensive care unit (ICU) patients than either of them.
METHODS. A prospective observational study was conducted in our multidisciplinary university intensive care unit (ICU). Patients requiring mechanical ventilation, without pre-existing chronic kidney disease were enrolled. Illness severity scoring systems (APACHE II and SOFA) were calculated on ICU admission. RRI measurements were obtained within the first 24 hours post-ICU admission, after the initial hemodynamic resuscitation. At the same time the ΔPCO2/ C(a-v) O2 ratio was calculated. A cutoff value ≥ 1.4 was used to characterize a high ΔPCO2/C(a-v) O2 ratio, whereas a cutoff ≥ 0.7 was used to characterize a high RRI value.
RESULTS. A total of one hundred and twenty-six critically ill patients (median age 61 years, 58.7% males) were included. Median values (IQR) for APACHE and SOFA scores, RRI and ΔPCO2/ C(a-v)O2 ratio were 18 (15-25), 9 (7-10), 0.7 (0.7-0.8) and 1.7 (0.6-3.4) respectively. Shock was present in 60 patients (47.6%) and sepsis in 57 patients (45.2%). The ICU mortality rate was 27.8% (35/126 patients). Patients with high values of both RRI and ΔPCO2/ C(a-v)O2 had an increased likelihood of shock presence (77.2%), compared to those who had only one of these markers high (30.4%) or those with both values low (12.5%), p=0.001. Similarly, patients with high values of both RRI and ΔPCO2/ C(a-v)O2 were more likely to have a fatal ICU outcome (49.1%), than those having one of them high (13%) or those with both values low (2.5%), p=0.001.
CONCLUSION. The combination of RRI and ΔPCO2/ C(a-v) O2 measurements was better associated with the presence of shock and the prediction of clinical outcome, than either of them.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001258

INTRODUCTION. Infections due to extensively drug-resistant (XDR) Acinetobacter baumannii is a therapeutic challenge in critical care patients.
OBJECTIVES. We aimed to study prospectively clinical characteristics and outcomes of patients with ventilator associated pneumonia (VAP) due to XDR Acinetobacter baumannii (VAPxdrAB) and to compare them with similar characteristics and outcomes of patients with non-XDR VAP or no-VAP
METHODS. The present is an one-centre prospective study. Consecutive patients were recruited from the ICU of a tertiary hospital of central Greece in a three month period in 2018. Inclusion criteria included mechanical ventilation and ICU stay > 48 hours while patients with pneumonia at admission or COPD, Asthma were excluded. Diagnosis of VAP required microbiologic confirmation of the bacterial agent.
RESULTS. Sixty-one patients were assessed. Mean(SE) age was 62.6(1.9), APACHE II score 18.5(1.9), SOFA score 7(0.4). There were 16(26.2%) patients with VAP, 8(13.1%) of them had VAPxdrAB. No patient presented a second VAP episode. Mean(SE) age and APACHE II scores in VAPxdrAB , VAP-non-XDR and no-VAP patients were 60.2(6), 57.0(4), 61.9(2) and 16.5(1.4), 17(2.5), 18.2(1.2) respectively, (p=ns). Mean ICU day of VAP diagnosis in VAPxdrAB and VAP non XDR were 6.4(0.9) and 7.8(1.1)(p=ns). VAP treatment duration and overall antibiotic treatment duration were not significantly different; ICU duration (days) were 31.4(3), 24.1(3), 11.3(1) (p=0.001 between VAPxdrAB and non VAP and p=0.15 between VAPxdrAB and VAP non-XDR). ICU mortality in VAPxdrAB , VAP-non-XDR and non VAP patients was 0(0%), 2(25%) and 10(22.2%).
CONCLUSION. VAP due to XDR Acinetobacter baumannii was associated with significant prolongation of ICU stay in our population, underlying that the necessity of the implementation of strict infection control measures.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001471

INTRODUCTION. Trauma is characterized by endothelial dysfunction and is especially apparent in patients in hemorrhagic shock. A disruption of intercellular connections may be an underlying mechanism(1). Vasopressin analog ddAVP (desmopressin) acts through a cAMP-dependent pathway, resulting in reorganization and redistribution of adhesive and tight junction molecules, enhancing endothelial barrier function. Furthermore, ddAVP increases von Willebrand Factor plasma levels and thereby potentially enhances platelet-based coagulation
OBJECTIVES. We aimed to assess whether the use of ddAVP will result in a restoration of the endothelial barrier function and an improvement in platelet-based coagulation without aggravating organ failure in a rat model of trauma and transfusion.
METHODS. Blood products were prepared from syngeneic rat blood according to blood bank standards. Polytrauma was induced in

Sprague Dawley rats by crush injury to the intestines and liver and by fracture of the femur. The rats were hemorrhaged by phlebotomy until a mean arterial pressure (MAP) of 40mmHg was reached. Rats were randomized (n=8 per group) to receive transfusion of RBCs, FFPs and platelets in a 1:1:1 ratio to achieve a MAP of 60 mmHg, with or without a single dose of ddAVP. Blood samples were taken up to 6h after trauma to assess biochemistry and coagulation status by rotational thromboelastometry (ROTEM). Organ damage was assessed by histopathology and biochemical parameters. Animals were continuously monitored with an arterial and urinary catheter.
RESULTS. Rats receiving ddAVP had significantly higher MAP values after the bolus was given. As reflected by their pH levels, a trend towards a more effective correction of shock was found in rats treated with ddAVP (7.36 vs 7.25, p=0.10). EXTEM CT and MCF remained stable in the ddAVP group, while rats in the control group showed a prolongation of their CT and a decrease in their MCF. This difference between the groups increased for both parameters over time. Platelet function relative to baseline values (reflected by EXTEM minus FIBTEM) also remained stable in the ddAVP group (around 100%), while it dropped markedly in the control rats (90%, 88% and 83% after 45, 75 and 120 minutes respectively). A trend towards lower soluble VE-cadherin levels was found in rats having received ddAVP compared to controls (133 vs 311%, p=0.17). No difference in organ injury was found between groups.
CONCLUSION. The use of ddAVP in a rat trauma-transfusion model increased blood pressure and improved ROTEM parameters of clot formation, with a trend towards an increased endothelial barrier function. However, this did not abrogate the amount of organ injury. The use of ddAVP should be further studied as an adjunctive therapy in trauma hemorrhage.

The impact of blood product ratio and pro-coagulant therapy on the development of thromboembolic events in severely injured hemorrhaging trauma patients

MR. Wirtz[1], D. Schalkers[1], J. Goslings[2], N. Juffermans[3]
[1]Department of intensive care medicine, Amsterdam University Medical Centers, location AMC, Amsterdam, Netherlands; [2]Department of surgery, Onze Lieve Vrouwe Gasthuis, Amsterdam, Netherlands; [3]Intensive care, Academic Medical Centre, Amsterdam, Netherlands
Correspondence: M.R. Wirtz
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001480

INTRODUCTION. Current treatment of trauma-induced coagulopathy consists of large volumes of plasma and early administration of anti-fibrinolytic and pro-coagulant medication. While half of trauma-related deaths occur in the first hours post-injury due to bleeding, the other half occurs during or after hospital admission(1). The development of thromboembolic events is an important contributor to morbidity and late mortality(2). Currently it is unknown whether the changes in resuscitation strategies increases the risk of developing thromboembolic complications.
OBJECTIVES. The aim of this systematic review is to identify risk factors of current resuscitation strategies for the development of thromboembolic complications.
METHODS. An electronic search was conducted in MEDLINE, PubMed and Embase. Relevant studies were screened by two independent reviewers and were included if they reported on thromboembolic complications in patients with severe trauma (ISS≥16) who received transfusion. Thromboembolic events was the primary outcome measure, either diagnosed when patients showed clinical symptoms or by routine screening using ultrasound or CT scan.
RESULTS. A total of 11.074 bleeding trauma patients were included, in which a total of 1.145 thromboembolic events were reported (incidence 10%). In studies performing routine screening for thromboembolic complications, the incidence was 12 to 23%. The risk of thromboembolic events in trauma patients was increased after administration of tranexamic acid (OR 2.6, 95%CI 1.7-4.1, p< 0.001) and after fibrinogen concentrate (OR 2.1, 95%CI 1.0-4.2, p= 0.04). Blood product ratio, the use of prothrombin complex concentrate or the use of recombinant factor VIIa showed no association with thromboembolic complications.
CONCLUSION. This systematic review of the literature identified an incidence of thromboembolic events of 10% in severely injured hemorrhaging trauma patients. The use of tranexamic acid and fibrinogen concentrate showed an association with the development of a thromboembolic complication. These results may beg the question whether routine screening in these patient populations should be implemented, in particular in patients treated with tranexamic acid and/or fibrinogen concentrate.

Prevalence, Determinants And Outcomes Of Hypoxic Hepatitis In Critically Ill Cirrhotics

R. Maiwall, P. Jain, S. Sarin
[1]Hepatology, Institute of Liver and Biliary Sciences, New Delhi, India
Correspondence: R. Maiwall
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001351

INTRODUCTION. Hypoxic hepatitis or "shock liver" is an acute liver injury characterised by a massive and transient rise in serum aminotransferases secondary to the anoxic necrosis of centrilobular liver cells. It is frequently observed in the intensive care units varying from 10-15%, however currently there is no study evaluating the prognostic relevance of this entity in critically ill cirrhotics. We evaluated the prevalence, predictors and outcome of hypoxic hepatitis in a prospective cohort of cirrhotics admitted to a dedicated liver intensive care.
METHODS. Consecutive patients with cirrhosis admitted to the liver intensive care were screened for presence of hypoxic hepatitis. Hypoxic hepatitis was defined as an increase in AST more than 5 fold from the baseline in the absence of viral or drug induced liver injury in an appropriate clinical setting of cardiac, respiratory or circulatory failure.
RESULTS. Five hundred and fifty-three patients with mean age 44(± 12) years, 89% males with mean MELD 32 (±9) and SOFA score of 11 (±3.5) were evaluated. Alcohol was the predominant etiology in 310 (56%). Hypoxic hepatitis was seen in 119 (21%) patients. On multivariate logistic regression analysis it was significantly associated to the MELD score (P,OR,95%CI) (<0.001,1.06,1.03-1.09), presence of hypoxia (<0.001,3.77, 1.78-7.98), variceal bleed (<0.001,3.19,1.72-5.93) and female gender (p<0.001,4.77,2.23-10.2). Patients with hypoxic hepatitis had significantly higher worsening of serum bilirubin (p= 0.002), Lactate (p=0.04), MELD (p=0.014) and SOFA (p<0.001) scores from baseline till day 15 as compared to patients without hypoxic hepatitis. On multivariate analysis, using Cox-Proportional hazard model, presence of hypoxic hepatitis (p<0.001, HR 2.06, 95%CI1.58-2.6), hepatic encephalopathy (p=0.018,HR 1.36,95%CI1.05-1.74), high MELD (≥32) (P<0.001, HR1.96, 95%CI1.52-2.52), Leucocyte counts(≥16,000) (p=0.005, HR1.38,95%CI1.10-1.74), serum sodium(≥130) (p=0.03,HR1.27,95%CI 1.01-1.60) and serum lactate(≥2) (p=0.003, HR1.42, 95%CI1.13-1.8) were independent predictors of mortality.
CONCLUSION. Hypoxic hepatitis is frequently seen in critically ill cirrhotics which correlates with the severity of liver disease. Development of hypoxic hepatitis is associated with worsening liver

functions and is an independent predictor of mortality in critically ill cirrhotics.

Cystatin C And Urinary Neutrophil-Gelatinase-Associated Lipocalin Can Predict Need Of Renal Replacement Therapy And Poor Outcomes In Critically Ill Cirrhotics

R. Maiwall, P. Jain, S. Sarin
Hepatology, Institute of Liver and Biliary Sciences, New Delhi, India
Correspondence: R. Maiwall
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001354

INTRODUCTION. Bacterial infections and systemic inflammation(SIRS) are the major precipitants of organ failure including acute kidney injury (AKI) in critically ill(CIC) and predispose to increased progression requiring dialysis. Timely identification of AKI is therefore an unmet need. Biomarkers can help in differential diagnosis and prediction of the trajectory of AKI course. We evaluated Cystatin C(CysC) and urinary neutrophil-gelatinase-associated lipocalin (NGAL) as biomarkers of glomerular and tubular injury respectively in predicting a progressive AKI requiring dialysis in CIC.
METHODS. CIC admitted to the Liver ICU were prospectively followed up. Dialysis was done for standard indications.
RESULTS. A total of 688 CIC, mean age 48.4±11.5 years, 87% males were followed until death or recovery. The median serum NGAL and CysC was 1004(803-1386) ng/ml and 2.1(1.7-2.6) mg/l respectively. SIRS was seen in 52% and sepsis in 60%. AKI at admission was present in 82% (Stage 1:2:3 18%vs 38%vs 44%) of which 65(11%) had progressive AKI requiring dialysis by day 7. On univariate analysis, lower MAP, higher arterial lactate, presence of leucocytosis and higher urine NGAL and serum CysC predicted requirement of dialysis at day 7. However, on multivariate analysis (OR,95% CI), u-NGAL (OR 6.3, 2.6-14.9), Cyst C (OR 6.4, 1.9-21.3) significantly predicted need of renal replacement therapy at day 7. The levels of NGAL (HR 2.3, 1.7-3.1) and Cyst C(HR 5.1,3.5-7.5) could also predict 30-day mortality in CIC.
CONCLUSION. Almost 80% of CIC have AKI at presentation, which in majority is a result of sepsis, is progressive and is associated with worse outcome. u-NGAL and CysC can accurately predict progression of AKI to dialysis and adverse outcomes which can help in stratifying patients for early therapeutic intervention.

INTRODUCTION. CT fat area at the level of the third lumbar vertebra is a gold standard of fat mass measurement, because it correlates very well with whole body fat mass. So far only abdominal but not appendicular ultrasound fat thickness has been validated to CT fat area (1). Moreover a large-scale study comparing US fat thickness to CT fat area in patients does not exist so far.
OBJECTIVES. The objective of the study was to validate appendicular ultrasound fat thickness in comparison to subcutaneous and visceral CT area in non-ICU patients.
METHODS. 119 non critically ill patients were recruited after routine abdominal CT scanning. Ultrasound fat thickness was measured at 2 measuring points on each upper arm and 3 measuring points on each thigh. Mean of upper arm fat thickness and mean of thigh fat thickness was calculated. Limb length was measured. Minimal compression was applied during ultrasound measurement. The ultrasound fat thickness was compared to CT L3 subcutaneous and visceral fat area by regression model. The covariables thigh fat thickness, upper arm fat thickness, thigh length, upper arm length, height, weight, age and sex were taken into account in multivariable regression models. Only statistically significant covariables were retained in the final model.
RESULTS. 79 men and 40 women were recruited. Median (IQR) age was 61 (47-69) years. Mean upper arm fat thickness better predicted CT L3 subcutaneous fat area (r2=0,69) than mean thigh fat thickness did (r2=0,54). In a multivariable regression model for prediction of CT L3 subcutaneous fat area only upper arm fat thickness and weight remained statistically significant (r2=0,73) (see Table 1). For prediction of CT L3 visceral fat area only age and weight were statistically significant covariables (r2=0,57).
CONCLUSION. Upper arm fat thickness but not thigh fat thickness correlated with subcutaneous L3 fat area in a multivariable model. Neither upper arm fat thickness nor thigh fat thickness correlated with visceral L3 fat area. Therefore upper arm fat thickness may be used as a surrogate for subcutaneous L3 fat mass but not for visceral L3 fat mass.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001388

INTRODUCTION. Intravenous administration of fructose leads to increased lactate levels [1]. Oral co-ingestion of fructose together with glucose during sustained exercise has been associated with both a better performance and higher lactate levels as part of the so called "reverse Cori cycle" [2,3].
OBJECTIVES. We examined whether a pre-operative drink containing fructose might affect intra-operative lactate levels.
METHODS. As part of the VAPOR-1 trial, renal transplant donors received 800ml of Preop® (Nutricia) orally the night before and 400ml at least 2h before surgery. This latter volume contained 0.8 g glucose, 5.2 g fructose, 2.4 g maltose and 40 g of polysaccharides. The transplant recipients did not receive Preop®. Mean ±SD lactate levels (reference value <1.5 mmol/L; <14 mg/dL) from preoperative arterial blood gas measurements were compared between renal transplant donors and recipients at four subsequent intra-operative time points (T1 through T4). Patients were carefully monitored for complications that might lead to increased lactate levels.
RESULTS. Significantly elevated lactate levels were found in the donor (Preop®) group compared to both the reference range (T1: 1.8 ±0.8 mmol/L, P<0.005), (T2: 2.2 ±0.7 mmol/L,P<0.0001) and also to

the recipients values at T1: 1.1 ±0.5 mmol/L (P<0.0001) and T2: 1.6 ± 0.8 mmol/L, (P<0.0001). Lactate levels normalized and were similar for the two groups at T3 (1.6 ±0.5 mmol/L) and T4 (1.5 ±0.5 mmol/L).
CONCLUSION. The early mild intra-operative lactate increase observed in the donor group may be related to the preoperative carbohydrate drink. This lactate may originate from hepatic conversion of fructose to lactate as part of the reverse Cori cycle [3]. If analogous to exercise physiology, this hepatogenic lactate may actually be a useful fuel for stressed tissues and should thus not be considered an adverse but a benign effect. Planned trials where oral preoperative feeding is randomized, can verify this phenomenon.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001431

INTRODUCTION. Secondary acute liver failure, also known as hypoxic liver injury (HLI) or shock liver, is the most frequent cause of liver failure in hospital. Up to ten percent of critically ill patients develop HLI during their stay at the intensive care unit and have dramatically increased mortality rates. The only established procedures in these patients are symptomatic therapy and treatment of the underlying disease. Liver transplantation is no therapeutic option. Albumin dialysis by molecular adsorbent recirculating system (MARS®) can be used in patients with acute liver failure as symptomatic therapy for bridging to regeneration or liver transplantation.
OBJECTIVES. The aim of this study is to investigate the clinical impact of MARS® therapy in critically ill patients with HLI.
METHODS. We performed a binational randomized controlled study in two tertiary care centers (Medical University Vienna, Austria and University Medical Center Hamburg-Eppendorf, Germany). Forty patients with severy hypoxic liver injury (defined as aminotransferase levels 40 times upper the limit of normal) were included in this study and randomized to early initiation of MARS therapy (MARS, 4 sessions) (n=20) or standard therapy (SMT) (n=20). One individual in the SMT group was not included in the subsequent analyses due to transfer to another hospital immediately after randomisation without receiving any study related treatment.
Primary end point was the difference of the indocyanine plasma disappearance rate (ICG-PDR) at day 7. ICD-PDR is an independent predictor of mortality and represents liver function idependently of established liver function parameters in patients with HLI. (1) Secondary end points included among others mortality, days free of vasopressors and mechanical ventilation within the first 28 days after randomisation.
RESULTS. There were no significant differences in the MARS and SMT group at baseline.
Patients in the MARS group had significantly higher median ICG-PDR at day 7 compared to SMT (17.75%/min, IQR 5.8-9.8 versus 6.3%/min, IQR 4-11.9, p < 0.05).
We observed a non-significant higher 90-day mortality rate in the SMT group (63%) compared to the MARS-group (40%). Median days free of vasopressors within the first 28 days after randomisation were significantly higher in the MARS group (24 days) compared to SMT, median days free of mechanical ventilation within the first 28 days after randomisation did not differ significantly in the MARS group (20.5 days) compared to SMT.
CONCLUSION. Early initiation of albumin dialysis using the MARS-system lead to significant improvement of the liver function represented by ICD-PDR in critically ill patients with severe HLI.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001562

INTRODUCTION. Indirect calorimetry is a reliable method for assessing resting energy expenditure (REE) in mechanically ventilated patients. The Deltatrac Metabolic Monitor (Datex-Ohmeda, Helsinki, Finland) has been considered the gold standard in the ICU setting, using a mixing chamber technology. The Beacon Caresystem (Mermaid Care, Nørresundby, Denmark) is a modern device allowing calorimetry with breath-by-breath analysis; however, it needs to be validated against the reference device.
OBJECTIVES. To determine the level of agreement between Beacon Caresystem and Deltatrac II for gas exchange and REE in mechanically ventilated ICU patients.
METHODS. Mechanically ventilated adult patients admitted to the ICU of a university hospital during June to October 2018 were screened for recruitment. Patients with respiratory rates >35, an air leak in the ventilator circuit of >10% of minute volume or requiring FiO2 ≥ 0.6 were excluded. Repeated measurements were allowed in the same patient on different days. Measurements of oxygen consumption (VO2) and carbon dioxide production (VCO2) with both devices were performed concurrently for at least 20 minutes. REE was calculated with the modified Weir equation using average values of VO2 and VCO2 for each measurement. Bland-Altman plots were used to depict bias and limits of agreement (bias ± 2 standard deviations).
RESULTS. 60 measurements were performed. 11 measurements were excluded (n=9 RQ <0.6 from Deltatrac, n=1 lack of informed consent, n=1 missing VO2 values from Beacon), with 49 valid measurements in 18 patients analyzed. Patients had a mean age of 54±17 and body mass index of 28±6 kg/m2. Mean VO2 between Beacon and Deltatrac was not different (289±90 vs 280±87 ml/min, p=0.068), while there were differences in terms of mean VCO2, RQ and REE (265±83 vs 201±62 ml/min; 0.92±0.06 vs 0.72±0.08;2063±643 vs 1909±586 kcal/day, respectively, p <0.001 for all). Compared to Deltatrac, Beacon had a bias for VO2 of +9 ml/min with limits of agreement (LoA) of ±68 ml/min and a percentage error (PE) of ±24%, whereas bias and LoA for VCO2 were +64 ml/min and ±58 ml/min (PE±25%). For REE there was a bias of +154 kcal/day (about 7% of REE measured by Beacon) with LoA of ±433 kcal/day (PE±22%). Linear regression did not show a proportional bias for VO2 and REE (R2=0.01 and 0.07; p=0.45 and 0.06, respectively).

CONCLUSION. In this validation study of Beacon Caresystem compared to Deltatrac, we found a good agreement between mean VO2 of both instruments. Despite a significant bias for VCO2, REE measured by Beacon was overestimated by only 7%, with similar limits of agreement compared to published data from other breath-by-breath devices in relation to Deltatrac [1].

INTRODUCTION. Stress-induced hyperglycemia is a common feature of intensive care unit (ICU) patients. Hyperglycemia and hypoglycemia have been highlighted as independent predictors of ICU and hospital mortality. Recent ICU recommendations suggest using insulin infusion protocols that can minimize glucose variability and reduce hypoglycemic risk.
OBJECTIVES. Our aim was to assess the efficacy, safety, and acceptance by nurses of a paper-based dynamic insulin protocol.
METHODS. This was a prospective study 7-month period, which included all adult patients admitted in the intensive/intermediate care unit of a private Hospital of Lisbon. Patients with diabetic ketoacidosis and hyperglycemic hyperosmolar state were excluded. Patients were divided in 2 groups: A, non-critical ill patients and B, critical ill patients. Critical ill patients were classified if they had one or more organ dysfunction, if they were submitted to cardiac surgery or to a major postoperative surgery. In A group, subcutaneous insulin protocol was applied. In B group protocol insulin was administrated according to modified Yale protocol. The target glucose level was between 140-180 mg/dl.
RESULTS. We included 999 patients, 75 (7,5 %) in B group and 924 (92,5%) in A group. In B group: 35 patients needed insulin perfusion; the mean time to achieve the target was 3,81 h; 9 patients needed more than 4 hours to achieve the target glucose level and only 1 episode of hypoglycemia was registered. In A protocol no hypoglycemia were observed; 3 patients transited to B protocol due to failure to glycemic control or presence of a critical event.
CONCLUSION. Our insulin protocols demonstrated to be very safe. Individualized protocols in Intensive/intermediate care units should be individualized according to patients severity. The great majority of our patients achieved the target glucose level in less than four hours, minimizing the potential risks of hyperglycemia.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001616

INTRODUCTION. Disturbances of the endocrine function are a frequent finding in critically ill patients. Among thyroid hormone system, the downregulated of the thyroid function may be an adaptative response to conserve energy. However, this condition can limit response to additional stress factors such as a onset of circulatory shock. In later stage, this adaptive response may result in the condition known as euthyroid sick syndrome. In the early stages, there is commonly observed a drop of the peripheral conversion of thyroxine (T4) to triiodothyronine (T3) with a consequent increase in reverse triiodothyronine level (rT3).
OBJECTIVES. To evaluate the association of increased level of rT3 and mortality in clinical critical ill patients.
METHODS. This was a retrospective analysis of observational data prospectively collected during a 7-month period (2018) in a mixed medical/surgical adult ICU in a tertiary hospital in Brasilia, Federal District, Brazil. All consecutive clinical patients, older than 18 years, admitted to the ICU were included. Free T4 (fT4), total T4 (tT4), thyroid-stimulating homone (TSH), free T3 (fT3) and rT3 was collected in the first 48 hours after admission. Patients with a prior diagnosis of hyperthyroidism or hypothyroidism and surgical patients were excluded. According to rT3 levels, patients were divided into 2 groups: increased rT3 group and non-increased rT3 group.
RESULTS. During the study period, 304 patients were included. Age was 68.3±18.2 years, APACHE II score 16.9±8.1, SOFA 3.2±2.9, and ICU mortality was 17.1% (n=52). Increased rT3 level was observed in 216 patients (71.1%). Patients with incresead rT3 level had higher mortality (19.9% vs 10.2%, p=0.042). Non-survivors patients also had higher age (75.2±16.3 years versus 66.5±19.4 years, p=0.001), APACHE II (23.5±7.5 versus 15.3±7.4, p<0.001), and SOFA (5.7±3.0 versus 2.6±2.5, p<0.001). In the multivariate analysis, increased rT3 (p=0.039), APACHE II (p=0.024), and SOFA (p=0.041) were independently associated with ICU mortality.
CONCLUSION. Increased rT3 was independently associated with ICU mortality. Determination of reverse T3 levels may be a valuable aid to improve identification of clinical critical ill patients with higher risk of mortality.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001716

INTRODUCTION. Sepsis, owing to its wide spectrum of pathophysiological mechanisms but limited treatment options, is a condition too difficult to manage and is the most important causes of increased mortality among critical patients admitted to intensive care units (ICUs). It is still hypothetical that vitamin D, with its immunomodulator function along with many other functions, has a therapeutic effect in sepsis when supplemented in critical patients.

OBJECTIVES. We aimed to determine if cholecalciferol treatment, when enterally administered in two different doses, had any relationship with infectious agent, sepsis, and mortality among critical patients diagnosed with vitamin D deficiency at the time of ICU admission.
METHODS. This study included all patients older than 18 years of age not meeting the exclusion criteria, who were admitted to and expected to stay for more than 24 hours at a tertiary, mixed type, 20-bed ICU for a period of 1 year between 2016 and 2017. Based on vitamin D level checked in the first 24 hours of admission, the patients were grouped into four groups as those with a normal vitamin D level; those with a low vitamin D level but not receiving therapy; those with a low vitamin D level receiving a single 300.000 IU bolus dose enteral cholecalciferol; and those with a low vitamin D level and receiving a bolus dose of 300.000 IU flowed by 2000 IU daily maintenance dose of cholecalciferol. Demographic data; APACHE-II, SOFA, and GCS scores as predictors of clinical prognosis; diagnoses of sepsis, septic shock, and MODs at the time of admission and during follow-up; the highest among SOFA scores daily calculated during follow-up; duration of ICU and hospital stay; clinical outcomes; infectious markers; liver and kidney function tests and parathormone (PTH) levels were analyzed and compared across the groups.
RESULTS. The study included a total of 210 patients of whom 185 had vitamin D deficiency (61.08% with severe deficiency, 24.32% with deficiency, and 14.59 with insufficiency). Patients with vitamin D deficiency had a significantly higher rate of sepsis ($p < 0.05$). The group with severe vitamin D deficiency had significantly higher rates of sepsis, septic shock, MODs compared to those with a normal vitamin D level ($p < 0.05$). The patients with higher PTH levels had significantly greater age, BMI, rate of immobility, and rate of tight dressing compared to those with a normal level ($p < 0.05$). Moreover, as compared to those with a normal PTH level, patients with a higher PTH level had a significantly higher admission APACHE-II and SOFA scores; higher rates of sepsis, septic shock, and MODs at admission; higher rates of sepsis, septic shock, and MODs during follow-up; higher rates of acute renal failure (ARF) and mortality ($p <0.05$). However, vitamin D levels of both groups were similar (p=0,691). The group that did not receive vitamin D supplementation had a higher rate of MODs at admission ($p <0.05$). Nevertheless, the groups without vitamin D supplementation had a significantly higher rates of sepsis, septic shock, MODs, ARF, and mortality than the group that received vitamin D supplementation. The rates of sepsis, septic shock, or MODs were higher, albeit statistically non-significant, in the group that received a single dose of cholecalciferol compared to those receiving a maintenance dose.
CONCLUSION. This study showed that critical patients with vitamin D deficiency and PTH elevation with and without vitamin D deficiency were prone to sepsis, septic shock, and MODs development. PTH elevation was also shown to increase mortality by exacerbating the severity and course of critical illness. Even though serum vitamin D levels similarly rose, patients put on maintenance therapy with cholecalciferol, as compared to those that were administered a single dose of the same drug, developed less sepsis, septic shock, and MODs and hence maintenance therapy was deemed superior to single dose treatment.

Vitamin D in adult critically ill patients. A systematic review and meta-analysis of randomized trials

A. Putzu[1]; G. Landoni,[2]
[1]Department of anesthesiology, pharmacology, intensive care and emergency medicine, Hôpitaux Universitaires de Genève (HUG), Genève, Switzerland; [2]Department of anesthesia and intensive care, San Raffaele Hospital, Milan, Italy

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001732

INTRODUCTION. Vitamin D, beside its involvement in bone and electrolyte metabolism homeostasis, has pleiotropic effects, including immunomodulatory, cardiovascular, and muscular effects. Low vitamin D blood levels are associated with high morbidity and mortality in critically ill patients. However, there is controversy about vitamin D supplementation in this population.
OBJECTIVES. The objective of this systematic review and meta-analysis was to evaluate if vitamin D administration reduces mortality in critically ill patients.
METHODS. PubMed, Embase, and the Cochrane Library were searched up to April 1st, 2019 for randomized placebo-controlled trials on the use of vitamin D in adult patients with critical illness in comparison to placebo. The primary endpoint was mortality at longest follow-up available. We performed a random-effects meta-analysis with results expressed as risk ratio (RR) and 95% confidence interval (CI). Cochrane methodology was employed [1].
RESULTS. Ten studies published between 2011 and 2019, for a total of 926 patients, were included in the present meta-analysis. Nine trials administered enteral or intramuscular vitamin D3, also known as cholecalciferol, while 1 trial administered intravenous calcitriol. Vitamin D administration was associated with a significantly lower mortality compared to placebo (119/474 [25%] in the Vitamin D group versus 143/452 [32%] in the placebo group, RR = 0.80 [95% CI, 0.66 to 0.97], p = 0.03, I2 = 0%) (Figure 1).
At subgroup analysis according to clinical setting, the positive effects were mostly evident in a subgroup of trials including a heterogeneous mixed intensive care unit population (Figure 1). The risk of mortality was similar in vitamin D-deficient patients randomized to receive vitamin D supplementation (3 trials and 551 patients, RR = 0.64 [95% CI, 0.37 to 1.11]) or in trials enrolling patients with low or normal vitamin D levels (RR = 0.78 [95% CI, 0.39 to 1.57]). Trial sequential analysis was inconclusive for a relative risk reduction in mortality of 15% (RR = 0.80 [adjusted 95% CI, 0.54 to 1.17]), since only 32.61% of the information size was accrued and no firm conclusions on benefit, harm, or futility of vitamin D could be supported at the current stage.
CONCLUSION. In critically ill patients, vitamin D administration may be associated with a reduction in mortality. However, the quantity of evidence is still insufficient to draw a firm conclusion. Large multicenter randomized trials are warranted before systematic implementation of this therapy in clinical practice.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001744

INTRODUCTION. Parenteral Nutrition (PN) is an alternative route to feed the critical patient, completely or partially, when the digestive tract can not be used for any reason.
PN monitoring has been established by the Spanish Society of Intensive Medicine and Coronary Care Unit (SEMICYUC) as a clinical quality indicator for intensive care units (ICU).
OBJECTIVES.
To evaluate the fulfillment of the Clinical Indicator: "adequate use of parenteral nutrition in an Intensive Medicine Service".
METHODS. Our investigation is a retrospective descriptive study. Data were collected from every patient admitted to our intensive care unit who received artificial nutrition (Enteral or Parenteral Nutrition) in the last four months. The variables collected were age, sex, PN indication and number of days from admission until PN was prescribed. The quality indicator was evaluated using SEMICYUC criteria: number of patients with indication of PN \ total number of patients needing artificial nutrition x 100 (standard = 16% with PN, and 25% with complementary PN). To assess whether the indication of PN is correct or not, we followed the criteria included in the guide of quality indicators in critical patient of SEMICYUC 2017.
RESULTS. During the study period 75 patients were analyzed. 66.6% were men, the mean age was 64.77 years and the average number of days from admission to the prescription of NP was 5.3 days. Only 24 were indicated to receive PN, 8 with complementary parenteral nutrition (CPN) and only 2 patients received PN without indication. 6 patients received PN as they were not expected to be fed in 5-7 days by oral or enteral route, 4 had intestinal insufficiency, 1 mesenteric ischemia and 5 intestinal obstruction. Using the formula described, the proportion of patients with NP indication was 32% and 10.6% with CPN.
CONCLUSION. The quality standard of this indicator is not reached. The exclusive administration of EN is impossible in certain scenarios like gastrointestinal dysfunction associated with the critical process. Depending on the clinical diagnosis at admission, the value of this standard will fluctuate, but monitoring this indicator is important to assess both, under and overprescription.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001757

INTRODUCTION. Parenteral nutrition (PN) is indicated when it is impossible or insufficient to cover the estimated energy requirements and substrates by enteral route but PN can be accompanied by a number of complications.
OBJECTIVES. The Aim of work is to determine the safety of PN in patients with severe combined traumatic brain injury (SCMT).
METHODS. 20 pts enrolled in the study in all patients started the EN from the 2nd day after the injury. From 8.8 ± 1.3 days after admission, PN is added. The average duration of a PN is 3-7 days. For PN - three-component blend Nutriflex Lipid 70/180 (B. Braun, Germany), volume 625 ml (amino acids 35.9 g, carbohydrates 90 g, fats 25 g, total nitrogen 5 g, total energy value 740 kcal). Mixture was infused during 12 hours (52 ml / hour). The concentration of triglycerides (TG) and glucose level in venous blood was determined and (PaO2 / FiO2) in arterial blood, were investigated according to the following scheme:
• Prior to the start of infusion of PN (11: 30-12: 00)
• 2 hours after the start of PN infusion (14:00)
• Immediately after the end of the infusion of PN (24:00)
• 6 hours after the end of the infusion of PN (06:00)
RESULTS. The introduction of PN was accompanied by the development of hyperglycemia and a slight increase in the concentration of TG. Glucose level increase was noted after 2 hours and 12 hours after the start of PN, 6 hours after the end of infusion the glucose concentration tended to decrease. An increase in TG 2 hours after the start of the infusion did not affect the pulmonary gas exchange.
The glucose concentration before the introduction of PN was 7.8 ± 1.9 mmol / l (n = 90), two hours after the start of the PN 9.6 ± 2.8 mmol / l (n = 90) (p <0.05), immediately after the end of the administration of PN 10.2 ± 3.9 mmol / l (n = 90) (p <0.05), six hours after the end of the administration of PN 8.9 ± 3 mmol / l (n = 90) (p <0.05). The concentration of TG before the introduction of PN was 1.48 ± 0.64 mmol / l (reference values <1.71 mmol / l) PaO2 / FiO2 333 ± 81 (n = 90), two hours after the start of PN TG 1.67 ± 0.9 mmol / l, PaO2 / FiO2 363 ± 72 (n = 90), immediately after the introduction of PN TG 1.53 ± 0.82 mmol / l, PaO2 / FiO2 357 ± 63 (n = 90), after the end of the introduction of PN TG 1.51 ± 0.8 mmol / l, PaO2 / FiO2 352 ± 64 (n = 90).
CONCLUSION. Introduction of parenteral nutrition as part of mixed artificial nutrition in patients with severe combined traumatic brain injury is not accompanied by hypertriglyceridemia and pulmonary dysfunction, but lead to slight glucose plasma level increase.

INTRODUCTION. Instability of daily body temperature rhythm is known to correlate with worse prognosis. Yet, the management of body temperature rhythm in critically ill patients remains elusive and is still left up to facilities. We aimed to assess whether body temperature variation beyond expected with circadian rhythm affect intensive care unit (ICU) mortality by machine learning. We also hypothesized if other physiological variables affect ICU mortality.
METHODS. We extracted 15,365 from 61,132 patients in the single center ICU database, MIMIC-III®, whose average Oxford Acute Severity of Illness Score (OASIS) was 37 points. They had at least two measurements of body temperature in a day and were compared the difference of body temperature between morning and afternoon for 28 days survival (OASIS=36) vs. non-survival (OASIS=40) patients in ICU.

Using a machine learning approach, we created a predictive linear regression model to investigate the effect of physiological variables of all extracted patients in the same database against ICU mortality.
RESULTS. Variations of nycterohemeral body temperature change in ICU were distinct between survival and non-survival groups (adjusted P=0.03). Hyperthermia (standardized weight (SW)=0.138), hypothermia (SW=0.514), and the chronological phase shift of body temperature circadian rhythm (SW=0.499) worsened ICU mortality.
CONCLUSION. Our study shows that permissive body temperature management for ICU patients is harmful by itself. Not only magnitudal but chronological deviation of body temperature directly increases ICU mortality. Further studies utilizing multicenter data are needed to evaluate this effect.

INTRODUCTION. Decision-making in the ICU is largely based on doctors' experience and intuition, due to a lack of patient-reported outcome information regarding long-term physical and mental functioning. Moreover, patients and relatives are often not involved in the decision-making process, which can lead to a decline in patient satisfaction and lower patient quality of life (QoL).
OBJECTIVES. To develop a prediction model for QoL one year after ICU admission.
METHODS. Adult patients admitted ≥12 hours to a university hospital ICU between July 2016 and December 2017 were included (MONITOR-IC study, clinicaltrials.gov NCT03246334). Moribund patients were excluded. Patients (or relatives) rated their QoL before and one year after ICU admission by completing the Short-Form (SF) 36, that consists of the following outcome domains: physical functioning, role limitations due to either physical or emotional problems, social functioning, pain, vitality, mental health, general health and change in health (ranging 0-100; higher scores indicate better functioning or health). Demographic and medical data were extracted from the patients' electronic health record (EHR). Multivariate linear regression analysis was utilized using a subset of selected variables based on expert opinion as predictors.
RESULTS. Modelling with candidate predictors in 2603 ICU patients showed that if there was an association, higher age, female gender, medical admission, emergency surgery, lowest haemoglobin level, APACHE-IV, COPD and immunodeficiency were generally negatively associated with the QoL domains, whereas QoL at baseline was positively associated with the domains. The explained variance of the prediction model was 0.17. Women scored worse for nearly all SF-36 domains, most notably physical functioning and role limitations due to physical problems (β= -10.24, p<.01 and β= -9.65, p<.01, respectively). Especially medical admission (compared to planned admission) was strongly negatively associated with these two domains as well (β= -10.38, p<.01 and β= -12.21, p<.01, respectively). None of the predictors except QoL at baseline (β= 0.13, p<.01) were associated with mental health.
CONCLUSION. From a subset of predictors, gender and admission type emerged as strong predictors for various SF-36 domains one year after ICU admission. The explained variance of this preliminary model needs to be improved. The final prediction model can be used before or during admission to facilitate healthcare professionals, patients and their relatives in the shared decision-making process, by providing them information regarding prognosis and by management of health expectations, thereby possibly enhancing long-term patient care satisfaction and QoL.

INTRODUCTION. Prediction analytics using machine learning and big data generated by the electronic health records and patients' monitoring have recently gained a lot of traction, especially in critical care. However, most algorithms are trained and evaluated at the population level, meaning that good overall performance may not translate into accurate individual predictions. We argue that online machine learning algorithms that can leverage time-series obtained from individual patients may generate better personalized predictions.
OBJECTIVES. The goal was to use innovative machine approaches to predict acute hypotensive episodes, defined as a mean arterial pressure (MAP) < 65 mmHg for more than 5 minutes.
METHODS. We used the data from the MIMIC II, a publicly and freely available database associating medico-administrative data, physiologic measurements and treatment administration prospectively and consecutively collected at the bedside over a seven-year period (2001-2008) from any of the five ICUs of Boston's Beth Israel Deaconess Medical Center (BIDMC).1 Our methodology extends the supervised ensemble machine learning algorithm called the SuperLearner, allowing for online, fast prediction tailored for each subject.2 In particular, we develop an online Super-Learner for a collection of unit-specific time-series that leverages information learned from the population of time-series, stratified population of time-series taking into account their baseline covariates as well as treatment, and individually trained single-unit fits. As such, we are able to utilize the wealth of subject trajectories in order to learn global patterns in data, while tailoring the prediction for the single-unit of interest. We demonstrate the benefits of using the Online Super-Learner for a collection of unit-specific time-series, and clear advantages over population-based on one-sample prediction settings in a clinical setting using MIMIC II data.
RESULTS. 200 patients were included in this pilot study, with 50 samples having at least one hypotensive episode. The performance of the Combined Online SuperLearner to predict acute hypotension are illustrated in figure 1. The area under the receiver operating curve for the Combined Online SuperLearner was 98%.
CONCLUSION. Most algorithms are trained and evaluated at the population level, while the clinicians are interested in taking accurate clinical decisions at the individual levels. We show for the first time that online machine learning algorithms that have the ability to leverage the information encompassed in individual time-series may be extremely useful in predicting short-term outcomes such as acute hypotension episodes in critically ill patients.

Right Data, Right Now - Robust external validation of a deep reinforcement learning model to optimize hemodynamic treatment of critically ill patients with sepsis

L. Roggeveen[1], T. Guo[1], L. Fleuren[1], PJ. Thoral[1], A. Girbes, AE. Eiben[2], M. Hoogendoorn[2], PWG. Elbers[1]

INTRODUCTION. Sepsis is defined as life-threatening organ dysfunction caused by a dysregulated host response to infection [1]. Sepsis leads to haemodynamic changes, low blood pressure and insufficient tissue oxygenation. To determine whether a patient has received 'adequate fluid resuscitation' or needs vasopressor therapy, no criteria can be explicitly specified. Furthermore, it is recommended to individualize the target blood pressure during shock resuscitation [2]. Truly, there is a need for a more personalised treatment protocol.
In 2017, Raghu et al. developed a deep reinforcement learning algorithm to determine optimal treatment policies for septic patients by using a continuous state space reinforcement learning model [3]. Their model was developed on data 24hours prior to 48hours after the onset of sepsis. They found that their model could reduce patient mortality in the hospital. To the best of our knowledge, no external validation of this model design has been performed.
OBJECTIVES. To perform a clinical external validation of reinforcement learning models for the haemodynamic treatment of sepsis. The goal is to evaluate whether a reinforcement learning model could improve sepsis treatment if incorporated in an intensive care clinical workflow.
METHODS. We perform a quantitative and qualitative analysis of reinforcement learning for sepsis treatment. Due to data limitations, we redeveloped a double deep duelling Q-learning model on the US based on Raghu's design on the MIMIC dataset. We applied the model to a new Dutch dataset of over 4000 critically ill patients treated in the ICU between 2003 and 2016. We perform robust external validation by assessing model performance and transferability under clinically applicable inclusion criteria on two time periods with different data granularity. Furthermore, we develop a sparse model based on physiological parameters only to investigate the importance of severity scores in relation to transferability. We quantify the performance using the weighted doubly robust (WDR) estimator and the weighted importance sampling (WIS) methods.
RESULTS. Physician performance on the MIMIC dataset was 9.2 (WDR) and 7.8 (WDR) on the Dutch dataset consistent with the higher observed mortality in the Dutch dataset. Further results of the model performance are pending.
CONCLUSION. Reinforcement learning based model performance varies across different patient populations. It is possible to develop a model based on sparse physiological parameters only. It is vital to evaluate model performance under clinical settings that simulate how a model would be incorporated into a clinical workflow. Model performance should be robust against conceptual drift; differences in data granularity, treatment plans and patient populations. More research is needed to evaluate model performance before such models can be applied in a clinical setting and potentially help reduce ICU mortality.

Clinical scores may not predict Delayed Cerebral Ischemia in aneurismatic subarachnoid hemorrhage: Two-year observational prospective study

M. Santafe[1], AE. Mera[1], A. Sánchez[1], RM. Gràcia[1], F. Arikan[2], E. Santamarina[3], O. Maisterra[3], M. García-De-Acilu[4], R. Ferrer Roca[1]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000900

INTRODUCTION. Delayed Cerebral Ischemia (DCI), manifests in approximately 30% of patients with Aneurismal subarachnoid hemorrhage (aSAH), and is one of the most important causes of morbidity (1). Several clinical and radiological scales have been proposed to predict DCI. We hypothesized that easy-to use clinical scales, such as Hunt and Hess (HH), World Federation of Neurosurgical Societies (WFNS), Glasgow Coma Scale (GCS), Fisher Scale and the recently proposed VASOGRADE scale may be associated with DCI development (2,3).
OBJECTIVES. To analyze if higher values in the above mentioned clinical scales may be associated with DCI development in patients with aSAH.
METHODS. Single-centre observational prospective cohort study including adult (+18 years) patients with aSAH diagnosis who were admitted to a tertiary ICU between June 1st 2017 and April 1st 2019. Patients with do-not-intubate order were excluded. DCI was defined as the occurrence of focal neurological impairment or a decrease of $\geq$ 2 points on the GCS for at least 1 hour (4). Cerebral ischemia was defined as hypodensities on CT or MR imaging. Vasospasm is defined as a radiological finding, either CT angiography, MR angiography, or digital subtraction angiography. GCS, HH, WFNS, Fisher and VASOGRADE were assessed at ICU admission. Quantitative variables are presented as mean (95%CI) and categorical as frequency (percentage). Differences between DCI and non-DCI patients were assessed using Chi square or Fisher's *exact test*, as appropriate.
RESULTS. Sixty-six patients were included, with a mean age of 58.77(55.56-31.98) years, 49(74.2%) were female. Mean SOFA at ICU

admission was 3.36(2.52-4.21) and APACHE-II score was 18.26(16.30-20.21). Twenty-one(31.8%) aneurisms were located at *anterior* communicating artery, 17(25.8%) at *posterior* communicating artery and 12(18.2%) at *middle cerebral* artery. Twenty-three (34.8%) patients developed DCI. Nine(39.1%) of them showed radiological signs of cerebral ischemia, and 10(43.5%) had radiologic signs of vasospasm. Mean GCS and GOS at ICU discharge of all patients were 13.60(13.06-14.11) and 3.39(2.99-3.78) respectively. The scales: GCS≤8 [5(22.7%) vs. 18(41.9%);p=0.173], WFNS≥4 [6(24.0%) vs 17(42.5%); p=0.18)], HH≥4 [5(21.7%) vs 18(42.9%);p=0.11], Fisher=4 [18(36.7%)vs 5(31.3%);p=0.77] and Vasograde=3 [4(20%)vs19(42.2%);p=0.10] were not associated with a higher incidence of DCI.

CONCLUSION. worse values of clinical-radiological scales were not statistically associated with DCI development in patients with aSAH, probably by the small sample size. However, more studies are required to identify predictors of DCI in patients with aSAH.

Thromboembolism in stroke patients in an ICU setting

I. Andrianopoulos, G. Papathanakos, X. Zikou, A. Papathanasiou, M. Saranti, E. Kostanti, V. Koulouras
[1]Intensive care unit, University Hospital of Ioannina, Ioannina, Greece

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000911

INTRODUCTION. Patients with acute stroke may develop venous thromboembolism (VTE) during their hospitalization. The incidence of clinically evident deep vein thrombosis (DVT) and pulmonary embolism (PE) is 1-5% and 1% respectively. When stroke patients are routinely assessed using imaging techniques VTE incidence rises to 40%. Patients admitted in Intensive Care Unit (ICU) have high VTE risk and the incidence of DVT and PE in the general ICU population is 5.4%-23.6% and 7-27% respectively. Although ICU stroke patients have prolonged immobilization, undergo interventions that increase their VTE risk (i.e. central venous catherization (CVC), surgical operations etc.) and have high mortality, their incidence of clinically evident thromboembolism is not well known.

OBJECTIVES. Our objective was to identify the incidence of clinically evident VTE in our ICU stroke population and to assess whether the outcome of these patients differed from non VTE stroke patients.

METHODS. We retrospectively identified all stroke patients admitted in our academic ICU over a three-year period (2016-2018) and investigated which of them developed clinically suspected VTE confirmed by imaging techniques during their ICU stay. It must be emphasized that not all patients underwent a diagnostic test for VTE but only those with a clinical suspicion of a possible VTE. A descriptive statistical analysis followed comparing survival, disability and length of ICU hospitalization between VTE- and non VTE- ICU stroke patients.

RESULTS. Seventy-five patients, 47 (62.7%) men and 28 (37.3%) women, mean-aged 66.5±12 years with stroke were admitted in our ICU over a three-year period. Thirty-six (48%) patients had an ischemic stroke and 39 (52%) a hemorrhagic stroke. Eleven out of 75 (14.6%) patients (4 ischemic/7 hemorrhagic stroke) developed clinically evident VTE (5 DVT and 6 PE cases). All DVT cases were related to a central venous catheter placement. There was no difference in age or gender among VTE and non-VTE group. Stroke patients with a VTE episode had higher mortality (45% vs 36%), longer ICU hospitalization (30.7 days vs 16.9 days), required more often a tracheostomy (72% vs 50%) and had more severe disability on discharge (modified Rankin scale 4.2 vs 3.7). Adverse events related to anticoagulation were noted in 3/11 stroke VTE patients (2 patients developed subcutaneous hematoma requiring blood transfusion and a patient suffered hemorrhagic transformation of his ischemic stroke.

CONCLUSION. Clinically evident thromboembolism is more common in ICU stroke patients than in the general stroke population. Patients suffering a thromboembolic event have a longer ICU hospitalization, higher mortality and more disability than non-VTE stroke patients and maybe these patients should be routinely assessed for VTE using imaging techniques. Larger multicenter studies are required to confirm the above findings.

Non-atherosclerotic ischemic stroke vasculopathies in ICU

I. Andrianopoulos, X. Zikou, G. Papathanakos, D. Kantas, A. Kittas, V. Koulouras
[1]Intensive care unit, University Hospital of Ioannina, Ioannina, Greece
Correspondence: G. Papathanakos
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000913

INTRODUCTION. The main causes of an ischemic stroke are embolism or vascular atherosclerosis. Stroke can also occur because of inflammatory, infectious, congenital, vasospastic and other non-atherosclerotic vascular causes. This heterogeneous group of disorders is called non-atherosclerotic vasculopathies and its true incidence and outcome in an Intensive Care Unit (ICU) setting is unknown.

OBJECTIVES. The purpose of this study was to identify the patients with a non-atherosclerotic vasculopathy admitted in our academic ICU with an ischemic stroke over the last three years and compare their outcome with that of patients with an atherosclerotic/embolic ischemic stroke.

METHODS. All cases of ischemic stroke admitted in our ICU over the last three years were retrospectively identified. They were divided in two groups according to their cause: either atherosclerotic vascular/embolic or non-atherosclerotic vascular. Clinical outcome (ICU survival, ICU length of stay and the modified Rankin scale for measuring the degree of disability or dependence in the daily activities) was assessed and compared using descriptive statistical analysis.

RESULTS. Overall, the last three years 36 patients, 22 (61%) males, 14 (38.8%) females, mean-aged 66.5±12.6 years, with ischemic stroke were admitted to our ICU. Thirty-one patients suffered an atherosclerotic/embolic ischemic stroke while the remaining 5/36 patients suffered a stroke of non-atherosclerotic vascular origin: one case of thrombotic thrombocytopenic purpura, one case of HELLP syndrome, one case of Listeria-associated stroke, one tuberculous meningitis-associated stroke case and one case of reversible vasoconstriction syndrome. The two groups were of similar average age and sex distribution. The non-atherosclerotic vasculopathy group had worse ICU survival (60% vs 67.7%), longer ICU length of stay (41.6±28.6 vs 11.42±11.6 days) and more disability (modified Rankin scale 5±0.89 vs 3.77±1.9). All survivals of the non-atherosclerotic vasculopathy group had a prolonged rehabilitation period for several months after

their initial admission, requiring assistance for most of their daily activities.
CONCLUSION. Although non-atherosclerotic vasculopathies represent only a minor proportion of patients suffering an ischemic stroke, they are an existent entity in ICU, with a high impact on mortality, ICU length of stay and disability.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000937

INTRODUCTION. Neurologic injury is one of the most frequent causes of death in patients undergoing extracorporeal membrane oxygenation (ECMO). As neurological examination is often unreliable in sedated patients, additional neuromonitoring is needed. However, the value of electroencephalogram (EEG) in adult ECMO patients has not been well assessed.
OBJECTIVES. To assess the occurrence of EEG abnormalities and their relationship to outcome in patients treated by ECMO.
METHODS. Single-center analysis of all patients undergoing veno-venous (VV) or veno-arterial (VA) ECMO with a contemporary (either intermittently or continuous) EEG monitoring (April 2009 - December 2018). EEG findings of interest were: a) "mild-moderate encephalopathy" (i.e. diffuse slowing with reactivity/variability) vs. "severe encephalopathy" (i.e. diffuse slowing without reactivity/variability); b) "burst suppression" or flat; c) epileptiform activity (i.e. ictal EEG pattern, sporadic epileptiform discharges or periodic discharges); d) EEG reactivity. EEG findings were analyzed according to the primary diagnosis (presence of cardiac arrest (CA) or not) and the use of VA vs. VV ECMO.
RESULTS. We studied 139 sedated patients (54 [41-62] years; 60 [43%] male gender) out of 596 treated with ECMO. ICU mortality was 65% (n=90). There were more unreactive EEGs among VA-ECMO (n= 98) patients than in VV-ECMO (n=41; 58% vs. 37%; p=0.03). As expected, patients after cardiac arrest (n=86) more frequently had burst suppression or flat EEG than the others (n=53; 28% vs. 13%; p=0.05) but less epileptiform activity (6% vs. 21%, p=0.01). Severe encephalopathy (28/42, 67%) or burst suppression/flat EEG (30/31, 97%; p< 0.001) had a higher mortality than mild/moderate encephalopathy (32/66, 48%); the frequency of epileptiform activity was similar in survivors and non-survivors. Burst suppression/flat EEG was strongly associated with ICU mortality (OR 24.02 [4.16-251.25]; p<0.001), even after adjustment for confounders.
CONCLUSION. EEG monitoring can identify sedated patients with severe neurological injury during ECMO.

Physiological parameters to predict successful ventilator liberation in brain injured patients

Z. Shi[1], AH. Jonkman[1], YL. Yang[2], GQ. Chen[2], M. Xu[2], JX. Zhou[2], L. Heunks[1]
[1]Intensive care medicine, Amsterdam UMC, locatie VUmc, Amsterdam, Netherlands; [2]Critical care medicine, Beijing Tiantan Hospital, Capital Medical University, Beijing, China
Correspondence: Z. Shi
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000951

INTRODUCTION. Nearly 50% of the brain-injured patients require acute invasive mechanical ventilation. Very few studies have investigated predictors for successful ventilator liberation in these patients.
OBJECTIVES. To identify physiological parameters obtained during a successful spontaneous breathing trial (SBT) to predict successful ventilator liberation in brain-injured patients.
METHODS. A prospective study was conducted in a general ICU. Patients meeting criteria for a SBT [1] and who successfully passed this 30-min. SBT (CPAP 5 cmH2O) were enrolled. Respiratory rate (RR), tidal volume (Vt), esophageal pressure (Pes) and diaphragm electrical activity (EAdi) were continuously measured during the SBT. From these data, RR/Vt, neuromechanical efficiency (Pes/EAdi) and neuroventilatory efficiency (Vt/EAdi) were calculated breath-by-breath. Successful liberation from the ventilator was defined as breathing without ventilator support for more than 48 hours after the SBT.
RESULTS. Forty-five patients (51.6±14.6 years; 60.0% male) were enrolled. The proportion of patients without requirement for ventilator support is shown in Fig.1. 68.9% patients were successfully liberated. There were no differences in baseline characteristics or physiological parameters (see Table) between patients in successful and failed ventilator liberation groups.
CONCLUSION. These data provide new and clinically relevant insights in ventilator liberation in brain-injured patients. First, 30% of patients successfully completed a SBT failed liberation < 48h. Second, in depth respiratory physiological parameters obtained during a SBT do not predict liberation success.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001016

INTRODUCTION. Second level therapeutic maneuvres for controlling intracranial hypertension (ICH) proposed by the European Brain Injury include barbiturates, moderate hypothermia and decompressive craniectomy (DC) but outcome is controversial. Our aim was to evaluate the factors associated with disability and mortality after ICU discharge in patients undergoing DC.
OBJECTIVES.
METHODS. Prospective study of patients admitted from January 1, 2013 to March 2019 who required DC. DC was performed due ICH refractory to medical treatment. We analyzed: main admission diagnosis; demographic data; neurological data (clinical examination and Glasgow Coma Score: GCS); hypotension type of craniectomy and DC complications; Rankin scale, and Glasgow outcome scale (GOS) at 30, 60 days after ICU admission, at ICU discharge and 6 months after ICU discharge; preoperative serum lactate levels ; hypo and hyperglycemia; application of mannitol or hypertonic saline solution before and after DC; leukocytes and platelets previous and after DC and other factors related to prognosis. Univariate analysis of disability (Rankin > 3) and mortality in ICU, 60 days after DC and 6 months after ICU discharge were performed. Statistical significance was set at $p \leq 0.05$.
RESULTS. Twenty eight DC patients were collected. Demographic data and types of admission are shown in Table 1.Most DC were subarachnoid haemorrhages (SAH) 13 (46%) and 75% of then were hemicranial. The most frequent complications were reoperation due to complications (50%) and hydrocephalus (46%). Six patients died at ICU discharge (39.3%), 4 (66,6%) of them were SAH. Rankin score at ICU discharge was 4,5 and GOS was 3..Rankin score 6 months after ICU discharge was 2 and GOS was 4. Reoperation due to complications and the highest ICU GCS was associated with disability, 60 days after DC (Table 2).Mortality 6 months after discharge was significantly associated with bilateral pupillary reactivity prior DC (less mortality), female sex, the presence of focal contusion with edema and expansivity, Rankin 30 days after admission and at ICU discharged (Table 3). We found no significant risk factors associated with disability in the ICU and six months after discharge.
CONCLUSION. DC patients showed low ICU mortality (21,4%) Rankin and GOS reflected moderate / severe disability of these patients, at ICU discharge. Rankin and GOS also showed disability deterioration, sixty days and 6 months after ICU discharge. Reoperation due to complications and the highest ICU GCS was associated with disability and 60 days after DC. Mortality at 6 months after discharge was significantly associated with bilateral pupillary reactivity prior DC, female sex, presence of focal contusion with edema and expansivity, Rankin 30 days after admission and at ICU discharge.

INTRODUCTION. In the acute phase of subarachnoid haemorrhage (SAH), patients may develop neurogenic stress cardiomyopathy (NSC), expressed as cardiac necrosis markers elevation, ECG alterations and left ventricular wall motion abnormalities (WMA). A catecholamine storm induced by SAH is central in its pathogenesis. NSC may worsen the patient outcome. Several predictors have been proposed in literature for the development of NSC, without definitive evidences.
OBJECTIVES. Primary aim of this study was to evaluate the occurrence of cardiac dysfunction measured as cardiac necrosis markers, ECG and echocardiographic abnormalities in SAH patients, during the first 5 days after admission. Secondary aim was to evaluate whether polymorphisms of adrenergic receptors and related proteins may be associated with an increased risk of cardiac injury after SAH.
METHODS. Adult SAH patients (World Federation of Neurosurgical Societies score IV-V) admitted at the university ICU in Torino were enrolled. Exclusion criteria: admission >48hrs, previous myocardial infarction, prior left ventricle ejection fraction <40%, pregnancy. Myocardial necrosis markers, ECG and WMA were evaluated daily during the first 5 days. Severity indices and physiological variables were collected at the same time points. For the genetic analysis, we evaluated polymorphisms of Catecol-OssiMethyl Transferase (COMT) rs4680, endothelial Nitric Oxide Synthase (eNOS) rs20707144, β2 adrenergic receptor (ADRB2) rs1042713 and ADRB2 rs1042714 and their association with cardiac dysfunction.
RESULTS. 49 patients were enrolled in this pilot study: 82% female, 63±12 yrs. Median (IQR) for APACHE II (Acute Physiology and Chronic Health Disease Classification System II) and SAPS II (Simplified Acute Physiology Score II) were 19 (16-23) and 48 (39-53) respectively. Aneurysm was secured by coiling in 67% of patients, clipping in 25%. The prevalent location of aneurysms was the mean cerebral artery (24.5%), followed by anterior communicating (2.4%) and intracranial carotid arteries (8.2%). In-hospital mortality was 24.5%. Troponin T was elevated in 53% of patients, with median (IQR) decreasing from 56 (16-261) ng/L at day0 to 23 (10-75) at day4. NT pro-BNP increased in 59% of patients and its value remained stable during the first 5 days. Copeptin was elevated in all patients and remained elevated during the study period. ECG abnormalities were recorded in 76% of patients and WMA in 25%. Genetic analysis was performed in the first 25 patients and the AA genotype of COMT rs4680 polymorphism was more common in patients with WMA (p= 0.042). This genetic variant is associated with a reduction in catecholamines degradation, suggesting a possible catecholamine toxic injury on myocardium.
CONCLUSION. We demonstrated a high incidence of cardiac abnormalities in the early period of ICU admission after SAH. A possible association between NSC and specific genetic polymorphisms has been observed. Larger studies are needed to confirm these results and to evaluate the role of other possible predictors.

INTRODUCTION. Neurocritical care patients are at risk of developing secondary brain injury (SBI) following primary lesion. Prevention, detection and treatment of SBI are of paramount importance for the clinical outcomes of patients with acute brain injury (ABI). Taking into account the complex pathophysiology of ABI, the use of multimodal neuromonitoring, including brain tissue pO2 (PbtO2), may have a major role in this purpose.
OBJECTIVES. To investigate the association between PbtO2 monitoring and prevention of SBI in neurocritical care patients.
METHODS. An observational (preliminary) study was performed in a Greek ICU from July 2018 to March 2019, including 23 patients with ABI (11 Traumatic brain injury, 9 Subarachnoid haemorrhage, 2 Intracerebral haemorrhage, 1 Ischemic stroke) and intracranial pressure (ICP) / PbtO2 monitoring. We selected 19 of them who survived and we divided them in two groups. The first group included all survivors who developed SBI and the second group all survivors without SBI. Monitoring of ICP and PbtO2 was performed, considering as critical thresholds of ICP > 22 mmHg and PbtO2 < 15 mmHg. We collected data from ICP and PbtO2 measurements in the first 24 h and > 24 h.
RESULTS. Included 23 patients had a mean age of 48.7 (± 16.8) years, ICU admission GCS 7.8 (± 3.9) and APACHE II score 17 (± 6.3). An external ventricular drain was inserted in 11 patients. 19 patients (82.6%) survived and 4 (17.4%) died. Among survivors, 7 patients (36.8%) developed SBI. In this group during the first 24 h PbtO2 < 15 mmHg was detected in all patients (100%) and remained low for time interval > 24 h in 5 patients (71.4%). It was remarkable that ICP > 22 mmHg was detected in only 2 patients (28.6%). We observed that 4 patients with SBI (57.1%) had a low PbtO2 and a normal ICP. From the group of 12 patients who did not develop SBI 7 of them (58.3%) had brain hypoxia in the first 24 h, but after 24 h of treatment none had.

CONCLUSION. Brain hypoxia may occur despite normal ICP. Therefore, monitoring of PbtO2 can provide additional information on early detection and prevention of SBI. Measurement of brain tissue oxygenation may be part of multimodality monitoring in order to achieve appropriate guidance of treatment and consequently improve outcomes. However, there remains a need for more, high quality trials in patients with ABI.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001075

INTRODUCTION. Acute respiratory distress syndrome (ARDS) is associated with a high mortality rate (1). In patients with ARDS without intracranial pathology, prone positioning (PP) sessions significantly decrease mortality and improve oxygenation (2). We can presume similar benefits on ARDS in patients with acute brain injury; however the effect of PP on cerebral hemodynamics remains controversial.

OBJECTIVES. Our objective was to evaluate the tolerance of PP on intracranial pressure (ICP), in patients with acute brain injury and ARDS.

METHODS. This study was conducted in three intensive care units (ICU) in France between January 2013 and January 2018. We retrospectively analyzed data from patients with moderate and severe ARDS (PaO2/FiO2 ratio < 150, according to Berlin definition(3)) and a continuous monitoring of intracranial pressure. Cerebral, respiratory and hemodynamic parameters were collected hourly before, during and after PP. The primary endpoints were PP efficacy on PaO2/FiO2, and tolerance through the number of patients who had at least one ICP measurement over 25 mmHg during PP. Secondary endpoints were the effect of prone positioning on cerebral oxygenation via the measuring of brain oxygen partial pressure (PbtO2). This study was conducted in accordance with French and European ethical guidelines.

RESULTS. Twenty-seven patients (46 years old [36.5-55], 5 female) were included: 10 traumatic brain injury, 11 subarachnoid hemorrhage and 6 stroke. During PP, PaO2/FiO2 rose from 100 [89.5-126] to 216 [171-257] and was at 146 [122-186] after PP. During PP, ICP increase of +10.5 mm Hg [5.25-17.75] and rose above 25 mmHg in 14 (52%) patients. The ICP increase was greater in patient who had intracranial hypertension (ICH) than those without ICH during PP (+19mmHg [13.5-20] *vs* +6mmHg [3.5-8.5] respectively, p=0.025). Before PP, patients who developed ICH had a significantly higher ICP compared to those without ICH (20mmHg [13-26] *vs* 11mmHg [7-12], p = 0.005) and the cerebral perfusion pressure was also significantly lower (67 [64.25-74.75] *vs* 79 [77-87] respectively, p = 0.04). Other variable before prone position onset were not significant different. In this population, all patients with an ICP > 17.5 mmHg before PP had ICH during PP.

There were no significant differences in the duration of mechanical ventilation, mortality and Rankin Scale at ICU discharge between patients with or without ICH during PP. PbtO2 was monitored in 4 patients and rose from 20.5 mmHg [18.75-23.5] before PP to 28mmHg [22-31] during PP. Two patients with initial PIC at 19mm Hg and 9mm Hg died of brain death following complicated refractory ICH after PP. In total, the mechanical ventilation time was 23 days[11.5-36], mortality rate was 25.93% and Rankin's score at ICU discharge was 4[4-5.5].

CONCLUSION. These data suggest that PP could be beneficial safe in brain injured patient with ARDS. However, patients with ICH before are at risk of worsening ICH during PP, and require precautions. Special handling would have to be defined for PP in patients with ICH for securing such maneuver.

INTRODUCTION. Although high meropenem concentrations have been associated with clinical neurological deterioration in septic patients, no data have been reported

OBJECTIVES. To assess the association between meropenem concentrations and EEG abnormalities in ICU patients with sepsis.

METHODS. We reviewed all ICU patients over a 5-year period (2012-2017), who were treated with meropenem and in whom at least two β-lactam concentrations (trough, Cmin; concentration 2 hours after the bolus injection, C2H) and a concomitant EEG monitoring were available. Drug levels were measured using high-performance liquid chromatography. An "altered" EEG was defined when at least one between ictal EEG pattern, generalized periodic discharges (GPDs) or burst suppression was identified.

RESULTS. We collected 526 meropenem concentrations (263 at Cmin and 263 at C2H) from 193 patients over the study period. Altered EEG was found in 52 (20%) of cases, with ictal EEG pattern in 32 of them. Meropenem Cmin and C2H were higher in patients with an altered EEG than others (7.2 [5.1-11.8] vs. 4.8 [2.2-8.1] mg/L; p<0.001 – 25.1 [17.5-33.9] vs. 19.6 [12.9-29.1] mg/L, p=0.01). A multivariate analysis (adjusted for patients) identified the following as independent predictive factors for altered EEG: mechanical ventilation (OR 1.225 [1.072-1.978], p=0.04), high Cmin (OR 1.128 [1.072-1.188], p<0.001) and high pH (OR 1.072 [1.019-1.128], p=0.007).

CONCLUSION. There was a significant association between both trough and maximal meropenem concentrations and an increased occurrence of EEG abnormalities in ICU patients with sepsis. However, only high Cmin were the main determinant of potential drug toxicity.

INTRODUCTION. Delayed cerebral ischemia (DCI) is a major contributor to the high case fatality rate and morbidity of aneurysmal subarachnoid hemorrhage. About 30% of the subarachnoid hemorrhage (SAH) patients develop DCI but it is difficult to predict which patients will develop it

OBJECTIVES. To assess the development of DCI risk factors in patients with SAH, admitted in a neurotraumatic ICU.

METHODS. Prospectively collected data of patients admitted from October, 2013 to December 2017 to a 10-bed Neurotraumatic ICU. We analyzed: main diagnosis at admission; demographic data including sex and race; neurological data (clinical examination, pupils reactivity and size, and Glasgow Coma Score: GCS; localization and aneurysm size; presence of intracranial hematoma (ICH); presence and volume of intraventricular bleeding; days to develop vasoespam; development of DCI; Fisher scale, Modified Fisher scale, Hunt and Hess scale, Word Federation of Neurosurgeons (WFNS) scale; presence of vasoespasm in doppler or arteriography; delayed of admission in ICU; treatment of the aneurysm; complications, including infections; Glasgow Outcome Scale (GOS) at ICU discharge and 6 months after ICU discharge and several other risk factors. A univariate and a multivariate logistic regression analysis of DCI were performed. It was considered significant if $p \leq .05$.

RESULTS. Eighty three SAH patients were collected, 24 (28,9%) of them developed DCI. Demographic data and types of admission are shown in Table 1a and 1b. Anterior /Aco) and posterior (Pco) communicating artery aneurysms were the most frequently found and most of them were localized in the left side. The most frequent complications were hydrocephalus 36 (43.9%) and ventriculitis 9 (11.4%).The Fisher scale was 3 in SAH and in DCI patients, modified Fisher scale was 4 for the SAH and DCI patients. Hunt and Hess scales was 2 for SAH patients and DCI patients. WFNS was 2 in SAH and DCI patients. GOS at ICU discharge was 4 and, six months after ICU discharged, was 5 in patients with SAH. Patients who developed DCI had GOS at ICU discharged of 4 and it was also 4 six months after ICU discharge. Eleven SHA patients died (13.4%) Three DCI patients died.To be orientated OR, IC 95% (IQR): 0.184 (0.058 ; 0.579) and PCo aneurysms OR, IC 95% (IQR): 4.559 (1.314 ; 15.817) were independently associated with DCI.

CONCLUSION. Our data showed 28,9 % of DCI patients. GOS reflect low disability of DCI patients both at ICU discharge and six months after it. To be orientated and PCo aneurysm were independently associated with the development of DCI.

Cerebral haemorrhage secondary to aneurysms and arteriovenous malformations in pregnant women. follow-up and prognosis

D. Arias-Verdú[1], MP. Benitez Moreno[1], J. Barrueco-Francioni[1], A. Muñoz-López[1], G. Quesada-García[1]; R. Rivera-Fernández[2]
[1]Intensive care, Regional Hospital of Malaga, Málaga, Spain; [2]Intensive care, Hospital Neurotraumatologico Universitario , Jaén, Spain, Spain
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001144

INTRODUCTION. Stroke in women of child-bearing age could be more common during pregnancy. Subarachnoid haemorrhage (SAH) is the third leading cause of non-obstetrical death in pregnant women
OBJECTIVES. We aimed to study the clinical and epidemiological characteristics of pregnant patients with spontaneous brain haemorrhage or SAH secondary to aneurysms or arteriovenous malformations (AVM).
METHODS. This descriptive retrospective study was undertaken in 2008-2013 in a third-level ICU attending pregnant patients. All pregnant women with brain haemorrhage were included. Analyses were made of the scores of severity, Glasgow on admission and discharge from the ICU, clinical and epidemiological variables, CT, cause of the haemorrhage, treatment if given, term, pregnancy outcome and delivery, and prognosis according to the GOSE scale and Barthell index, among others.
RESULTS. During the 6-year study period 6 patients experienced a brain haemorrhage. The mean age was 37.16±55 years. The haemorrhages presented in the third term, except for one in the second term. The mean Glasgow score on admission was 12.33±2.8 and on discharge 14.33±0.63. All had SAH, and 4 patients also had associated parenchymal haemorrhages. The mean Hunt and Hess on admission was 2.5±0.84 and the Fisher 3.67±0.82. The cause detected was: 3 with anterior communicating artery aneurysms, 1 with AVM, 1 with vasculitis and haemorrhage at the time of delivery, and another with gestosis and haemorrhage at the time of delivery. The aneurysms (3 patients) were treated with embolization at a mean of 2.66 days. Only one of the hematomas required neurosurgical evacuation. Caesarean section was required in all 6 pregnancies, 4 between 3 months and 4 days posthaemorrhage, and in 2 (gestosis and vasculitis) the haemorrhage occurred at the time of delivery. The GOS at 6 months and one year was 4 (moderate disability) in three patients and 5 (good recovery) in the other three. Sequelae included headache, epilepsy without aura and depression. No mother and no newborn died.
CONCLUSION. SAH in pregnant women is a severe condition, requiring diagnosis and interdisciplinary treatment. In our series, as in others, the attitude was to treat the aneurysm and/or its cause as soon as possible, and to use a caesarean delivery.

INTRODUCTION. Subarachnoid hemorrhage (SAH) is an acute cerebrovascular event associated with high morbidity and mortality. Several studies showed the independent impact of a lymphopenia with poor outcome during critically illness but no data are available for SAH.
OBJECTIVES. To evaluate the prevalence of lymphopenia among SAH patients and its association with infections occurrence
METHODS. Retrospective analysis of an institutional database of adult (>18y) patients admitted to the Department of Intensive Care after non-traumatic SAH between January 2011 and May 2016. Lymphocyte count was obtained daily for a maximum of 5 days; lymphopenia was defined as lymphocyte count < 1000/mm3. We collected the occurrence of infection during the hospital stay as well as ICU mortality and unfavorable neurological outcome (UO; i.e. Glasgow Outcome Scale of 1-3 at 3 months).
RESULTS. Data from 270 patients were analyzed (median age 54 years; male 45%); 62 (23%) patients developed infections during hospital stay. Mortality was 29% and UO 40%. The median lymphocyte count on admission was 1280 (890-1977)/mm3 and 45% (n= 121) had lymphopenia. Lymphopenic patients had more frequently infections (38/121, 31% vs. 24/139, 17% - p= 0.003), while mortality and UO were similar when compared to non-lymphopenic patients. In a multivariate analysis, seizures on admission and the use of mechanical ventilation were independent predictors of infection, while lymphopenia was not. Independent predictors of lymphopenia was the Fisher score on admission and the development of fever
CONCLUSION. Early lymphopenia is common after SAH; however, it is not significantly associated with the development of infections.

INTRODUCTION. Fever is a modifiable complication contributing to poor functional outcome and increased mortality in traumatic brain injury (TBI) patients.
OBJECTIVES. We sought to identify risk factors for the development of fever in TBI patients admitted to the intensive care unit (ICU).
METHODS. This is a retrospective analysis of data acquired in a European prospective, multicenter, observational cohort study (CENTER-TBI). Patients were included if they were admitted to an ICU as a direct consequence of TBI and data on highest body temperature were available on at least 2 different days. Fever was defined as body temperature above 38.3°C. Statistical analysis was performed using binary logistic regression models.
RESULTS. Two-thousand and seventy-four patients were included. Median age was 49 (29-65) years. Pre-injury variables associated with the development of fever were younger age (p=0.035), male sex (p< 0.001) and a medical history of a neurologic disease (p=0.036). Fever was most common in patients with diffuse brain injury as primary intracranial pathology (59%), followed by subdural hematoma (49.6%), contusions (49.1%), traumatic subarachnoid hemorrhage (43.3%) and epidural hematoma (34.7%). Regarding injury details and pre-ICU management, a Glagow Coma Scale score below 14 (p< 0.001), injury severity score above 30 (p<0.001), episodes of hypoxia (p<0.001), hypotension (p=0.004), or hypothermia (p=0.009), neuroworsening (p<0.001), clinical symptoms of skull base fracture (p< 0.001), a focal neurological deficit (p<0.001), any airway treatment (p<0.001), and any circulatory support (p<0.001) were associated with a more common occurrence of fever. During the ICU stay, any surgery (p<0.001), any infectious complication (p<0.001), seizures (p<

0.001), and intracranial lesion progression (p<0.001) were risk factors for the development of fever.
CONCLUSION. In this study we identified risk factors for the development of fever in a European cohort of TBI patients admitted to the ICU. Demographic variables, markers of injury severity, pre-ICU course and complications during the ICU stay were associated with the development of fever. Multivariable models and a differentiation between infectious and non-infectious fever will be presented at the meeting.

INTRODUCTION. The pulsatility index (PI), measured by transcranial Doppler (TCD), is useful to assess cerebrovascular resistances. Although it has been associated with septic encephalopathy, the relationship between PI and cerebral autoregulation (CAR) in septic patients has not been well defined.
OBJECTIVES.

- To evaluate if pulsatility index (PI) is a surrogate of CAR in critically ill septic patients.

METHODS. Observational study of 50 adult septic patients (with or without shock). Exclusion criteria were: any intracranial disease; major arrhythmias; treatment with extracorporeal membrane oxygenation; any supra-aortic arteriopathy. Transcranial Doppler (DWL, Germany) was performed by insonating the left middle cerebral artery (LMCA) with a 2MHz probe. LMCA blood flow velocity (FV) and arterial blood pressure (BP) signals were simultaneously recorded for at least 6 minutes; Pearson´s correlation coefficient between BP and FV (MXa) was calculated using MATLAB (MathWorks, USA). Impaired CAR was defined as MXa > 0.3. High PI was defined as > 1.2. The first PI available was registered from the same TCD recording.
RESULTS. The 50 patients had a median age of 64 [54-74] years. Median MXa was 0.25 (-0.07 - 0.43) and median PI was 0.97 (0.76 - 1.18). There was no correlation between MXa and PI (p=0.83). Both in the 24 patients with altered and in the 26 patients with intact CAR, there was no significant correlation between MXa and PI (p=0.58 and 0.93, respectively). Mean PI were similar in patients with altered and intact CAR (1.04 and 1.06, respectively). Also, the number of patients with high PI was similar in patients with altered (7/24) or preserved CAR (6/26).
CONCLUSION. Pulsatility index cannot reliably assess cerebral autoregulation in septic patients.

INTRODUCTION. An integral part of neuroregulatory systems of the brain stem are opioid and adrenergic antinociceptive systems. The use of anesthesia, including a combined effect on opioid and adrenergic antinociceptive systems, creates favorable conditions for performing operations on brain tumors.
OBJECTIVES. To assess changes in SVI and SVRI during anesthesia, including alpha2-adrenoagonist.
METHODS. The study included 118 patients (mean age 50.5±13.6 (Mean ± Std)) who underwent planned surgical treatment about brain tumors.
In all patients induction of anesthesia included: muscle relaxants, hypnotics (propofol), opioid analgetic (fentanyl 4.8±0.6mcg/kg) + alpha2-adrenoagonist (clonidine or dexmedetomidine). Maintenance of anesthesia: hypnotic (propofol), opioid analgetic (fentanyl 1.3±0.4mcg/kg/h) + alpha2-adrenoagonist (clonidine or dexmedetomidine).
All patients were divided into three groups, depending on the alpha2-adrenoagonist used and its dosage.
In group I (26 patients) induction of anesthesia: clonidine 1.5± 0.4mcg/kg; maintenance of anesthesia: clonidine 0.4±0.15mcg/kg/h. In group II (58 patients) induction of anesthesia: dexmedetomidine 1.5±0.4mcg/kg; maintenance of anesthesia: dexmedetomidine 0.4± 0.2mcg/kg/h. In group III (34 patients) induction of anesthesia: dexmedetomidine 0.7±0.1mcg/kg; maintenance of anesthesia: dexmedetomidine 0.2±0.1 mcg/kg/h. All three groups are statistically comparable by sex, age, initial blood pressure, initial heart rate, position on the operating table and localization of the brain tumor.
RESULTS. In group I, after induction anesthesia, SVI 37,4 ± 6 ml/m2, SVRI 2487 ± 620 dyn·sec/cm5/m2. After positioning the patient on the operating table, SVI 34,4 ± 11 ml/m2, SVRI 3078 ± 1490 dyn·sec/cm5/m2. At the stage of tumor removal, SVI 34,2 ±9 ml/m2, SVRI 3176 ± 921 dyn·sec/cm5/m2. At the stage of wound closure, SVI 34,1±8 ml/m2, SVRI 3265 ± 1201 dyn·sec/cm5/m2.
In group II, after induction anesthesia, SVI 36,2± 8 ml/m2, SVRI 4006± 1692 dyn·sec/cm5/m2. After positioning the patient on the operating table, SVI 34,2±7 ml/m2, SVRI 3971±1179 dyn·sec/cm5/m2. At the stage of tumor removal, SVI 33,6±6 ml/m2, SVRI 3894±1042 dyn·sec/cm5/m2. At the stage of wound closure, SVI 34,5±7 ml/m2, SVRI 3842±1123 dyn·sec/cm5/m2.
In group III, after induction anesthesia, SVI 38,9±8 ml/m2, SVRI 3294± 1198 dyn·sec/cm5/m2. After positioning the patient on the operating table, SVI 35,4±9 ml/m2, SVRI 3170±808 dyn·sec/cm5/m2. At the stage of tumor removal, SVI 36,1±7 ml/m2, SVRI 3400±795 dyn·sec/cm5/m2. At the stage of wound closure, SVI 36,9±6 ml/m2, SVRI 3747±1001 dyn·sec/cm5/m2.
CONCLUSION. SVI lower and SVRI higher, than the reference value in the during anesthesia, including alpha2-adrenoagonist. These values are stored at all stages of the operation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000114

INTRODUCTION. The functionality of platelets during coagulation is essential for stopping bleeding. Our study aims to assess the disturbance of platelet aggregation capacity in spontaneous cerebral hemorrhages (SCH), both intraparenchymal hemorrhage (IPH) and subarachnoid hemorrhage (SAH), and its correlation with severity and mortality.
METHODS. Patients with SCH admitted in ICU were included. A blood sample is analyzed with the Multiplateâ platelet function test at admission (day 0) and at 24h (day 1). This system measures platelet aggregability to arachidonic acid (AA), adenosine diphosphate (ADP), collagen (Col), Ristocetin (Ris) and thrombin (Trom). Hematoma volume was determined as a marker of severity in HIP and Hunt and Hess scale for HSA. Patients with oral antiplatelet

therapy were excluded. The prevalence of the platelet alteration was estimated, and it was related to severity and mortality using the chi-square test or Fisher's exact test.
RESULTS. 69 patients included. IPH 37 (53.62%), SHA 32 (46.38%); Mean age 50-60 years. Mean hematoma volume 48.28 cc. In SHA Hunt & Hess scale were IV-V in 35.48% of patients. Mortality rate at 6 months 33.33%.
A disturbance in platelet aggregability (at least one of the tests) was observed in 100% of patients, both on day 0 and day 1. Platelet dysfunction is associated with higher mortality in all tests, although it was only significant with Collagen test (p 0.048). It´s also associated with a greater hematoma volume in IPH, only significant with Ristocetin test (p 0.015) (Figure 1).
CONCLUSION. There is a disturbance in platelet aggregability at the global of SCH, also correlated with a higher mortality and greater hematoma volume in the group of IPH.

INTRODUCTION. Recent studies have shown that in-bed exercises are the most prevalent activity performed in mechanically ventilated patients receiving early mobilization. However, the barriers to achieving a higher activity level may vary in different cultures, and the reasons for this may be both clinical and structural. The objective of this study was to evaluate the clinical and structural barriers to achieving a higher activity level in mechanically ventilated patients. Recent studies have shown that in-bed exercises are the most prevalent activity performed in mechanically ventilated patients receiving early mobilization. However, the barriers to achieving a higher activity level may vary in different cultures, and the reasons for this may be both clinical and structural.
OBJECTIVES. The objective of this study was to evaluate the clinical and structural barriers to achieving a higher activity level in mechanically ventilated patients.
METHODS. A multicenter observational study performed in 3 ICUs in Sao Paulo, Brazil during a 3-month period (from January to March 2019). Demographic data, prevalence of early mobilization, types of mobility activities, clinical and structural barriers to achieving a higher activity level were collected daily from all adult patients in mechanical ventilation longer than 24 hours.
RESULTS. In total, 85 patients were included in this study, with a total of 327 observations. The mean (SD) age was 72(4.5) years and 58% of patients were male. Early mobilization during MV was performed in 92% [301/327] of the observations. Early mobilization activities encompassed in-bed exercises (n=301; 92%), a sit over the edge of bed (n=21; 6.4%), and actively transferring from bed to chair (n=5; 1.5%); no patients were engaged in standing or walking activities. Sedation represented the most common clinical barrier to achieving a higher activity level (n=125; 38.2%), followed by use of vasoactive drug (n=107; 32.7%), consciousness impairment (n=107; 32.7%), hemodynamic instability (n=91; 27.8%), respiratory instability (n=54; 16.5%), continuous hemodialysis (n= 46; 14%), and delirium (n=16; 4.9%). Limited resources were identified as the most common structural barrier (n= 17; 5.2%), followed by time for therapy (n= 3; 0.9%) and limited staff (n=2; 0.6%).
CONCLUSION. In order to achieve a higher activity level during mobilization of mechanically ventilated patients, clinical barriers were more prevalent than structural barriers. The most prevalent clinical barriers were sedation, use of vasoactive drug, and consciousness impairment. Structural barriers were more related to limited resources.

Family involvement at the ICU, needs are changing

T. van Galen, EE. Rouw
[1]Intensive care, Amsterdam UMC - locatie VUmc, Amsterdam, Netherlands
Correspondence: T. van Galen
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001000

INTRODUCTION. There is growing interest in involving family members at the ICU. Family Centered Care (FCC) and Shared Decision Making (SDM) are becoming more common in hospitals (Burns, Gerritsen). However, introducing FCC and SDM at the ICU is difficult due to limited evidence and despite a widely supported 23 recommendations guideline as provided by Davidson. At our 20 bed referral teaching ICU we developed a small size questionnaire to assess families needs, based on the five components of family involvement as described by Olding.
OBJECTIVES. To perform a small volume qualitative study to assess new or growing needs of family members of ICU patients to improve our medical and/or nursing services as provided on a daily basis. The questionnaire was aimed at five areas: ICU presence; having needs met/families being supported; communication and information; shared decision making (related to family expectancy) and families contributing to ICU care.
METHODS. The study was performed using a semi structured questionnaire (20 questions) and questions to determine patient and respondent characteristics (3 questions). During a six month period 34 families, usually one or two representative(s), were interviewed. Only families from patients with a ICU length of stay over 48 hour were included.
RESULTS. Family members of ICU patients endure a lot of stress and hardship during ICU admittance of their loved one. They experience disturbed sleep (76%), mental exhaustion (86%) and struggle balancing work (36%) and family (13%) as key issues. Despite their problems, 85% of families are coping sufficiently to still be able to support the ICU patient during the recovery period. 25% of families stated needing an (undefined) form of support from the hospital. Also a surprising need is found in a high number of families wanting to attend medical and nursing meetings and/or handovers and access to specific information as quality of life, incidents and risks of treatment and procedures. These needs are supported by almost 80% of the interviewed respondents, however the current offering of information and accessibility at our ICU is valued very positively. With concerns to SDM expectations, 18% of families stated needing no influence at all and 76% wanting only a consulting role. Only 3% stated that all (medical) decisions must be made by the family or only with full family consent. Despite insecure positive effects, families are willing to participate in daily ICU care. This is applicable on non-physical and physical (nursing) tasks. In general no statistical significant differences were found between patient or respondent characteristics.

CONCLUSION. Not only ICU or critical care is developing, needs of patient's' family members are developing as well. This provides a growing challenge for hospitals and ICU nurses and doctors to meet these needs of those family members and balance it with the daily care for the ICU patient. It is time to define new frontiers related to the role and participation of family members at the ICU. Maybe it is also time to shape the ICU workflow more to patient and families needs instead of being based on the doctors and/or nurses workflow. This will not be an easy transition. One simple question can be asked to family members today and immediately: what are your current needs and how can we support this?

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001053

INTRODUCTION. The significance of multidisciplinary rounds and patient care where family members and parents of critically ill children are actively involved in their child's care is receiving increased recognition as a vital complement to medical treatment. There are several studies in adults showing that the use of ICU diaries has decreased anxiety and depression in both patients and families. Despite the potential benefits, there is a paucity of information regarding the use of family care journals (FCJ) in the Pediatric Intensive Care Unit (PICU).
OBJECTIVES. The objectives of this quality improvement study are: 1) to develop a reliable process to learn about the experiences of families in the PICU, 2) to give families a resource tool to enhance their critical care stay, and 3) to develop improvement strategies for communication with families and enrich their PICU experience.
METHODS. An electronic point of care (POC) 10-item questionnaire was designed to obtain a baseline assessment during the first phase of the project. The survey was administered upon transfer from the PICU. Gaps were identified and the FCJ, developed by the Family-Centered Care Program, was distributed in the second phase. Throughout the second phase of the project, the survey administration continued to evaluate the impact of the FCJ on the identified gaps.
RESULTS. A total of 500 FCJ were distributed and 188 completed surveys were collected. A significant improvement in all of the questions between the two phases of the project was seen: Encouraging families to write down questions (+35%), inviting families to join rounds (+16%), and understanding the patient's plan of care (+9.7%). Of all the respondents, 90% found the FCJ to be a useful tool during their PICU stay. Open-ended questions revealed more improvement opportunities including: communication with non-ICU consultants, comfort level at the time of transfer to a lower level of care environment. Additionally, the majority of respondents gave positive feedback about the excellent nursing care provided while in PICU.
CONCLUSION. Using a readily-accessible electronic POC survey in combination with the FCJ can provide teams with real-time meaningful and actionable information to improve the partnership between clinical providers and families. The clinical team can use this information to drive improvement strategies focused on the partnership between families and ICU teams.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001174

INTRODUCTION. Health care disparity in critically ill children according to health insurance status is not well known.
OBJECTIVES. We aim to study whether there are differences in management and outcome between health insurance and Medical aid patients.
METHODS. We conducted a retrospective cohort analysis of the Health Insurance Review and Assessment (HIRA) database. All pediatric admission (<18 years of age) to intensive care units in Korea from August 1, 2009, through September 30, 2014, were enrolled, and we excluded i) admissions to neonatal intensive care units, ii) patients under 28 days of age, iii) primary diagnosis Z of International Classification of Disease, and iv) other than the first admission during study periods. We compared the management procedure and hospital death, Intensive care unit (ICU) length of stay between health insurance group and Medical aid group.
RESULTS. A total of 18,291 patients were enrolled, and 17,147 (93.7%) were health insurance status and 1,144 (6.3%) were Medical aid status. Age was higher in Medical aid patients (11 vs. 7 years, P< 0.001), the proportion of tertiary hospital admission was lower in Medical aid patients (67.5 vs. 39.5%, P<0.01). The proportion of mechanical ventilation (43.2 vs. 35.1%, < 0.01) and vasopressor drugs (15.8 vs. 12.0%, P<0.01) were lower in Medical aid patients. Crude mortality rate was not different between 2 groups (5.0 vs. 5.9%, P= 0.223). In adjusted analyses, medical aid state was not significant risk factor of mortality (Odds ratio 1.09, Confidence interval 0.79-1.51). However medical aid state was a risk factor of re-admission (Odds ratio 1.25, confidence interval 1.11-1.43) and visit to emergency room (Odds ratio 1.32, confidence interval 1.07-1.62).
CONCLUSION. The mortality rate of critically ill children who admitted to intensive care unit was not different between health insurance and medical aid patients, but the incidence of hospital re-admission and emergency room visits within 3 months after discharge was significantly higher in medical aid patients. Further studies about health care disparities outside ICU are neede according to health insurance status.

Use of high frequency oscillatory ventilator in neonates with respiratory failure: the clinical practice in Taiwan and risk factors of treatment failure

MH. Tsai[1], FH. Jen[2], CY. Mei[3]
[1]Pediatrics, Chang Gung Memorial Hospital, Yunlin, Taiwan; [2]Pediatrics, Linkou Chang Gung Memorial Hospital, Linkou, Taiwan; [3]Pediatrics, Taipei Chang Gung Memorial Hospital, Linkou district New Taipei City, Taiwan

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001200

INTRODUCTION. High-frequency oscillatory ventilation (HFOV) is often considered as the final rescue therapy for patients with refractory respiratory failure. However, there is limited data regarding the treatment outcomes and the risk factors of mortality after neonates on HFOV.
OBJECTIVES. To describe current clinical practice and predict the mortality risk for neonates receiving HFOV.
METHODS. A single retrospective, observational study was conducted and all neonates treated with HFOV during the study period from January 2010 to December 2017 were enrolled. Patients were classified into five cohorts based on underlying diagnosis. We used univariate analysis to identify factors associated with 30-day mortality following HFOV use and multivariate logistic regression to identify independent predictors of mortality risk.
RESULTS. A total of 1036 neonates ever supported on HFOV were enrolled, of which 64.1% had HFOV as the rescue therapy, 27.2% as elective use, and 8.7% for air leak. 755 (67.1%) had good response to HFOV and can be weaned within 3 days, whereas 87 (7.7%) patients died within 3 days after initiation of HFOV. The overall in-hospital mortality rate was 31.7%. An average oxygenation index (OI) greater than 25 within the first 24 hours after initiation of HFOV and patients with secondary pulmonary hypertension exhibited the greatest predictive power ($p < 0.001$) for increased mortality risk. After decision tree regression analysis, a pre-HFOV OI of more than 20.5 was identified as the cut-off point to be highly associated with final in-hospital mortality.
CONCLUSION. We identified the predictive factor and cut-off point that is independently associated with treatment failure in neonates on HFOV. Further efforts to optimize the outcomes are still needed.

Current physiotherapy practice in Albanian Intensive Care Units

V. SHPATA, M. Kreka, X. Prendushi, T. Çlna
Faculty of Medical Technical Sciences, University of Medicine, Tirana, Albania
Correspondence: V. SHPATA
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001226

INTRODUCTION. Although the physiotherapists are routinely involved in the critical patients care, the albanian intensive care units (ICU) have no exclusive ICU Physiotherapists.
OBJECTIVES. To give a view of physiotherapy practice in the ICU, to determine the role of intensive care nurses and their involvement in physiotherapeutic techniques.
METHODS. ICU nurses of 6 Intensive Care Units in the university hospitals of Tirana were requested to fill a questionnaire. The questionnare consisted of 25 short-form questions, which examined the nurses' involvement in respiratory care, early mobilisation and other physiotherapeutic techniques.
RESULTS. Physiotherapists do not work exclusively in the ICU-s, they perform therapeutic procedures only in some patients, they work in the ICU for 2-3 hours during the morning shifts. They are absent during the afternoon and night shifts, and also on public holidays and at the weekends.
100 completed questionnaries were analyzed. Nurses are routinely involved in ICU patients care. Treatment techniques performed "very often" included out-of-bed mobilisation (60%), passive and active limb mobilization (23%), in-bed mobilisation and positioning (81%) and airway suctioning (100%).
The nurses were no involved in the adjustment of mechanical ventilation, in weanings from mechanical ventilation, in extubation and in the implementation of invasive mechanical ventilation, considering these procedures the doctors' responsibility.
ICU nurses had graduated as general nurses, and had not post-graduate specialisation in ICU therapy or respiratory therapy. They also state that their knowledge in ICU physiotherapy is insuficient (73%), and absolutely absent (27%).
CONCLUSION. There is a lack of regular physiotherapy service in Albanian ICU-s. The low availability shows that the need and importance of regular physiotherapists in ICU is still not clearly recognized in Albania. Physiotherapists should be part of multidisiplinary intensive care team, in order to offer high-quality physiotherapy servises and improving the outcome of patients. Besides, systematic educational programs are necessary for improving nurses knowledge on physiotherapeutic procedures, especially in early mobilisation and respiratory physiotherapy.

Musculoskeletal complications following critical illness: an under recognised source of disability

O. Gustafson[1], S. Mckechnie[1], PJ. Watkinson[2], M. Williams[3], MJ. Rowland[2]
[1]Adult intensive care unit, John Radcliffe Hospital, Headington, UK; [2]Critical care research group, University of Oxford, Oxford, UK; [3]Department of sport and health science, Oxford Brookes Unversity, Oxford, UK, UK
Correspondence: O. Gustafson
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001227

INTRODUCTION. Patients surviving an admission to an Intensive Care Unit (ICU) frequently experience long-term physical impairment, decreased health related quality of life (QoL) and low rates of return to employment.$_1$ Despite this there has been limited investigation of the reasons for poor physical function. Musculoskeletal (MSK) conditions are wide raging, affecting approximately 25% of the UK population and are one of the main causes of sickness absence at work.$_2$ Patients in ICU experience rates of muscle mass loss of 20% in the first week of admission,$_3$ which may put them at risk of developing further MSK complications. However, the MSK complications experienced by ICU survivors are unknown.
OBJECTIVES. To undertake a scoping review to gain an understanding of the evidence base surrounding the long term MSK complications experienced by ICU survivors.
METHODS. A systematic search was conducted of the following databases: Cochrane, CINAHL, AMED and EMBASE. Studies were included if they evaluated at least on aspect of MSK health in ICU survivors following hospital discharge. Abstracts and case reports were excluded.
RESULTS. Of the 22 included papers: 8 reported decreased muscle mass or muscle weakness; 7 reported MSK related chronic pain; 3 reported abnormal neuromuscular function; 3 reported joint related complications; and 1 paper reported increased fracture risk. Most papers (n=21) reported on a single aspect of MSK health.
CONCLUSION. The nature of critical illness and its long term consequences, along with the prevalence and detrimental effect of MSK conditions in the general population, means that it is highly likely that MSK conditions are having a negative impact on patient's physical function and QoL. The small number of studies investigating long-term MSK complications to date has identified a variety of problems extending beyond weakness. Further investigation of MSK complications following critical illness may guide future post-ICU rehabilitation interventions.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001316

INTRODUCTION. The application of prone positioning (PP) during veno-venous extracorporeal membrane oxygenation (VV-ECMO) has shown to be a safe and reliable technique when performed in a recognized ECMO center with the appropriately trained staff and standard procedures. [1] Several clinical studies evaluated the safety and efficacy of PP in mechanically ventilated patients, however a higher frequency of pressure ulcers has been reported. [2]
OBJECTIVES. To detect the incidence and the characteristics of pressure ulcers in PP patients with severe acute respiratory distress syndrome undergoing ECMO treatment.
METHODS. Observational retrospective analysis of all the patients admitted to our intensive care unit (ICU) of a tertiary level hospital from January 2013 to December 2017. Only the patients undergoing PP for at least 12 hours were included. The Braden scale was used to assess the patients' risk of developing a pressure ulcer at ICU admission while the pressure ulcers were staged according to the NPUAP staging system (National Pressure Ulcer Advisory Panel). Age, sex, BMI, ICU length of stay, SAPS and SOFA score and mortality were recorded.
RESULTS. A total of 50 PP patients undergoing ECMO were identified in the medical records. The pressure ulcers incidence was 46% and the main part of the body with skin lesions were: face (51.3%), rib cage (15.4%), hip bones (7.7%) knees (5.1%) and others (20.5%). Fourteen patients (28%) report 3 pressure ulcers present simultaneously in different anatomical sites. During all PP maneuvers, no adverse events, like ECMO cannula dislocation, were recorded.
The other results are summarized in table 1.
CONCLUSION. In this sample, PP is a safe procedure but it is associated with a high risk of pressure ulcers on the face. For this reason, further preventive measures to protect the skin should be implemented.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001403

INTRODUCTION. Autophagy executes an intracellular recycling process through the lysosomal-mediated pathway. Previous studies have revealed a possible association between insufficient autophagy and a detrimental outcome in critically ill patients. However, the autophagy flux and its dysregulation by critical illness is not well described and cannot be measured in critically ill pediatric patients in vivo.
OBJECTIVES. To examine how serum from critically ill children influence the autophagy flux in human skeletal muscle cells in vitro, compared with serum from healthy children.
METHODS. Three independent experiments were conducted. Serum from 82 pediatric ICU (PICU) patients (age < 18 years) and 50 age-matched healthy subjects were incubated with cultured primary human skeletal muscle cells in 96-well plates for 24 hours. The expression of p62 protein in the muscle cells was analysed with and without an autophagy blocker (chloroquine or bafilomycin A1) using In-Cell Western assay. The autophagy flux was determined by the difference in p62 levels between the conditions with and without the autophagy blocker. Serum-free media was used as a control condition and the autophagy flux was reported as the percentage of this control. Clinical parameters of the PICU patients were also recorded. Mann-Whitney U test and Kruskal-Wallis H test were used for statistical analysis because of non-parametric distribution of the data. Data is presented as median and interquartile range[IQR].
RESULTS. The levels of basal p62 expression were comparable between PICU and control group (98.7 [88.0-111.1] vs 91.9 [86.4-104.5] A.U., p=0.13). No difference in autophagy flux was observed between the PICU and control group (44.4 [19.3-76.6] vs 54.7 [25.9-78.0] %control, p=0.21). However, the PICU group had more outliers of autophagy flux, with 13% (n=11) of values lower than the mean minus SD (blockers) and 15% (n=12) of values higher than the mean plus SD (inducers). The blockers group had significantly higher p62 levels than the non-responder group (autophagy flux within mean ± SD, n=59) and the inducers group (121.5 [100.7-164.2] vs 98.3 [90.6-110.3] vs 87.8 [82.2-99.6] A.U. respectively, p=0.015). There was no difference in terms of number of organ failure among these groups (p=0.675); however, days of mechanical ventilation tended to be higher in the blockers group (7 [4-18.5] vs 3 [0.3-7] vs 2.5 [0-4] days respectively, p=0.07).
CONCLUSION. We observed a variation of autophagy in muscle cells modulated by serum from critically ill children with 13% of serum initiating a block in autophagy.

Right Data, Right Now: paving the way for implementation of a machine learning ICU readmission model by validating on external datasets and adjusting for concept shift

PJ. Thoral[1], M. Fornasa[2], AM. Curth[2], DP. De Bruin[2], H. Hovenkamp[2], RH. Driessen[1], A. Girbes, PWG. Elbers[1]
[1]Department of intensive care medicine, Amsterdam UMC, Vrije Universiteit Amsterdam, Amsterdam, Netherlands; [2]Pacmed.ai, Pacmed B.V., Amsterdam, Netherlands
Correspondence: P.J. Thoral
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001538

INTRODUCTION. Transfer of care from the ICU to the ward may lead to preventable errors and adverse events. In particular, unexpected ICU readmission is associated with longer length of stay and an increase in mortality.[1] Many prediction models have been developed but none are currently widely implemented to prevent ICU readmission. Our recently developed model employed extensive feature engineering and start-of-the-art machine learning algorithms and achieved an ROC AUC of 0.82. (P.J. Thoral, et al, ESICM LIVES 2018 Meeting Abstract. Manuscript in preparation). An important part of implementation is applying the model to external datasets, different from and independent of the one it was originally trained on, in order to both validate the model and increase its versatility and value.
OBJECTIVES. To increase the performance and implementability of our prediction model for ICU readmission and mortality by extending the training dataset with clinical data collected during the last two years in the electronic health records (EHR) at the ICU of Amsterdam UMC, as well as datasets from other Dutch ICUs.
METHODS. Our model was developed using patient data from 2004 to 2016 extracted from our Patient Data Management System (MetaVision, iMDsoft). We tested performance of our model on data extracted from our current EHR (EpicCare, Epic Systems) from 2016-2018 and are currently testing performance on data from other Dutch ICU's. Since a change in clinical practice associated with transition to another EHR (e.g. different standardization of orders using order sets) and different patient populations between ICUs will lead to datasets with features characterized by different distributions, we explore multiple methods suggested in the literature to ensure external validity.[2, 3] To address possible covariate shift caused by different patient populations, we implement importance weighting to better align feature distributions between ICUs. To address potential concept shift, due to, for example, differences in practice, we add data from multiple sources to the training set and restrict the feature set to features that are expected to generalize well. Code for model development and analysis was written in Python using the scikit-learn package.
RESULTS.
Applying our model without adjustments to our current EHR results in a lower ROC AUC of 0.77 with an average precision (AP) on the precision-recall curve (PRC) of 0.21. (Fig. 1 and 2). Through careful feature selection, combination of training data and domain shift mitigation techniques we improve the model performance and increase the ROC AUC to 0.83 and the AP to 0.26. Results for validation on and combination with datasets from other Dutch ICUs are pending.
CONCLUSION. Our validation approach overcomes the problem of concept shift due to datasets originating from different sources and leads to a model with increased performance and versatility that is ready for implementation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001514

INTRODUCTION. Immunotherapy with CAR-T cells is a new approach to treat B-cell lymphoblastic leukemia in children and young adults. The most important acute adverse event is the cytokine release syndrome (CRS).
OBJECTIVES. To evaluate the CRS after infusion of CAR-T cells in children that required admission to the pediatric intensive care unit (PICU).
METHODS. Retrospective review of the patients that had received CAR-T therapy between April 2016 to February 2018 and needed PICU due to the CRS. During these period two different CAR-T cells therapies were used (Group 1 and group 2), both with 4-1BB as costimulatory signal. The CRS was graded using the Penn definitions.

RESULTS. Twenty-five patients were treated with CAR-T cells, 2 required a reinfusion. Seven patients required intensive care due to CRS (7/27, 25.9%). Four were girls (57.1%), and the median age was 8 years (IQR 6-19). Five patients were in the group 1 and 2 in the group 2. Six patients presented a high percentage of blasts before infusion.
In group 1 there were 3 girls (60%) and the median age was 8 years (IQR 7-21.5). The CRS began in the 3th day (IQR 2.5-4.5) and the median day since the infusion until the admission to the PICU was 6 day (IQR 3.5-6). Four presented CRS grade 3 (80%) and one presented CRS grade 4 (20%). All required inotropic support with a median inotropic score of 15 (IQR 9-92.5). None required mechanical ventilation. Three patients received one dose of tocilizumab (60%) in the day 1 of admission to the PICU. Two patients (40%) received steroids (prednisone) in the day 2.5. Three patients (60%) presented mild neurological impartment. The median days in the PICU was 5 (IQR 2-6.5) and in hospital was 31 days (IQR 15-47.5).
In group 2 there were 1 girl and 1 boy with an age of 4 and 11 years old, respectively. Both patients began the CRS symptoms in the day of infusion and were admitted to the PICU at the day 2 and day 1 after infusion. The maxim CRS were grade 4 and 5, respectively, and the second patient presented mild neurological toxicity. Both required inotropic support and mechanical ventilation. They were intubated at the second and third day after be admitted to the PICU. Both received 2 dose of tocilizumab and prednisone. The first patient was extubated at the day 5 and was transferred to the ward at the day 10th. The second patient behaved like a hemophagocytic lymphohistiocytosis and died due to the CRS at the 4th day of admission. This patient presented higher values of procalcitonin, lactate and ferritin.
The global survival of the CRS was 85.7%, considering all the infusion of CART-T cells 96.3% (26/27).
CONCLUSION. CRS was a frequent adverse event after infusion CAR-T therapy. In a third cases needed admission to the PICU. Tocilizumab was administered in CRS 3 and 4, always before steroids. The most severe CRS began with symptoms in the first day of infusion and needed two dose of tocilizumab. The survival of CRS was high.

INTRODUCTION. Clinical data science, and machine learning in particular, is on the rise with new ICU related prediction models being published continuously. However, few models make it to the bedside and are able to influence clinical decision making. Recently, we developed a machine learning based ICU readmission model (P.J. Thoral, et al, ESICM LIVES 2018 Meeting Abstract. Manuscript in preparation). We hypothesize that a tool based on our model should be adapted to be explainable to the intensivist and offer an intuitive user interface (UI).

OBJECTIVES.
To test both model output explainability from a software prototype based on our ICU readmission model and usability of the UI.
METHODS. A two-phase multicentre usability study was performed at the Amsterdam University Medical Center, location VUmc, Amsterdam, the Elisabeth-TweeSteden Ziekenhuis, Tilburg and the University Medical Center Utrecht, Utrecht. The study was performed using a software prototype of our ICU readmission model showing twelve representative patients, predicting the combined 7-day risk of ICU readmission or mortality on the moment of ICU discharge (see Figures 1 and 2).
As part of the technical file for CE application of the software, the study was set up according to the applicable guideline[1]. In phase 1 the software was tested by scripted end-user interaction. Results of these tests were used to improve the software. In phase 2 the improved software was tested. Both phases focused on the users' understanding of the model predictions and the user
-friendliness of the interface design. All responses were scored against the requirements of the software in order to evaluate safe use of the tool.
RESULTS. Phase 1 was completed by 15 individual intensivists; the second phase by six new and three recurrent intensivists. In phase 1 the explainability of the predictive features shown per patient was insufficient with the average number of difficult to interpret features being 4.9 out of 10 displayed features.
Table 1 shows the identified problems.
Furthermore, the graphical indicators and their meaning for specific ICU supportive care were potentially confusing. Based on these results explainability was improved by removing some less predictive features and by simplifying feature aggregates. The UI was enhanced by changing the display of feature importance and the supportive care indicators. In phase 2, after these modifications, the participants showed better understanding of the model output. The average number of clinically difficult to interpret features dropped to 2.2/10. In both phases all safety related equirements were met, meaning that >90% of participants correctly understood and applied the intended purpose of the tool.
CONCLUSION. We evaluated the use of an ICU readmission model in a software prototype and improved both the explainability of the model and usability of the software towards a valuable tool intensivists can understand and safely use in their decision on discharging a patient from the ICU.

Table 1 (abstract 001497). See text for description

Base Feature	Potential issue
Origin department	Poor generalizability when used as a substitute for admission diagnosis.
Serum urea	Poor generalizability when not measured frequently in all ICU's
Serum albumin	Unsafe use: may lead to clinicians directly targeting albumin (e.g. by albumin infusion)
Ionised calcium	Difficult to appreciate clinically since is often targeted directly (e.g. during renal replacement therapy)
Feature aggregation	**Potential issue**
Average over whole admission	Difficult to interpret since these averages are often not known by clinicians
Minimum first 24hrs – minimum last 24hrs Maximum first 24hrs – maximum last 24hrs SD first 24hrs – SD last 24hrs Slope first 24hrs – slope last 24hrs	Difficult to interpret without absolute values and reference values.
Minimum first 24hrs Maximum first 24hrs Standard deviation first 24hrs Slope first 24hrs	Difficult to interpret without absolute values or trend of the value. Disagreement among clinicians whether this is clinically relevant for patients with longer length of stay
Standard deviation last 24hrs Slope last 24hrs	Difficult to interpret without absolute value or trend of the value
Binary: measured in first/last 24 hours? Binary: at least measured once during admission?	Poor generalizability: could be process dependent, e.g. dependent on ICU routines and customs

INTRODUCTION. Intensive Care Unit –acquired weakness (ICUAW) is a clinical syndrome that develops while a patient is critically ill. In a recent multi-centre cohort study, ICUAW was present in more than 50% of patients at ICU discharge. In an official American Thoracic Society Clinical Practice Guideline, ICUAW was reported to be more common in patients with severe sepsis, prolonged mechanical ventilation, or difficulty with liberation from mechanical ventilation. There is no consensus on the approach to diagnosis of ICUAW. Physical examination of three muscle groups in each of the upper and lower limbs has been developped by the medical research council (MRC) in the UK and it results in a composite score of 60. This method has been proven reliable in a cooperative patient. In a prospective, multicentre cohort study, hand-held dynamometry was used in non cooperative patients to identify ICUAW and this method was independently associated with increased hospital mortality in patients with ICUAW. The leuven protocol is the most frequently used in ICU and it also correlates with mortanily.
OBJECTIVES. To identify the incidence of ICU-AW in patients admitted to a tertiary neursugical ICU in a large teaching hospital. To implement measures to prevent ICU-AW
METHODS. The study was conducted in a 24 beds neuro ICU in a teaching hospital. This is an adult ICU admitting over 2000 neurneurosulgical patients per year and with over 200 cases per year remaining in the ICU for over 7 days. One doctor and one physiotherapist performed daily rounds to assess the incidence of ICU AW, shoulder subluxation and ankle limitations in all neurosurgical patients. General characteristics were collected including age, gender, reason for admission, length of ICU stay, others. The Leuven protocol and planning was used to assess ICU-AW. Investigators collected data related to the position of the patient, presence or supporting devices for the shoulders, for the ankles, and the time and duration of physiotherapy provided every day. Data collected were daily compared and the diagnosis was agreed among doctors and the rehabilitation team. The nurses educators were involved in implementing new meaasures to prevent ICU-AW and to support the rehabilitation team .
RESULTS. Data were collected between the 13th decemebr and the 11 of November 2018. Interventions to reduce the incidence of ICU AW were implemented in January 2019. Data were anonymous and patients consented for the study. 101 measurements were performed in 25 patients. 100% of the patients had low cooperation (0-2) and low MRC score. 28% of the patients had shoulder subluxation at ICU discharge. 36% of the patients had ankle limitations (of whom 5% bilateral). Doctor was more likely to detect the shoulder subluxation (80% of relevations) and physiotherrapists the ankle limitations (65%). Nurses were not aware of this problem and they did not felt this could affect outcome.
CONCLUSION. ICU-AW and limitations are frequent in long standing neuro-surgical patients. Nursing staff is not aware and physiotherapy cannot prevent alone this complication. Combined complex interventions are needed to prevent ICU-AW. The nursing staff should be trained in positioning adequately the patient and support shoulders and ankles. Pillow and simple support devices are sufficient. Physiotherapy cannot provide enough resources to prevent these complications and these are frequently not diagnosed. Doctors should be trained in examining and recognise ICU AW because mortality is associated with the presence of sub-luxations or ankle limitations at ICU discharge. The Leuven protocol is ideal because it has a progression and an intervention scale which is easy to use. However, awareness and training of the staff in the ICU is needed.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001731

INTRODUCTION. ICU nurses are sometimes criticized as "high tech. & low touch" in the medical literature, which may create patient and nurse dissatisfaction patient but also to nurses. Stayt (2007) studied ICU nurse's emotional experiences and reflected ICU nurses face a fundamental conflict both between the role expectations of patient care, professional ideals and being a human which may contribute to occupational stress.
OBJECTIVES. To test a "Therapeutic Nurse Relationship Program" designed to improve nursing communication skill with patients and relatives in ICU
METHODS. From Nov.2018, a pre-survey was conducted to explore nurse communication within established therapeutic relationships with patients/families. Inclusion criteria: patient ICU stay > 72 hours, either patient or relatives were recruited by convenience sampling.

The survey questions included 6 questions used an anonymous 5-item questionnaire with a 5-point Likert response scale (1=poor to 5=excellent).
It focused on nursing communication with patient / relatives regarding: 1. Explanation before performing a procedure (such as suction/turning), 2. Care about patient's comfort, 3. Proactively updating the condition, 4. Providing psychological / mental support, 5. Offering religion support / referral, and 6. Overall satisfaction to nursing care
3 qualitative questions were also used to explore the subject's views of nursing communication. A teaching program was conducted at Dec., 2018 & focused on: 1. Different skills on communication - including verbal & non-verbal, and 2. Promotion of various referral service from hospital
79 (70%) of nurses attended the program and a post survey was conducted from Jan.- Feb.,2019 for comparison.

RESULTS

Data in table one shows that there was a substantial increase in positive response in three areas: 1. Providing explanation to patient / relatives before perform procedure (from 65% to 90%), 2. Providing psychological / mental support (from 55% to 70%), and 3. Offer religion support / referral (from 15% to 25%).
There was no substantial increase in the other domains, although overall baseline responses in the remaining domains were already good (>70%). Overall satisfaction baseline responses (excellent & very good) was already 80%, and increased to 90%.

CONCLUSION. The post-survey demonstrated a more positive feedback from patient's relatives than the pre-survey. This positive trend was confirmed in the in qualitative descriptions. It suggests the program may enhance nursing communication to improve the therapeutic relationship between nurses to patient & patient's relatives.

Table 1 (abstract 001731). Results of pre-intervention and post-intervention survey

Questions:	Pre-test (% rated excellent OR very good)	Post-test (% rated on excellent OR very good)
1.Explain before perform procedure (such as suction / turning)	65%	90%
2.Care about patient's comfort	70%	75%
3.Proactively update the condition	75%	80%
4.Provide psychological / mental support	55%	75%
5.Offer religion support / referral	15%	25%
6.Overall satisfaction to nursing care	80%	90%

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001735

INTRODUCTION. Cardiac arrest (CA) is a leading cause of mortality in Europe and United States. The average survival to discharge rate in out-of-hospital cardiac arrest patients (OHCA) is approximately 10%, in contrast to in-hospital cardiac arrest (IHCA) where it is 17-20%. The risk of neurological disability remains high among survivors in both groups.
Machine Learning (ML) is a type of artificial intelligence that provides systems the ability to automatically learn and improve from experience without being explicitly programmed.

OBJECTIVES. The aim of this study was to develop a type of ML algorithm using data from the Wardwatcher Intensive Care Unit (ICU) Swansea database to predict 30-day survival of patients admitted to ICU post cardiac arrest.

METHODS. All cardiac arrest patients admitted to our regional intensive care unit in South West Wales, United Kingdom between January 2007 and June 2018 were included in this analysis. Data included were age, gender, comorbidities, biochemical and haematological results as well as temperature within 24h of admission, length of stay, follow-up time and survival status.

RESULTS. Of the 1034 patients (532 OHCA and 502 IHCA) included in the study, 600 (58%) patients died within 30 days. Random forest (RF) was used as the type of ML algorithm. The area under the receiver operating characteristic curve (AUROC) and area under the precision-recall curve (AUPRC) predicting survival within 30 days of admission was AUROC: 0.89 and AUPRC: 0.91 (.80-.90= good and .90-1= excellent). For patients admitted with OHCA alone, the same RF algorithm showed AUROC: 0.86 and AUPRC: 0.91. The ML modelling took 0.99-2.32 seconds to be built.

CONCLUSION. ML modelling of the data of post cardiac arrest patients admitted to ICU can predict 30-day survival with a reasonable level of accuracy. Therefore, the data obtained from ML modelling may be used as an adjunct in making treatment decisions in these group of patients, however larger studies comparing different ML modelling are required to establish this.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001751

INTRODUCTION. Coding of diagnoses based on the International Classification of Diseases (ICD) is a world-wide standard used for the identification of health trends and statistics. Coded data is used for multiple purposes including billing, health care allocation, and research, presenting thus an urgent need for valid routine data. However, data validation of ICD-10 routine data in relation to the completeness and correctness of comorbidity documentation is rare.

OBJECTIVES. Purpose of this study is to examine whether co-morbidities of the Charlson-Comorbidity Index (CCI) that are derived from routinely documented ICD-10 codes in patient records correspond to manually assessed co-morbidities by a health professional on the basis of anamnesis data.

METHODS. This is a secondary analysis of the FRAIL-AMB project, a prospective observational study of elderly patients undergoing surgery in a German university hospital between 2017 and 2018. Ethical approval from the local authorities was obtained (EA1/227/16). The CCI was calculated according to Quan et al. from the ICD-10 coded routine data and compared to prospectively collected data from the FRAIL-AMB project that was defined as gold standard. We drew on result pair analyses.

RESULTS. A total of 1,186 patients were included into analyses. CCI completeness of 52% (95% CI: 51.4-52.7) and a correctness of 60.5% (95% CI: 59.9-61.2) was calculated for all comorbidity classes in the ICD-coded routine data (Figure 1, SAP_CCI1=ICD-coded routine data). Overall, a general undercoding was found.

CONCLUSION. The study suggests that ICD-10 routine data cannot provide consistently reliable information on all CCI comorbidity classes and should be used with caution. In a next step, improvement potentials of critical CCI comorbidity classes should be investigated.

Association of mean arterial pressure and acute kidney injury after high risk surgery

M. Greco, S. Falini, G. Angelotti, M. Cecconi
[1]Department of anesthesia and intensive care, Humanitas Clinical and Research Center, Milano, Italy
Correspondence: M. Greco
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001755

INTRODUCTION. Acute Kidney Injury (AKI) is a frequent and severe complication after major surgery, and is a common critical care outreach call and a frequent reason for ICU admission. With millions of surgeries performed worldwide every year, AKI have a high impact in terms of morbidity, mortality and costs. According to KDIGO guidelines, AKI is amenable to prevention, treatment and resolution (1). However, early AKI detection and patients stratification in standard surgical wards remains a significant challenge.
OBJECTIVES. To assess if mean arterial pressure (MAP) is associated with AKI after high-risk surgery
METHODS. Deidentified data from Electronic Health Records (EHR) of a large teaching hospital were included in the analysis. We selected a mixed surgical population of 1700 adult patients undergoing high risk vascular and thoracic surgery from Jan 2015 to Dec 2018. AKI was defined according to KDIGO guidelines (1), applying urinary and creatinine criteria to vitals and laboratory data derived from EHR. A subset including the first 7 postoperative days (POD) was selected for the analysis. MAP was estimated from systolic and diastolic pressure. Standard statistical regressions and machine learning techniques were applied using R (R Core Team 2019) for data analysis.
RESULTS. 1441 patients were finally included in the analysis, with 245 patients (17%) developing AKI. Mean MAP was lower in patients with AKI compared to controls on POD 1, 2 and 3, while there was no difference on the day of surgery or after POD 4. (Fig 1). A similar pattern was detected when plotting mean MAP up to AKI development against control MAP (Fig2). The association between mean MAP and AKI was confirmed when controlling for baseline variables and type of surgery in a logistic regression model, (OR 0.96 [0.94-.98]), while statistical significance was lost when adjusting for panel data. Machine learning models resulted in lower accuracy than standard models.
CONCLUSION. MAP in the first days after high-risk surgery is associated with AKI development. While both AKI and lower MAP can reflect an insult occurred during surgery, models based on EHR data may permit early stratification and detection of AKI, allowing to start timely treatment.

The complex effect of protamine on platelet function: an in vitro study using impedance aggregometry and flow cytometry

M. Törnudd[1], S. Ramström[2], JP. Kvitting[3], J. Alfredsson[4], S. Berg[5]
[1]Department of Cardiothoracic and Vascular Surgery and Department of Medical and Health Sciences, University hospital, Linköping, Sweden; [2]Cardiovascular research centre, school of medical sciences, Örebro University, Örebro, Sweden; [3]Department of cardiothoracic surgery, Oslo University Hospital, Oslo, Norway; [4]Department of cardiology and department of medical and health sciences, University hospital, Linköping, Sweden; [5]Department of cardiothoracic and vascular and department of medical and health sciences, Linkoping University Hospital, Linköping, Sweden

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001301

INTRODUCTION. In cardiac surgery, heparin and protamine are fundamental for management of anticoagulation, and its management is known to affect bleeding. The effect of protamine on platelet function, however, is not fully understood. In previous *in vivo*-studies(1) using impedance aggregometry, a decrease in platelet function after exposure to protamine has been seen.
OBJECTIVES. The aim of this study was to further examine the effect of protamine on platelet function *in vitro,* using both aggregometry and flow cytometry.
METHODS. Seven elective CABG patients were studied using impedance aggregometry (Multiplate). Blood was mixed with protamine to a concentration of 0, 20, 40 and 80 µg/ml. Adenosine diphosphate (ADP) was used as activator and aggregation was expressed as the area under the curve (AUC).
Blood from 7 healthy volunteers was studied using flow cytometry with protamine added in the same concentrations as above, either alone or together with ADP. Median fluorescence intensity (MFI) from the monoconal antibody PAC-1-FITC, which binds to the activated fibrinogen receptor on activated platelets, was studied. We also studied expression of P-selectin using the antibody anti-P-selectin-PE (CD62P, clone: AK-4).
Statistics used were ANOVA and paired T-test. Data are expressed as mean ± standard deviation.
RESULTS. With aggregometry, mean AUC for platelets activated by ADP decreased with protamine from 73.8 ± 29.4 U (no protamine) to 61.8 ± 29.4 U (20 µg/ml), 51.7 ± 26.8 U (40 µg/ml), and 46.9 ± 26.1 U (80 µg/ml); p= 0.003. With flow cytometry, when activated with ADP, protamine reduced platelet activation seen by MFI from 5.1± 2.0 (no protamine) to 4.1 ± 0.7 (20 µg/ml), and 3.1 ± 0.4 (40 µg/ml); p=0.02. When only activated with protamine, mean MFI increased from 0.4 ± 0.04 (no protamine) to 0.7± 0.2 (20 µg/ml), 1.9± 1.0 (40 µg/ml), and 3.1± 0.8 (80 µg/ml); p<0,001. At 80 µg/ml protamine, mean MFI was similar both with and without activation with ADP (3.4 ± 0.2 and 3.1 ± 0.8, respectively).
Protamine with and without any activator, produced a significant concentration-dependent increase in the proportion of platelets exposing P-selectin, which indicates release of alfa-granule. The mean proportion of P-selectin-positive platelets when no other activator was used, increased from 4.0 ± 2.7 % (no protamine) to 95.3 ± 3.0 %(80 µg/ml); p<0.001. When activated with ADP, the proportion increased from 22.8 ± 17.6 % (no protamine) to 95.8 ± 2.5 % (80 µg/ml); p<0.001.
CONCLUSION. Protamine *in vitro* interacts with platelets with both a direct activating effect and impairment of activation by other activators. This impairment is consistent with previous *in vivo*-data showing reduced platelet function after protamine exposure. The direct activating effect may have significance for the risk of thrombosis in cardiac surgery.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001336

INTRODUCTION. Alterations in microcirculation have been shown to influence patient outcome and survival in different types of shock. [1] Spinal cord is extremely sensitive to changes in microcirculation and spinal cord hypoperfusion or ischemia with consecutive paraplegia are major complications in thoraco-abdominal aortic repair [2] The positive effects of albumin administration on macro and microcirculatory state in shock have recently been described [3]. However none of this studies primarily focused on the effects on spinal cord microcirculation.
OBJECTIVES. To date the direct effect of albumin administration on spinal cord microcirculation has not been systematically assessed. Therefore the aim of this study was to test whether a albumin based volume resuscitation can improve spinal cord microcirculation in a experimental model of shock
METHODS. The study was designed as prospective trial in 10 domestic pigs. Animals were anaesthetized and mechanically ventilated. A laser – Doppler fluxmetry (LDF) Needle probe was directly placed in the lumbar spinal cord for measurement of microcirculatory blood flow (mFLUX). After baseline measurements (M0) . Shock was in induced by hypovolemia (M1) (withdrawal of blood 20ml/kg bodyweight). Thereafter volume loading was performed using 5 % human albumin until no positive macro-hemodynamic response to volume administration occurred (M2). An increase in stroke volume >10% was considered as a positive volume response.
RESULTS. Spinal cord mFLUX significantly decreased (47,8 at M0 to 22,7 at M1 p<0.05) during shock and was significantly increased after albumin administration (22,7 at M1 to 51,2 at M2 p<0.05). Furhtermore there was no significant difference between the mFLUX values at M2 and baseline.
CONCLUSION. In our experimental animal model albumin based volume resuscitation was able to improve spinal cord microcirculation.

Protein kinase C expression and cardioprotective effects of remote ischemic preconditioning in cardiac surgery

D. Tashkhanov, A. Bautin, S. Datsenko, A. Marichev, A. Radovskiy
[1]Anesthesiology and intensive care medicine, National Medical Research Center. VA Almazov, Sankt-Peterburg, Russia
Correspondence: D. Tashkhanov
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001340

INTRODUCTION. Remote ischemic preconditioning is a perspective method of cardioprotection.
OBJECTIVES. To evaluate cardioprotective effects of remote ischemic preconditioning (RIPC) and myocardial protein kinase C epsilon (PKC-

ε) release in patients undergoing aortic valve replacement under different types of anesthesia.
METHODS. In prospective randomized study we enrolled 48 patients, aged 64(56;69) years, which were scheduled for elective aortic valve replacement using cardiopulmonary bypass (CPB). We divided them into 4 groups: 1) RIPC performed during propofol anesthesia (RIPC prop, n=12), 2) RIPC performed during sevoflurane anesthesia (RIPC sevo, n=12), 3) propofol anesthesia without RIPC (CONTROL prop, n=12), 4) sevoflurane anesthesia without RIPC (CONTROL sev, n=12). Initial data of participants was similar in all groups. RIPC protocol consisted of 3 simultaneous 5-min ischemic episodes of both lower limbs with 5-min reperfusion intervals. Right atrium myocardium incision biopsy was performed for PKC-ε expression assessment using Western immunoblot. Troponin I levels (cTnI) were measured before anesthesia induction, after 30 min, 6, 12, 24, 48 hours after CPB completion. Data were assessed using Mann-Whitney U-test and Newman-Keuls method for multigroup comparison. $p<0.05$ was considered significant. The data are presented as median (25th;75th percentile).
RESULTS. RIPC showed cardioprotective effects only after sevoflurane anesthesia: significant differences in cTnI were found between RIPC sevo and CONTROL sevo groups at 6, 12 and 24 hours: 1.68(1.28;2.09) ng/ml vs 3.66(2.07;4.49) ng/ml, respectively at 6 hours ($p=0.04$); 1.89(1.59;2.36) ng/ml vs 3.66(2.91;5.64) ng/ml, respectively at 12 hours ($p=0.001$); 1.68(1.55;2.23) ng/ml vs 3.32(2.10;5.46) ng/ml, respectively at 24 hours ($p=0.01$). There were no differences found in cTnI between RIPC prop and CONTROL prop groups in all timepoints. RIPC applied during sevoflurane anesthesia also significantly increased PKC-ε expression: 1221(921;1438)Units in CONTROL sev group vs 1882(1564;2131)Units in RIPC sevo group ($p<0.05$). Performing RIPC during propofol anesthesia was not associated with any significant difference in PKC-ε expression compared with control group: 620(436;782)Units in CONTROL prop versus 788(574;1063)Units in RIPC prop group. PKC-ε expression between control groups was significantly higher in sevoflurane anesthesia than propofol anesthesia.
CONCLUSION. RIPC showed cardioprotective effects only during sevoflurane anesthesia. This was confirmed by PKC-ε expression increase and lower value of cTnI.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001344

INTRODUCTION. The ability to assess and appropriately interpret a patient's fluid responsive status is a critical skill for all ICU staff when managing complex patients with hemodynamic compromise. There are several techniques of varying complexity available to assess preload responsiveness. Intravenous fluid administration is not risk-free and should only be used under the right circumstances.
OBJECTIVES. The primary outcome was to assess the overall change in knowledge about fluid responsiveness assessment amongst the ICU staff in response to interventional educational processes. Secondary outcomes looked at the changes amongst the varying groups and the change in opinion/practice following education.
METHODS. A 25-question survey was composed based on a landmark paper by Monnet et al and it was given out to all ICU staff, including consultants, trainees, nurses and medical students. Results from this were determined at baseline and after education by means of a fact sheet, a tutorial and it being a "hot topic of the week". Each stage of the project was administered over 2 weeks: that is, the first round of surveys was given out and collected over the first 2 weeks, then the educational processes were delivered over the following 2 weeks, and finally, the second round of surveys was given out and collected over the subsequent 2 weeks. There were 25 participants in the first round and 14 participants in the second round.
RESULTS.
CONCLUSION. There was an overall improvement in the knowledge of fluid responsiveness assessment in the critical care unit healthcare workers in response to the educational processes. There was a decrease in the number of people who used CVP, CXR and lactate in their assessment, for which there is no role in gauging fluid responsiveness. There was also a decrease in the number of people who used fluid challenges as their technique of choice with increased usage of other techniques, such as pulse pressure variation and passive leg raising. This highlighted an increase in awareness of the fact that a fluid challenge is a treatment in and of itself with associated risks and less invasive means should be used, where feasible. Review of cases of iatrogenic fluid overload is needed in the future to assess the impact of this increase in knowledge, change in opinion and change in practice of fluid responsiveness assessment on patient outcome.

INTRODUCTION. Right ventricular (RV) dysfunction has been largely investigated in ARDS in terms of acute cor pulmonale (ACP). However, ACP represents the last stage of RV failure. We aim to investigate early RV dysfunction signs with echocardiography in patients undertaking whole lung lavage (WLL) for pulmonary alveolar proteinosis (PAP).
OBJECTIVES. To evaluate the correlation between echocardiographic parameters of RV function and respiratory mechanics at different steps of transpulmonary pressure during WLL.
METHODS. Prospective observational study of patients undertaking WLL for PAP from January 2014 to March 2019. All patients were intubated with selective orotracheal tube. WLL entails the performance of alternatively single-lung ventilation while large-volume (20 L) lavages are instilled and drained on the non-ventilated lung along with chest physiotherapy and postural positioning. Calibrated values of oesophageal pressure were used as surrogate for pleural pressure (Ppl); transpulmonary pressure (PL) was calculated during end-inspiratory (insp) and end-expiratory (exp) occlusion manoeuvres (1). Paw is the airway pressure. Right ventricular longitudinal function (TAPSE) and the ratio between trans-tricuspid early diastolic flow (E wave) and tricuspid annular tissue velocity displacement (E') were collected to evaluate respectively systolic and diastolic function of RV (2). Ratio of RV to LV end-diastolic area – RVEDA/LVEDA- is a marker of ventricular interdependence sensitive to RV afterload variations (3). Respiratory mechanics and echocardiographic parameters were collected at ZEEP (t0), at clinical PEEP right before the procedure (t1), after the first lung lavage (t2), and at end of procedure after the lavage of the second lung (t3).
RESULTS. Preliminary results on 13 patients (69% males). RVEDA/LVEDA ratio correlates with Paw insp ($p < 0.0001$, r 0.61), Paw exp ($p < 0.0001$, r 0.6), PL insp (p 0.0001, r 0.5) and PL exp (p 0.0006, r 0.46), but not with Ppl. RV E/E' was related to Paw insp ($p < 0.001$, r 0.47), Paw exp ($p< 0.001$, r 0.49) and PL insp ($p<0.001$, r 0.5269). TAPSE was not related to respiratory mechanics parameters. **Table** Values of respiratory and echocardiographic variables tested: mean (± standard deviation)
CONCLUSION. In the setting of WLL, the increment in RVEDA/LVEDA and in E/E' could be considered sensitive markers of early RV dysfunction. Absolute values of transpulmonary and alveolar pressures, and not their respiratory variations (the driving pressures), are correlated with RV function.

INTRODUCTION. Circulatory shock is common, accounting for one third of all ICU admissions. Despite current resuscitative practices aimed at restoring macro-hemodynamics, mortality remains high at over 50%. (1) This residual mortality has been attributed to microcirculatory failure, yet clinical monitoring of microcirculatory function remains elusive. Venous-to-arterial carbon dioxide difference (Pcv-aCO2 gap) has emerged as potential clinical marker of microcirculatory function, with some studies suggesting that values greater than 6 mmHg are predictive of poor outcomes. (2,3)
OBJECTIVES. We carried out a systematic review and quantitative meta-analysis to determine if high Pcv-aCO2 gap is associated with increased mortality in adult critically ill patients presenting with circulatory shock admitted to medical, cardiovascular and surgical ICUs.
METHODS. We conducted a systematic search using MEDLINE® and EMBASE® electronic databases, using OvidSP search interface, from inception through October 2017. Searches were restricted to studies published in English language. The MOOSE checklist was followed and methodological quality was assessed using Newcastle-Ottawa Scale (NOS).
RESULTS. We included 50 studies (n=3948 patients) from medical (n=26), cardiovascular (n=15), surgical (n=5) and mixed (n=4) ICUs. The majority of studies were observational with prospective (n=40) or retrospective (n=8) designs, and two were randomised controlled trials (RCT). Eighteen studies reported the primary outcome (either hospital or 28-day mortality). In these studies, high Pcv-aCO2 gap (> 6mmHg) was associated with higher hospital mortality with an odds ratio of death of 2.6 (95% CI [1.6, 4.4], $P<0.001$). Subgroup analysis, showed that Pcv-aCO2 gap may be a stronger predictor of mortality in the medical ICU patients in comparison to cardiac and surgical population. This occurred on the background of similar cardiac index (0 hr: $P=0.07$; 6 hrs: $P=0.2$; 24 hrs: $P= 0.96$), lactate (0 hr: $P=0.15$; 6 hr: $P=0.06$; 24 hrs: $P=0.49$), and central venous oxygen saturation (0 hr: $P=0.5$; 6 hr: $P=0.41$; 24 hrs: $P=0.93$) between high and low Pcv-aCO2 gap groups. Meta-regression showed that the high gap has a predictive power even if the differences in the established predictors of mortality (APACHE II and SOFA) are accounted for ($P= 0.0296$, $R^2 = 0.60$ and $P= 0.0151$, $R^2 = 0.83$, respectively). There was no statistical difference in terms of secondary outcomes such as ICU and hospital length of stay, mechanical ventilation days and requirements for vasopressors and inotropes between the two groups. However, a high Pcv-aCO2 gap was associated with an increased odds of requiring renal replacement therapy (odds ratio: 1.95, 95% CI [1.32, 2.9], $P= 0.001$).
CONCLUSION. In patients with circulatory shock, high Pcv-aCO2 adds predictive power over established predictors of hospital mortality despite similar indices of macro-circulation and tissue perfusion. Future studies should evaluate whether resuscitation aimed at closing the Pcv-aCO2 gap Improves mortality in shock.

Assessment of volumresponsivness (VR) by ultrasound parameters of carotic blood flow in patients with heart failure (HF) or cardiogenic shock (CS)

M. Janotka, P. Ostadal, A. Krüger, D. Vondrakova, J. Naar, P. Neužil
[1]Cardiovascular center, Na Homolce Hospital, Prague, Czech Republic
Correspondence: M. Janotka
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001489

INTRODUCTION. Fluidoverload in critical ill patients leads to worse prognosis.Therefore the assessment of VR is crucial and we should refrain from blind administering of volume in order to evaluate the VR.Tests looking at change of cardiac output (CO) using reversible increase of preload (e.g. passive leg raise PLR) are preferred instead.Continual monitoring of CO for assesment of fast changes is necessary e.g. echography or pulse contour analysis (PCA) monitors.Recent data showed promising results of assessing the VR by easy ultrasound (US) examination of carotic blood flow changes in patients on ICU.Unlike echography this method has short learning curve and does not need expensive PCA monitor.But there are no data for patients with HF or CS yet.
OBJECTIVES. The first aim was evaluating the relationship between changes of CO measured by echography and PCA monitor and changes of carotic flow measured by US in patiens with HF or CS on mechanical ventilation.The second aim was to find out cut-off values of these parameters for determination of VR.
METHODS. We examined 21 patients with HF or CS on mechanical ventilation from Jan 2018 to Mar 2019.17 patients required inotropes at the time of examination being in state of CS either alone or combined with distributive shock.All patiens underwent complex analysis of VR (increase of CO by 15% after volume challenge or after PLR were considered as VR).All patients had PLR test and stroke volume variation examined,measured by echography (velocity-time integral in outflow tract) and PCA monitor.Additional parameters were taken into account-echographic signs of left ventricle(LV) filling pressure (transmitral diastolic flow /E,A,E´/,gradients on pulmonary and mitral regurgitation jets) and colabsibility of inferior vena cava,-pulmonary capillary wedge pressure (4patients had Swan-Ganz/SG/catheter).Patients considered as volumresponsive underwent volum challenge.Those considered nonresponsive underwent volum challenge only if it was regarded as safe.We examined following carotic parameters: respiratory variation of peak velocity(Vmax),effect of PLR test on corrected carotic flow time (CFT) and carotic blood flow (CBF).
RESULTS. Average LV ejection fraction was 35.6%.10 patients were deemed as volumresponsive.All of them had positive response on volume administration.11patients were deemed as nonresponsive.5 of them had volum challenge done without positive response, remained 6 patients were considered not safe for volume challenge but 4 of them had SG catheter and PCWP above 20torr.Linear regression analysis revealed relationship between relative change of CO (ΔCO) and CBF calculated by equation ΔCBF=1,21*ΔCO+8,53. We found linear relationship also between ΔCO and changes of both Vmax and CFT (ΔVmax=0,62*ΔCO+3,64 and ΔCFT=0,61*Δ+1,82)The cut-off value for volumresponsivness was found by ROC analysis 15% for ΔCBF,10.7% for ΔVmax and 6.2% for ΔCFT.
CONCLUSION. Although it is a small cohort of patients, our data imply possible applicability of easy carotic US examination in fluid management in patients with HF or CS.Change of ΔCBF seems to be the most promising parameter.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001499

INTRODUCTION. Although inflammation is recognized as a major contributor for heart failure (HF) progression, clinical trials targeting proinflammatory cytokines in HF have been disappointing. A better understanding of the inflammatory pathways triggered in acute HF (AHF) is urgently needed to identify putative therapeutic targets to alter the course of this disease. A new paradigm of the inflammatory process has emerged recently, introducing endogenous specialized pro-resolving mediators (SPMs) that stimulate the resolution of inflammation and tissue regeneration. These include resolvins (Rvs) and lipoxins (LXs) that were never studied in human AHF.
OBJECTIVES. To evaluate SPMs and their correlation with markers of inflammation, oxidative stress, cardiovascular dysfunction and also with prognostic scores/biomarkers in human AHF.
METHODS. AHF (n=10) and cardiogenic shock (CS) (n=9) patients were included and blood samples were collected at days 1-2, 3-4 and 5-7. Blood donors were used as controls (n=10). LXA4, 15-epi-LXA4, RvD1, RvE1, endocan (endothelial dysfunction/proinflammatory marker), IL-10, myeloperoxidase (MPO) and nitrotyrosine were measured with ELISA kits. C-reactive protein (CRP), B-type natriuretic peptide (BNP), high-sensitivity troponin I (hsTi), lactic acid, APACHE II and SAPS II scores were also evaluated.
RESULTS. At admission, CS was associated with significantly lower RvD1 (CS vs AHF, p=0.024) and higher values of RvE1 (CS vs controls, p=0.004) and IL-10 (CS vs controls, p=0.044). Both AHF and CS groups exhibited higher endocan and MPO serum concentrations ($p<0.05$ or $p<0.001$ vs controls) and unaltered LXs values. During hospitalization, we only observed significant marked reductions for LXs values. Within patients, we observed that RvD1 presented inverse correlations with endocan (r=-0.38, p=0.009), lactic acid (r=-0.51, p=0.041), 15-epi-LXA4 (r=-0.32, p=0.029), IL-10 (r=-0.35, p=0.004) and SAPS II (r=-0.50, p=0.029), while positive correlations were observed for RvE1 with CRP (r=0.30, p=0.047) and MPO (r=0.29, p=0.048), LXA4 with 15-epi-LXA4 (r=0.70, $p<0.001$), and IL-10 with endocan (r=0.43, p=0.004), nitrotyrosine (r=0.35, p=0.018), hsTi (r=0.37, p=0.017), CRP (r=0.41, p=0.007) and APACHE II (r=0.62, p=0.006).
CONCLUSION. RvE1 increases with clinical severity, being positively associated with proinflammatory status. RvD1 appears to be exhausted/inactivated in worse clinical scenarios in AHF spectra, being probably a protective mediator and a potential therapeutic target as suggested by its inverse correlations with biomarkers of endothelial dysfunction, inflammatory status and prognostic scores/biomarkers. The drastic reductions in LXs values during

hospitalization may be related to poor prognosis in AHF after discharge, as higher severity of chronic HF was previously shown to be associated with lower values of these SPMs.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001500

INTRODUCTION. Nowadays, the prevalence of aortic stenosis is increasing and some of these patients present comorbidities where the surgical replacement is contraindicated. As an alternative solution, there is TAVI intervention, available in our hospital since 2010 with an important rise in survival for this population.
OBJECTIVES. Mortality rates review during hospital stay and one year mortality, for patients who underwent TAVI in a tertiary level hospital without Cardiac Surgery Department.
METHODS. Between January 2011 and November 2018, all patients undergoing TAVI with transfemoral self-expandable and balloon-expandable bioprotesis at Burgos University Hospital, were included in a retrospective registry (CEIC: 2062). Demographic characteristics, periprocedural complications and comorbidities were recorded in Excel database with posterior analyses in SPSS. Survival was estimated using the Kaplan-Meier method.
RESULTS. During study period, 103 TAVI were implanted in our hospital. 30-day mortality was 7%, one year mortality was 18% instead. Mortality during Intensive Care Unit stay was 4%. Survival probability was calculated with mortality rates: 50% at 45 months since TAVI implantation.
Once all mortality causes were bundled, a 6,8% of patients died due to severe complications during the implantation, predominantlyvascular issue. During post-implant period, 7% of the patients died because of acute heart failure, 1,9% cardiac block, 1,9% had severe hemorrhage to death and 3,9% had systemic infection to death with organ failure.
Presenting previous malignant illness or an active one, was associated with global mortality independently (OR 1,42, 95% [IC] 0,258 – 7,896; p= 0,027).
CONCLUSION. TAVI implantation is being introduced as a treatment with high survival in our center with similar outcomes comparing with the available data. The careful selection of best candidates for TAVI implantation based on patient risk factors and comorbidities is the clue for success.

INTRODUCTION. Acute heart failure (AHF) is a high mortality disease with a complex pathophysiology, including renin angiotensin aldosterone system disorders. Therapeutics of AHF are lacking (1). Dipeptidyl peptidase 3 (DPP3) is a protein whose main substrate are angiotensin II and enkephalins (2). Recently, high DPP3 levels were associated to a high mortality and organs failure in septic patients (3).
OBJECTIVES. The aim of our work is to describe consequences of high DPP3 levels and effects of its inhibition in an experimental mice model of AHF.
METHODS. Our study obtained approval of local ethic committee and used 3 month old C57Bl6 mice. (A) DPP3 was IV injected in mice followed during 2h after injection. (B) In an isoproterenol (ISO) induced stress protocol mice followed during 24h were blinded injected by a antibody against DPP3, the Procizumab (PCZ), or PBS. Myocardial oxidative stress staining was realized by dihydroethidium (DHE) immunofluorescence. Datas were expressed as mean ± SEM (intergroup comparison by 2 ways of ANOVA and Mann Whitney test, $p<0.05$ was significant).
RESULTS. (A) 7 mice were included in DPP3 injection protocol (n=3 sham, n=4 DPP3). Shortening fraction (SF) decreased and reached low value at 15 min after DPP3 injection (53 ± 1 vs 62 ± 1, $p<0.05$), renal resistive index (RRI) increased at 60 min (0.77 ± 0.05 vs 0.56 ± 0.01, $p<0.05$) and increased myocardial oxidative stress at 120 min (4.8±0.7 AU vs 1.4±0.3 AU, $p<0.05$). (B) 15 mice were included in ISO + Procizumab protocol (n=5/group). In ISO + PCZ group, SF increased from the first hour (48 ± 1% vs 60 ± 1, $p< 0.0001$), RRI decreased at 6h (0.62 ± 0.02 vs 0.81 ± 0.06, $p<0.05$), and decreased myocardial oxidative stress at 1h (2.6 AU ± 0.5 vs 9.3 AU ± 0.9 $p<0.05$) after Procizumab injection, compared to ISO + PBS group.
CONCLUSION. Excess of circulating DPP3 induced myocardial depression. DPP3 inhibition by Procizumab restore cardiac function and kidney hemodynamics and decrease oxidative stress. Studies are necessary to understand the role of DPP3 in AHF pathophysiology. Procizumab could be an interesting therapeutic in AHF.

Effects of transfusion of two units of red blood cells on haemodynamics in severely anaemic critically ill patients: an observational study in patients with MASIMO (Radical 7) and PiCCO monitoring

A. Herner, W. Huber, R. Schmid, I. Hartter
[1]Medizinische klinik und poliklinik ii, Klinikum rechts der Isar; Technische Universität München, Munich, Germany
Correspondence: W. Huber
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001559

INTRODUCTION. Anaemia due to acute or chronic loss of blood or due to dilution is frequent in critically ill patients. Thresholds to initiate transfusion with red blood cells (RMC) are matter of an ongoing debate. Nevertheless, there are only few studies investigating the impact of transfusion on extended haemodynamic monitoring (1).
Therefore, we investigated changes in haemodynamic parameters induced by transfusion of two units of red blood in 45 critically ill patients under haemodynamic monitoring with Radical 7 (MASIMO, USA; 45 patients) and PiCCO (35 patients; 10 patients required transfusion before initiation of PiCCO-monitoring).
METHODS. This prospective observational study was performed on a general ICU of a University Hospital in Munich. Only patients at predefined need of blood transfusion (laboratory haemoglobin Hb < 7mg/dL; in case of pre-existing severe cardiovascular disease: Hb <8 mg/dL; measured with RAPIDPoint 500 Blood Gas analyzer (Siemens, Germany)) were included. All measurements were performed prior and after the transfusion of two units of red blood cells. Statistics: Wilcoxon-test for paired samples. IBM SPSS 25.
RESULTS. 12 (27%) female and 33 (73%) male patients, height 175±8cm, weight 79±17kg. Hb measured by the blood gas analyzer increased from 6.7±0.6 to 8.8±0.8g/dL (p<0.001). Among MASIMO-parameters, perfusion index PI decreased from 2.7±2.3 to 2.3±1.7 (p=0.024) and pleth variability index (PVI; only analyzed in patients with sinus rhythm SR and controlled mechanical ventilation CMV) increased from 10.4±5.5 to 14.5±10.4; p<0.001. By contrast, PiCCO-derived stroke volume variation SVV (9.4±7.9 to 8.5±7.2%; p=0.442) and pulse pressure variation PPV (6.8±5.9 to 7.6±7.3%; p=0.719) did not change. Among the other PiCCO-derived parameters, the most pronounced change was an increase in mean arterial pressure MAP (87.6±11.6 vs. 97.2± 14.1mmHg; p<0.001). Furthermore, cardiac power index CPI increased from 0.82±0.25 to 0.91±0.26W/m^2 (p=0.009), and SVRI increased from 1093±483 to 1353±653dyne/cm2/m5; p<0.001. Global ejection fraction decreased from 25.3±6.6 to 23.7±6.8% (p<0.001). All other parameters did not change significantly from before to after transfusion: Heart rate 93±15 vs. 92±17/min (p= 0.154); cardiac index CI 4.9±1.4 vs. 4.7±1.3L/min/m^2; p=0.064; stroke volume index SVI 53.6±13.2 vs. 52.2±14.1mL/m^2; p=0.098; extravascular lung water index EVLWI 10.9±3.8 vs. 11.4±3.2mL/kg; p=0.099; CVP 19.9±17.8 vs. 17.7±8.1mmHg; p=0.203; global end-diastolic volume index GEDVI 878±187 vs. 894±172mL/m^2; p= 0453; dPmax 1328±414 vs. 1354±393mmHg/s; p=0.184. Furthermore, the noradrenaline dosage was comparable before and after transfusion (413±317 vs. 398±345µg/h; p=0.465).
CONCLUSION. 1.) Transfusion of two units of red blood cells in severely anaemic patients resulted in marked increases in MAP (11%) and CPI (11%). 2.) In patients with SR and CMV, changes in dynamic indices of fluid responsiveness derived from MASIMO and PiCCO were not congruent: While PVI increased despite the volume load, SVV and PPV did not change. 3.) MASIMO-measured perfusion index PI decreased despite the volume load by two units of red blood cells.

Evaluating the accuracy and reliability of sublingual microcirculation measurements as an adjunct to fluid management in cardiac surgery patients

G. Guven[1], J. Montomoli[2], S. Roelen[3], P. Giaccaglia[2], BAD. Mol[3], C. Ince[2]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001570

INTRODUCTION. Fluid administration is the first therapeutic response in perioperative patients where there are signs of decreased tissue oxygenation and impaired organ perfusion [1]. Inadequate fluid therapy can cause hypovolemia. Conversely, excessive fluid administration leads to a positive cumulative fluid balance which can lead to complications for the cardiac surgery (CS) patient [2]. No real endpoint for optimal administration of fluids is currently available and global macrohemodynamic parameters may not always reflect microcirculatory dysfunction [3]. Here we introduce a non-invasive integrative hemodynamic monitoring (IHM) approach to monitor the hemodynamic impact of fluid therapy by monitoring the systemic circulation microcirculation and tissue water composition. We propose this integrative hemodynamic platform as a comprehensive physiologically based approach for fluid management of the CS patient.
OBJECTIVES. We aimed to determine how microcirculation, macrocirculation, and body fluid compartments are affected in post-ICU CS patients.
METHODS. Twenty-five patients whom underwent open CS were included in the study. Non-invasive IHM was accomplished by measurement of sublingual microcirculation (Cytocam-IDF, Braedius Medical, Huizen, the Netherland), systemic hemodynamic parameters (Nexfin, BMEYE, Amsterdam, The Netherlands) and of the body fluid status (Body Composition Monitor, Fresenius Medical Care, Bad Homburg, Germany). Measurements were performed before CS (T0), first (T1) and on day 3 (T3) after admission to the ward from the ICU.
RESULTS. Seventeen patients with three-time points and eight patients with two-time points were analyzed using dedicated software. The baseline body weight was 84.5 kg (79.4; 93.8) which T0, increased to 89.4 kg (82;101) at T1 and 86.5 kg (80.9; 97.3) at T3 (p< 0.001). Total vessel density showed an inverse relationship to body weight (T0: 24 mm/mm2(22.9;25.3), T1: 20.2 mm/mm2(18.5;21;6), T3: 21.6 mm/mm2(19.4;23.5), p<0.001). Total body water and extracellular water changed in parallel with the change in body weight (p= 0.002 and p<0.001, respectively). Interestingly, intracellular water (ICW) at T3 was found to decrease significantly lower than baseline although ICW at T1 was not significantly different from T0 (T0: 20.3 lt (17.5; 22.8), T1: 20.7 lt (18.8; 23.1), T3: 18.9 lt (16.4; 21.1), p=0.012). Systolic, diastolic and mean arterial pressure at T1 and T3 were found to be lower than baseline (p=0.004, p=0.024, p=0.005, respectively). Cardiac output/index and dP/dt did not differ within time points (p= 0.08 and p=0.42, respectively). Stroke volume was 96 ml (85;104) at T0, and decreased to 82 ml (74; 94) at T1, and 85 ml (67; 93) at T3 (p=0.004).
CONCLUSION. Our study shows that non-invasive IHM allows comprehensive identification of behaviour of fluid therapy in CS patients. Results show that CS related microcirculatory perfusion disturbances and loss of hemodynamic coherence occur as a result of fluid therapy which persists even after discharge from the ICU.

Acute Myocardial Infarction in Polyvalent Intensive Care Units

AT. Ferreira, D. Tiago, V. José, G. Nuno, L. Bento
Intensive care unit, Centro Hospitalar Universitário de Lisboa Central, Lisbon, Portugal, Portugal
Correspondence: A.T. Ferreira,
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001587

INTRODUCTION. Acute Myocardial Infarction (AMI) is a potentially life-threatening condition, frequently diagnosed in critical care environment. The presence of concomitant medical conditions such as infection or hematological disorders may reduce therapeutic options. It is therefore important to characterize this subset of patients, since the medical approach is often challenging.
OBJECTIVES. To analyze the population of patients admitted in Polyvalent ICUs with the diagnosis of AMI in a two-year period.
METHODS. We performed a retrospective characterization of patients admitted in two Polyvalent Intensive Care Units between January of 2017 and December of 2018, with the primary or secondary diagnosis of AMI.
RESULTS. The final diagnosis of AMI was made in 72 patients, 31,9% of which (n=23) classified as STEMI. The median age of the population was 71 years.
72,2% (n=52) of the patients had a previous diagnosis of Arterial Hypertension, and 48,6% (n=35) of Diabetes mellitus. 26,3% of the patients (n=19) had previously known coronary heart disease.
51,4% (n=37) were admitted in circulatory shock (cardiogenic or other).
43% of the patients (n=31) did not perform coronary angiography, either due to clinical instability from concomitant medical conditions or to the likely diagnosis of type 2 myocardial infarction.
Among the STEMIs, 7 cases were admitted in Polyvalent ICUs after successful cardiopulmonary resuscitation and immediately after cardiac revascularization in order to initiate hypothermia protocol.
56,9% (n=41) of the total number of patients were submitted to coronary angiography, and in 33,3% (n=24) Primary Coronary Angioplasty of one or more coronary arteries was performed. Seven patients were proposed for Coronary Artery Bypass Graft surgery. The remaining patients were considered to have no benefit from revascularization.
The intra-hospital mortality was of 37,5% (n=27).
CONCLUSION. The patients diagnosed with AMI in Polyvalent ICUs require different medical and interventional approaches, since there are often distinct pathophysiology processes involved and conditions preventing early revascularization. An experienced team and availability of resources are fundamental to ensure the best outcomes among these patients.

How common is new onset atrial fibrillation in critical care? A single centre retrospective study

J. Macfarlane[1], B. Johnston[2], I. Welters[2], A. Waite[2]
[1]Institute of ageing and chronic disease, University of Liverpool, Liverpool, UK; [2]Critical care, Royal Liverpool and Broadgreen University Hospitals NHS Trust, Liverpool, UK
Correspondence: A. Waite
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001617

INTRODUCTION. Atrial fibrillation (AF) is the most common arrhythmia in critical ill patients (1). New onset AF (NOAF) is linked with severity of disease and is associated with poorer outcomes, including prolonged ICU stays and higher mortality rates (1-3). National guidelines exist in the UK for management of AF, but they are not specific to critical care (4). The most effective treatment for AF in critical care remains unclear.
OBJECTIVES. To retrospectively assess the incidence and management of new-onset atrial fibrillation in a single centre critical care setting.
METHODS. Notes of 909 patients admitted to critical care at the Royal University Liverpool Hospital between 2008 and 2014 were reviewed. Patients were identified as having pre-existing AF (PEAF, either chronic or paroxysmal), NOAF, or no AF during a period of up to 7 days. Pharmacological treatment regimes for rate or rhythm control of AF, heart rate before and after onset of AF, inotrope usage at onset of AF, presence of sepsis, age, APACHE II score and 28 day mortality rates were also recorded.
RESULTS. 199 patients (21.9%) were identified as having new onset AF; 53 patients had pre-existing AF (5.8%), and the remaining 657 patients (72.3%) did not have AF. The mean age of patients with new or pre-existing AF was higher than those without AF (72, 70 and 56 respectively) and APACHE II scores followed a similar pattern (21, 22 and 18). Mortality rates were higher amongst patients with NOAF than PEAF or no AF (30.7%, 24.5% and 16.2%). 481 patients had sepsis (52.9%); 142 of these patients had NOAF and 14 had PEAF. 55 patients only had electrolyte replacement (Mg2+ and K+) after the onset of AF, and 53% of these patients reverted to sinus rhythm; but the majority of patients were given amiodarone, in combination with electrolytes, alone, or with other anti-arrhythmics.
CONCLUSION. New-onset atrial fibrillation is more common in older patients with higher APACHE II scores, and these patients have a higher 28 day mortality rate than patients with pre-existing AF. Further research is needed to clarify the best treatment strategy for new onset AF in critically ill patients.

The impact of CCRT (continous renal replacement therapy) on survival of a specific geriatric subgroup (>80y.o.)

LF. Frade[1], P. Valério[2], M. Toscano[3], C. Pereira[4], C. Carvalho[5], I. Botelho[5], A. Ramos[5]
[1]Internal medicine, São Francisco Xavier Hospital, Lisboa, Portugal; [2]Nephrology, Hospital São Bernardo, Setúbal, Portugal; [3]Internal medicine, Hospital de Cascais, Alcabideche, Portugal; [4]Oncology, IPO Instituto Portugues De Oncologia De Lisboa, Lisboa, Portugal; [5]Intensive care unit, Hospital de Cascais, Alcabideche, Portugal
Correspondence: L.F. Frade
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001717

INTRODUCTION. There is an increased concern on the specifics of the geriatric population, still the role of continuous renal replacement therapies in survival is not very clear and most certainly not for a subgroup of very old patients (> 80y.o.)
OBJECTIVES. The primary objective of this study was to access the impact of CCRT (*continous renal replacement therapy*) on survival of a specific geriatric subgroup, the so called, very old patients (> or = 80 years old), comparing it with the younger population who was also submitted to CCRT on the same time period.
METHODS. 141 ICU patients were included, from March/2010 to March/2019 (84 patients were excluded due to lack of data needed for the analysis). Age group: the younger patient was 18y.o., the oldest was 92 y.o. (mean 69.4 ±14.1), from those, 80 patients were > 80 y.o. (it means 70.9% of the patients). Concerning the gender, 37.6 % (n=53) were females, 62.4% (n=88) were males and 95% (n=134) Caucasians vs. 5% (n=7) Blacks. The data was collected through a

retrospective analysis of these patient´s medical reports and analyzed using SPSS version 23.
RESULTS. The survival curve (Kaplan-Meier) showed that patients in an age range = or > 80y.o. submitted to CCRT had lower survival rates after starting the therapy, this data is of statistical significance (Log Rank test, p<0.05). Their survival was influenced by: age > 80 (H.R 4.3, confidence interval 95%, p value <0.05) and by duration of CRRT (measured in days), the shortest the therapy the highest the mortality (HR 15.7, confidence interval 95%, p- value < 0.01). Using Cox regression, it was found that the cause of patient´s admission on ICU had no impact on survival (p-value >0.05), likewise if it was a newly diagnosed acute renal failure or an acute renal failure on a patient with stablished chronic kidney disease. Serum levels of creatinine, urea, potassium, pH and HCO3 on arterial blood gas analysis, immediately before starting the CRRT also did not have impact on survival. Oliguria, defined as urine output < or = 0.3 mL/kg/min previous to the therapy, as well as type of therapy applied (hemodialysis, hemofiltration, both), type of anticoagulant (citrate or heparin), prescribed dose of therapy, did not have impact on survival of this geriatric subgroup (very old patients).
CONCLUSION. The geriatric patients, specially the very old patients (> or = 80 y.o.) should be thought as a particular population and that should guide the clinician to make a different clinical approach comparing to younger patients. The highlight of this study was to find out that regardless of the etiology of renal insufficiency, regardless of lab values or presence/absence of oliguria, age prevails and that variable itself should help on making decisions on weather to start/not to start CRRT since it showed no improvement on survival of this age group

Survival analysis of a group of patients submitted to CRRT (continuous renal replacement therapy) – convective vs diffusive techniques (CVVHF vs CVVHD)

P. Valério[1], LF. Frade[2], M. Toscano[3], C. Pereira[4], S. Cunha[5], I. Botelho[6], A. Ramos[6]
[1]Nephrology, Centro Hospitalar De Setúbal E.P.E., Setúbal, Portugal; [2]Internal medicine, São Francisco Xavier Hospital, Lisboa, Portugal; [3]Internal medicine, Hospital de Cascais, Alcabideche, Portugal; [4]Oncology, IPO Instituto Portugues De Oncologia De Lisboa, Lisboa, Portugal; [5]Anesthesiology, IPO, Lisbon, Portugal; [6]Intensive care unit, Hospital de Cascais, Alcabideche, Portugal
Correspondence: „P. Valério
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001718

INTRODUCTION. The prevalence of acute renal failure in intensive care units (ICU) is about 66%. From those, 13,5% meet the criteria for CRRT. The short term mortality of these patients is around 70%. The ideal CRRT technique is not yet stablished and some studies showed no difference on mortality.
OBJECTIVES. Retrospective survival analysis of patients submitted to CVVHF (continuous venovenous hemofiltration) vs CVVHD (continuous venovenous hemodyalisis).
METHODS. One hundred forty four ICU patients submitted to CRRT were selected, from March 2010 to March 2019. Seventy two patients were excluded, because they were submitted to continuous venovenous hemodiafiltration.
Those on regular program of hemodialysis were also excluded.
The demographic data were collected from patient's medical reports and it was analyzed through SPSS 23 statistics software.
RESULTS. Seventy two patients were included. From those 63,9% (n= 46) were male. The mean age was 69,0 ± 5,6 years old (18 to 87 years old).
Most of the patients were submitted to CVVHD (n=47; 65,3%). The mean survival was 4 days (0-33 days) and 70,8% (n=51) died during ICU admission.
The survival curve (using Kaplan-Meier method) showed lower survival for patients submitted to CVVHD, although it was not statistically significant.
Excluding the patients who died within 48 hours after hospital admission, in whom the mortality is strongly influenced by admission cause, the results weren´t any different.
The other variables analyzed (age, gender, cause of admission, previous diagnosis of chronic renal insufficiency, duration of CRRT, degree of metabolic acidosis or creatinine and urea serum levels) had no impact on survival.
CONCLUSION. This study showed that there is no statistically significant difference between the CVVHD vs CVVHF groups survival. Like other studies available, this analysis has a small sample and it's a retrospective and monocentric study.
A bigger scale study is needed so that we have more reliable information to approach these patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001762

INTRODUCTION. Acute kidney injury in trauma patients is a problem that has been little studied in the ICU. Its occurrence has been shown to be associated with high morbidity and mortality.
OBJECTIVES. To determine the outcome in ICU trauma patients with AKI, including the incidence of death in the ICU, of non-reversible renal impairment and ICU complications. As well as to identify predictive factors of ICU mortality and poor outcome.
METHODS. This is a ten-month long prospective cohort-study, conducted in the department of emergencies and intensive care unit (ICU) of a university hospital, including trauma patients with a minimum ICU stay of 7 days. Renal failure was defined based on the new KDIGO classification. Predictors of mortality and poor outcome were identified using univariate and then multivariate analysis.
RESULTS. One hundred thirty patients were admitted during the study period for the management of post-traumatic injuries, among which 86 patients were included. The incidence of AKI in the studied population was 53% (46 cases) with 26 (56%) diagnosed with stage one, ten (22%) with stage two and ten (22%) with stage three. The overall mortality of patients with post-traumatic AKI was 34.8% (16 patients) with a mean lengh of ICU stay (LOS) at 22 ± 18 days (extremes ranging from 5 to 68 days), and of days on ventilator at 17 ± 15 days (extremes ranging from 2 to 68 days). Eight patients (17.4%) needed renal replacement therapy and thirty-four had non-reversible renal impairement (74%). During ICU stay, thirty-two (69%) patients developed nosocomial infections and eight (17%) were diagnosed with pulmonary embolism.
On univariate analysis, the following variables were associated to mortality in patients with post-tramatic AKI including; age, hemodynamic instability on the day of diagnosis, the use of vaso-active support, transfusions and bilirubin levels on the day of AKI diagnosis.
Besides, according to our analysis, the use of renal replacement therapy and the non-reversibility of renal impairment during ICU stay were also associated to ICU mortality.
Among these factors, the non-reversibility of renal impairment in the ICU was a predictor of mortality on multivariate analysis (p = 0.009, OR = 29, CI: 4-142).
Moreover, in this cohort, the following variables were predictive of non-reversible renal impairment during ICU stay; including age (with

a best cut-off of 55 years old), medical history of diabetes or hypertension, high injury severity score and diuretics' administration.
The early delay to AKI from trauma was also predictive of the non-reversibility with a best cut-off at 2.5 days (AUC ROC= 0.87, Se= 83.3%, Sp=82.4%). On multivariate analysis, the age(p = 0.004, OR = 0.9, CI: 0.80-0.97) and use of diuretics (p = 0.003, OR = 33, CI: 3.1-359) were associated to non-reversible AKI in the ICU.
CONCLUSION. Our study confirms that post-traumatic AKI in the ICU is associated to high morbidity and mortality. The identification of outcome predictors could be valuable to guide the management AKI.

ICU mortality among oncological patients at a public cancer hospital in São Luís-Northeast Brazil: three-year evaluation

AP. Pierre de Moraes[1], G. Alves[1], JR. Lima[1], AA. Silva[2], Y. Assis[1]
Intensive Care Unit, Cancer Hospital of Maranhao Tarquinio Lopes Filho, São Luís, Brazil; [2]Public health, Federal University of Maranhão, São Luís - Vila Maranhão, São Luís - State of Maranhão, Brazil, Brazil
Correspondence: A.P. Pierre de Moraes
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000556

INTRODUCTION. Recent studies point out that the severity of acute complications, the number of organ disfunction, the management complexity and performance status have more impact on ICU mortality among cancer patients than the underlying neoplasm disease [1-3].
OBJECTIVES. To evaluate risk factors for ICU mortality among cancer patients
METHODS. A retrospective study conducted at a 11-bed ICU of a public cancer hospital in São Luis, one of the capitals of northeastern Brazil. We evaluated all cancer patients > 18 years old requiring ICU admission from January 2016 to December 2018, excluding those in palliative care support, readmission, and those that had ICU stay <24 hours. We evaluated demographic and clinical variables, ICU support at admission and during ICU stay by univariate and multivariate analysis. The risk factors for ICU mortality were investigated through multiple logistic regression analysis.
RESULTS. Out of 1021 patients, 699 (68%) had solid locoregional tumors, 182 (18%) had solid metastatical tumors and 140 (14%) were onco-hematology patients. The main solid tumor sites were gastrointestinal 254 (25%), gynecological 152 (15%), and urological 107 (11%). There were 438 (43%) admissions due to medical reasons, 553 (52%) and 50 (5%) for postoperative care after elective and emergency surgery, respectively. The overall ICU mortality was 34%. At multivariate analysis, the independent risk factors for ICU mortality were: admission due to medical reasons (OR = 7,57; 95%CI: 4,39-13,08) or due to emergency surgery (OR=2,78; 95%CI 1,27-6,08), high SAPS 3 (OR = 1,03; 95%CI: 1,01-1,04) and high SOFA scores at admission (OR = 1,17; 95%CI: 1,08-1,26), need of mechanical ventilation (OR = 2,94; 95%CI: 1,94-4,46), use of vasoactive drugs during ICU stay (OR = 2,19; 95%CI: 1,36-3,55) and nosocomial ICU infection (OR = 3,96; 95%CI: 2,26-6,93).
CONCLUSION. An unplanned ICU admission, higher severity scores upon ICU admission, complex support and infection during ICU stay were identified as risk factors for ICU mortality. The severity of acute illness at ICU admission may suggest that prompt recognition of organ dysfunction and the possibility of early ICU referral could offer opportunities to better management of acute critical complications. The expansion of prevention strategies to reduce hospital-acquired infection would be important for improving ICU mortality rates.

Characteristics and outcomes of patients with advanced uterine cervical cancer requiring intensive care in São Luís- Northeast Brazil

AP. Pierre de Moraes[1], G. Alves[1], JR. Lima[1], AA. Silva[2], Y. Assis[1], FJ. Lobato[3]
[1]Intensive Care Unit, Cancer Hospital of Maranhao Tarquinio Lopes Filho, São Luís, Brazil; [2]Public health, Federal University of Maranhão, São Luís - Vila Maranhão, São Luís - State of Maranhão, Brazil, Brazil; [3]Medicine, University CEUMA Matrix, São Luís - Vila Maranhão, São Luís - State of Maranhão, Brazil, Brazil
Correspondence: A.P. Pierre de Moraes
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000559

INTRODUCTION. Cervical cancer presents large geographic variations in incidence and mortality rates. Control and prevention measures also differ markedly worldwide. It is estimated that almost 90% of deaths occur in low- and middle-income countries. [1-2]
OBJECTIVES. To evaluate the characteristics and outcomes of cervical cancer patients requiring ICU admission and compare them to those with other solid cancer patients also requiring ICU admission
METHODS. This retrospective study was conducted at a 11-bed ICU of a public cancer hospital in São Luis, one lower income capital of northeastern Brazil. All patients > 18 years old with a solid tumor requiring ICU admission from January 2016 to December 2018 were included and were classified based on their primary solid tumor site in cervical and other solid tumor patients. We evaluated demographic and clinical variables at ICU admission, ICU support. The primary outcome were ICU and in-hospital mortality. Statistical differences were tested using Pearson´s chi-square or Mann-Whitney tests as appropriate. The significance level adopted was 0,05.
RESULTS. Out of 1369 patients, 148 (11%) had cervical uterine cancer and 1221 (89%) had other solid tumors. The main admission reasons were elective surgery 80 (54%), medical admission due to infection/sepsis 20 (14%) and renal disfunction 17 (12%). Compared to other solid cancer patients, cervical cancer patients were younger (p< 0,001), but did not differ in the presence of metastatical disease(p= 0,59), comorbidities (p=0,73), functional status (p=0,40), SAPS 3 score (p=0,58) and SOFA score on the first ICU day (p=0,38). Regarding ICI support, cervical cancer patients had higher need for renal replacement therapy (p<0,001), but lower need for mechanical ventilation (p=0.01). Compared to other solid cancer patients, ICU mortality was lower in cervical cancer patients (29% versus 19%, p= 0,02), but there is no difference between groups in in-hospital mortality (40% versus 39%, p=0,69).
CONCLUSION. There was a considerable occurrence of ICU admission of young or middle-aged women with a preventable disease that had high morbidity and mortality. The results of this study reinforce the importance of providing adequate prevention programs, early diagnosis, access to medical attendance and prompt reference in order to improve cervical cancer outcomes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001112

INTRODUCTION. Hidden mortality is a relevant problem in many critical conditions, including hematopoietic stem cell transplantation recipients (HSCT-R). Despite a significant number of HSCT-R die in the Hematology ward after been discharged from the Intensive Care Unit (ICU), this aspect has not been extensively studied. So, we believe that a better understanding of this population would help to improve their prognosis.
OBJECTIVES. Our aim was to analyze the differences between HSCT-R discharged from the ICU who died before being discharged from hospital and those who survived.
METHODS. Retrospective study, including adult (+18 years) patients who received an HSCT and required ICU admission between 2010 and 2018, and were discharged alive to the Hematology ward. X-Square, Fisher´s test, T test, U Mann-Whitney and logistic regression were employed as required. Quantitative variables are reported as median (IQR) and categorical as frequency (%).
RESULTS. During this eight year period, 79 HSCT-R were admitted to the ICU. Thirty-three (42%) of them were discharged to the Hematology ward and 20 (25%) finally survived the hospital admission. Nineteen (58%) were men, with an age of 57 (37-62) years. Twenty-five (76%) were allogeneic HSCT and 18 (55%) were neutropenic. APACHE was 20 (14-24) and SOFA score 8 (6-9). Twenty-one (64%) were treated with vasoactive drugs (VAD), 15 (47%) with high flow nasal cannula (HFNC), 9 (27%) received mechanical ventilation (MV) and 2 (6%) renal replacement therapy (RRT). Seven (6%) were readmitted to the ICU. Allogeneic HSCT (OR: 1.9, IC95%: 0.3-11.7, p= 0.476) and neutropenia (OR: 4, IC95%: 0.8-19.8, p=0.09) were not related to hidden mortality, nor were the use of HFNC (OR: 1.8, IC95%: 0.4-8.6, p=0.441), MV (OR: 1.1, IC95%: 0.2-6, p=0.890), VAD (OR: 0.75, IC95%: 0.2-3.6, p=0.75) or RRT (OR: 1.9, IC95%: 0.1-33.7, p=0.662). APACHE score (OR: 1.1, IC95%: 1-1.2, p=0.233) and SOFA score (OR: 1.2, IC95%: 0.9-1.7, p=0.268) were not different in both groups, but those who did not decrease their SOFA score at fifth day had a greater hidden mortality (OR: 18.3, IC95%: 1.5-222.9, p=0.022).
CONCLUSION. A significant amount of HSCT-R discharged from the ICU die before being discharged home. We did not find any relationship with the type of HSCT or the requirements of organ support, but we found a strong relationship between the persistence of organ dysfunction at day five. Those with no improvement in SOFA score in the first five days, despite being discharged to the ward are at greater risk of mortality before being discharged home.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001225

INTRODUCTION. Treatment of acute leukemia pts can be associated with the life-threating complications requiring ICU admission.
OBJECTIVES. To compare frequency of ICU admission and short and long-term outcomes of *de novo* ALL and AML pts who required and not required ICU admission during induction chemotherapy.
METHODS. All *de novo* ALL (median age 28 yo, 17-60 yo) and AML (median age 28 yo, 17-60 yo), treated from 2013 to 2017, were enrolled in the study. ALL and AML pts were divided into 4 groups: pts required ICU admission (ALL and AML ICU-groups), and pts not required ICU admission (ALL and AML non-ICU groups).
RESULTS. ICU admission was required in 18 (20.6%) of 87 ALL pts and in 44 (27.5%) of 160, (p = 0.2394) AML pts. The reasons for ICU admissions were similar for ALL and AML pts: acute respiratory failure (44% and 47.7%, p = 0.637), acute neurological events (28% and 13.6%%, p = 0.759), tumor lysis syndrome (17% and 4.6%%, p = 0.112), septic shock (SS) (11% and 20.4%%, p = 0.383) respectively. Needs of mechanical ventilation and infusions of vasopressors were independent predictors of ICU mortality (p<0.05) in ALL and AML pts. 28-day mortality was 47.5% for AML ICU-group and 50% for ALL-CU-group (p=0.196). Any pts did not die in both non-ICU groups during 28 days. In ALL pts 5-year overall survival (OS) was worse in ICU-group (44%) than in non-ICU group (44% vs. 76% p <0.05) (fig. 1). There were no significant differences in 5-year OS of AML pts from ICU and non-ICU groups (42.6% and 48.6%, *p=0.946)* (fig 2).
CONCLUSION. The frequency of ICU admission, reasons for ICU admission and 28-day mortality rate were similar for ALL and AML pts**.** The long-term OS was lower in discharged from ICU ALL pts than in non-ICU ALL pts. In AML pts long term OS was similar in pts discharged from ICU and non-ICU pts.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001327

INTRODUCTION. Acute leukemia (AL) is the most common cancer of childhood. AlthoughEven great advances have been made, admission to Pediatric Intensive Care Unit (PICU) is related with an increase inof mortality rate. Data in pediatric population is scarce, which leads to a lack in information regarding outcome of patients with AL admitted to the PICU.
OBJECTIVES. The objective was to describe the clinic and epidemiologic characteristics of the pediatric patients with AL admitted to PICU, and the differences between emergent or planned admission. Second goal was to evaluate mortality during their PICU stay.
METHODS. Retrospective study conducted in a tertiary referral hospital in Barcelona, Spain (July 2010-July 2016).
All patients with acute lymphoblastic leukemia (ALL) or acute myeloid leukemia (ALM) (28 days-18 years) who required PICU admissions were included. Patients with hematopoietic stem cell transplant and CAR-T cell therapy were excluded. Mortality was differentiated between PICU and out PICU mortality. The study was approved by the ethic review board of our hospital.
RESULTS. Out of 156 consecutive patients diagnosed with acute leukemia, 48 patients (69 episodes), required PICU admission, 58% were female, and the median age was 10.5 years (range 0-18). There were 38 (80%) diagnosed with ALL and 10 (20%) with AML. The admission was urgent in 45 episodes (65%), the planned admission was for bronchoalveolar lavage procedure (BAL) in 12 (50%) cases. Main reasons for admission were respiratory failure (11, 16%), sepsis (11, 16%) and BAAL (12, 17%). The Pediatric Risk Score Mortality resulted in 3 points. 23 (33.3%) patients required mechanical ventilation (MV) (mean days 1;1-7) due to pneumonia in 64,3%. Inotropic support was administered in 11 (15.9%) and 2 (2.9%) required hemofiltration. 28 (40.6%) patients had multiorgan failure, and 6 (12,5%) died (2 in PICU due to sepsis and 1 due to a BAL pulmonary haemorrhage). Mean days of PICU stay were 3,8 (0-58). All these variables were statistically significantly worse in emergency admission cases compared with a planned one, p< 0.001.
Two children died during the following 60 days after PICU discharge and one during the following 6 months; all of them were patients with relapsed ALL , 2 patients were in palliative care treatment and died from progressive disease and one due to treatment toxicity (hepatic sinosuoidal obstructive syndrome). Median length of stay for patients who died in PICU was 14 days (13-15.5).
PRISM ≥5 (OR 3,12; IC95%0,9-10,86), requiring MV (OR 9,47; IC95%0,99-90) or inotropes(OR 4,97; IC95%0,6-27,87) and severe neutropenia (OR 1,26; IC95%0,36-4,44) were independent factors for death
CONCLUSION. Pediatric patients with AL frequently required PICU admission (almost one third) and respiratory failure and sepsis were the main cause of admission. Patient who died were the higher risk ALL cases (relapsed patients) or AML. Accurate efforts need to be conducted when these patients require MV, or inotropes and if data of multiorgan failure are present.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000101

INTRODUCTION. Subclavian central venous access (SCVA) has a lower rate of infective and thrombotic complications compared to femoral and internal jugular venous access(1). This data also demonstrates higher rates of mechanical complications such as pneumothorax, but in the context of high rates of insertion guided by landmark technique(1). The subclavian vein's anatomical position is variable(2) and the rate of mechanical complications is reduced by the use of real time ultrasound scanning (USS)(3). We hypothesised that few anaesthetic or intensive care medicine (ICM) trainees in our region had received formal training in landmark or ultrasound-guided SCVA and are not confident in it. We sought to establish if a short teaching session with live human USS and subclavian gel phantom needling practice would improve confidence.

Having developed this teaching programme, we had a great deal of interest in developing these skills from consultants in anaesthesia and ICM. We therefore refined and extended it to further promulgate these skills in our region. We aimed to increase regional use of ultrasound-guided SVCA in order to minimise central line-associated bloodstream infection (CLABSI) and mechanical complications associated with SCVA.

METHODS. We conducted a survey of all Anaesthetic and ICM trainees in the Thames Valley deanery in the UK to ascertain previous experience of SCVA. Having identified this need for training, we conducted teaching sessions for anaesthetic and ICM physicians. These comprised a lecture, in vivo scanning of the subclavian vein and needling a subclavian gel phantom with USS.

We also gathered data on participant grade, formal teaching experience in SCVA and number of times they had performed SCVA. We compared their confidence in performing ultrasound-guided SCVA before and after the training session using a visual analogue scale (VAS) running from 0 to 100. Continuous data were checked for normality using the Shapiro-Wilk test. When this failed to detect normality, data were compared using the Mann-Whitney test.

RESULTS. 49 specialty registrars in anaesthetics or ICM responded to the SCVA training survey (response rate of 49% of deanery trainees). This revealed that 33% of respondents had sited no subclavian lines and 71% had sited 5 or fewer. Only 29% had any formal training in SCVA and mean confidence score was 35 out of 100 on the VAS.

42 physicians in total were then taught over four teaching sessions. 86% had received no previous instruction in ultrasound-guided SCVA. 64% had inserted no subclavian lines under ultrasound guidance and 93% had inserted five or fewer. The median baseline confidence in SCVA was 12 and after teaching this rose to 52 on the VAS ($p < 0.001$ by Mann-Whitney U test). The sessions were highly valued by trainees and consultants alike.

CONCLUSION. This study demonstrates that anaesthetic/ICM physicians in our region have little experience in inserting SCVA and receive little formal training in it. Furthermore, we have shown that a short training session can improve their confidence. We have used the teaching sessions to encourage use of this technique in order to help minimise overall complications of central venous access including CLABSI and mechanical complications. Further teaching sessions are planned given the ongoing demand for these skills in our region.

INTRODUCTION. In modern concepts of pathogenesis of inflammatory diseases, much attention is paid to nonspecific humoral factors of immune system, including lysozyme.

OBJECTIVES. The aim of the study was to evaluate level of lysozyme activity in serum in patients with ventilation-associated pneumonia.

METHODS. A complex examination of 43 patients with ventilation-associated pneumonia and 43 practically healthy people was performed. Blood was taken from the ulnar vein before meals into sterile test tubes.

RESULTS. We have created a simpler and a cheaper way of evaluating lysozyme activity in biological fluids, which demands little time and has clear evaluation criteria. The invention relates to medicine, namely to laboratory diagnosis. From cell walls *of Micrococcus lysodeikticus* culture ATCC 4698 peptidoglycan substrate was prepared, and the activity of lysozyme was calculated by the formula obtained after constructing calibration curve for lysozyme, which showed the dependence of the concentration of lysozyme and the optical density of the solution of Congo red. The positive effect of the proposed method was that the substrate for the production of reaction was prepared once and could be used for a long time. The way was easy and simple in play. The sensitivity of this method to lysozyme was 0.06 mg / ml. This is enough to determine immunodeficiency states, because the content of lysozyme in biological fluids varies according to various data in a wide range from 0.2 to 28 mg / ml in normal.

It was found that the lysozyme activity in the serum was lower in patients with ventilation-associated pneumonia (246.7; 141.2-298.7 mcg/ml) than that in donors (445.5; 350.1-816.1 mcg/ml). After inactivation of the complement both in patients with ventilation-associated pneumonia (116.0; 56.5-160.1 mcg/ml) and in donors (246,0; 183,6-305,7 mcg/ml) a statistically significant decrease in lysozyme activity occured.

CONCLUSION. There was a statistically significant decrease of nonspecific humoral resistance in patients with bacterial infection, namely, lysozyme, which was a risk factor for the development of ventilation-associated pneumonia.

INTRODUCTION. Surfactant protein B (SP-B), a member of Saposin-like family of proteins (SAPLIP), plays roles in both lowering surface tension and antimicrobial activity in the lung. Recent studies demonstrated the patients with the C allele of SP-B gene are susceptible to bacterial pneumonia. In the study we examined the effects and molecular mechanisms of the T and C alleles of human SP-B gene with humanized transgenic mice in bacterial pneumonia model.

METHODS. SP-B 1580 locus polymorphisms and SP-B protein level in BALF of thirty *S. aureus*-infected pneumonia patients and thirty-five age-matched, unrelated healthy subjects were analyzed. Then, humanized transgenic (hTG) mice, which expressed the C or T allele of human SP-B genetic variants in a mouse SP-B (-/-) background, was generated and used in this study. Pneumonia model was induced using *S. aureus*(CFU: 5x108/mouse) intratracheal injection in hTG SP-B mice. Lung tissue and bronchoalveolar lavage fluid (BALF) were harvested 24h after exposure to *S. aureus*or saline (control). Histological changes were consistent with pneumonia. Cellular and molecular analysis were performed by Western blot, ELISA, CFU counts.The p38 mitogen-activated protein kinase (MAPK) and the nuclear factor-kappa B(NF-κB) signaling pathways were measured by Western blot. In vivo imaging system was also used to analyze the dynamic bacterial clearance in the lung.

RESULTS. Human subjects with the SP-B1580 CC genotype were more susceptible to *S. aureus*-infected pneumonia.*S. aureus*-infected pneumonia patients with SP-B-1580CC genotype exhibited significantly lower SP-B level in BALF. *S. aureus*-treated hTG SP-B-C mice exhibited higher mortality than hTG SP-B-T mice ($p<0.05$). In vivo

results demonstrated that infected hTG hSP-B-C mice displayed decreased bacterial clearance 24h post-infection compared to infected hTG hSP-B-T mice. Infected hTG SP-B-C mice showed more severe lung injury ($p<0.05$), inflammation ($p<0.01$) and bacterial load in the lung compared to infected hTG SP-B-T mice 24 hrs after infection.The levels of surfactant phospholipid and surfactant proteins B, A and D in BALF, decreased significantly ($p<0.01$) in infected hTG SP-B-C mice, when compared with infected hTG SP-B-T mice. Moreover, infected hTG SP-B-C mice showed increased apoptotic cells and caspase-3 as well as decreased levels of Bcl-2 in the lung compared to infected hTG SP-B-T mice. Furthermore, levels of NF-κB P65, phosphorylated IkB-α and P38MAPK increased significantly in the lung of infected hTG SP-B-C mice which were related with significant increased levels of IL-6 and TNF-a in BALF than infected hTG SP-B-T mice.
CONCLUSION. Mice with C allele or T allele of human SP-B genetic variants exhibited different susceptibility to bacterial Staphylococcal pneumonia probably through regulating p38 MAPK-mediated NF-κB pathway related inflammation and apoptosis.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001373

INTRODUCTION. Rapid response system (RRS) has been developed for early detection of deteriorated patients. To improve the results of RRS, early detection and early intervention is warranted. However, there is no definite criteria of activation in RRS or no universal consensus for method of activations.
OBJECTIVES. The aim of study is to estimate the effect of a real-time automatic alerting system (AAS) based on electronic medical record (EMR) on RRS.
METHODS. We retrospectively reviewed the clinical data of patients who were activated by RRS in a tertiary university hospital. From August, 2015, RRS have been developed with activation by clinicians' calls and by active screening of high-risk patients in surgical wards. Activation criteria was suggested as Table. From November, 2016, we added a new real-time AAS to conventional activation systems. We compared the periods before and after the application of AAS in RRS as unplanned ICU transfer and other clinical outcomes; from January to October, 2016 (pre-AAS) vs from January to October, 2017 (post-AAS1) vs from January to October, 2018 (post-AAS2).
RESULTS. After application of AAS, the number of RRS activation significantly increased from 15.5 per 1,000 admissions in pre-AAS to 30.7 in post-AAS1 ($p < 0.001$), but decreased after adaptation (9.3 per 1,000 admission in post-AAS2). AAS activation (42.7%) was the most common cause of RRS activation in post-AAS1, followed by active screening (41.4%). Modified early warning score of activated patients in post-AAS2 was significantly higher than that of pre-AAS or post-AAS1 ($p < 0.001$). During study period, 264 unplanned ICU transfer occurred (2.88 per 1,000 admission in pre-AAS, 2.77 in post-AAS1, and 2.40 in post-AAS2, $p = 0.475$). In post-AAS1, 91.1% were activated by AAS before unplanned ICU transfer (62.5% in pre-AAS, 64.1% in post-AAS2, $p < 0.01$). There were no differences in ICU days and cardiopulmonary resuscitation rate among three groups ($p = 0.341$ and $p = 0.49$).
CONCLUSION. Use of a real-time AAS based on EMR might be helpful to detect unplanned ICU transfer. However, a learning period would be required for adaptation with increased RRS alarms.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000429

INTRODUCTION. Few studies have evaluated risk factors for ventilator-associated events (VAE) and there is no data comparing them between the adult and children population.
OBJECTIVES. To identify differences in factors associated with VAE in patients who underwent mechanical ventilation (MV) ≥48 h, between adults and children.
METHODS. Secondary analysis of a prospective combined multicentre cohort (adult and children). Six Intensive Care Units (ICU) in 4 European countries (France, Greece, Spain, and Turkey) and one children's ICU (Spain). Subjects who had undergone MV ≥48 hours were included. Age ≤ 16 yr was categorized as children. In subjects with multiple episodes of MV, only the first one was eligible. The adult definitions for VAEs were adjusted to the 2015 update of the 2013 United States Center for Disease Control and Prevention definition (1). The pediatric definition of VAE (PedVAE) was reported by Peña-López et al. (2). Association of risk factors with VAE and PedVAE was estimated through multivariate logistic regression analysis.
RESULTS. A hundred and sixty-three MV episodes in adults and 88 in children (2,178 and 731 ventilator-days respectively) were included. Median age was 60 yr in adults and 1.0 yr in children. Eighty-three adults (50.9%) and 43 children (48.9%) had high severity ICU index

(p=0.650). The median (IQR) duration of MV was 9 (6 – 20) in adults and 7 (4 - 9) days in children (p<0.005). We documented 76 VAE in adults (46.6%) and 23 PedVAE in children (26.1%) (p=0.002). The median (IQR) onset time of VAE and PedVAE was 6 (4-9) and 4 (3 - 6) days (p=0.065), with 52 (68.4%) and 19 (82.6%) presenting within the first 7 days of MV, respectively (p=0.186). MV> 7 days was associated with VAE (OR 5.03, 95%CI 1.95-13; p=0.001) and PedVAE (OR 4.55; 95%CI 1.3-15.86; p=0.017). Other independent predictors of VAE were selective digestive decontamination (SDD) absence (OR 4.45; 95%CI 1.78-11.12), tracheostomy (OR 3.55; 95%CI 1.35-9.32), midazolam use>3 days (OR 3.48; 95%CI 1.19-10.21), and surgical/trauma patients (OR 2.62; 95%CI 1.1-6.26) (p<0.05). High severity score, delirium, early mobility, and pharmacological paralysis did not show a statistically significant association with VAE or PedVAE on multivariate logistic regression analysis. In children, SDD and tracheostomy were not performed on the analysis due to the low number of cases. In contrast to adults, surgical/trauma patients and midazolam use>3 days in children did not show a statistically significant association with PedVAE and there was a trend toward increased risk of PedVAE in the pediatric population when the reason for intubation was respiratory failure (OR 3.35; 95%CI 0.89-12.57; p=0.071).

CONCLUSION. Future bundles should include SDD implementation and midazolam restriction as potential strategies to prevent VAEs in adults. Respiratory failure as cause of intubation may be more determinant for PedVAE than prolonged midazolam use in children.

Reducing Unplaned extubation and 48 hours re-intubation rate by implantation of Informatics System and Care Bundle in ICU

CC. Chao
{street_address}, Taipei, Taiwan
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000495

INTRODUCTION. The ventilator protects airway in patients who are critically ill, and there are many reasons for a patient with failure to wean from ventilator. How to successfully wean patients from ventilator requires consideration of various factors.

OBJECTIVES. We want to detect the effect of implantation of informatics system and care bundle in ICU on unplaned extubation and re-intubation rate in the ICU.

METHODS. Taipei Medical University Hospital is a community based teaching hospital with 736 beds capacity (includes 58 ICU beds). We set up electronic ICU (e-ICU) to automatically upload ventilator parameters and clinical data within critical care unit for providing real time information to the care team in Feb 2017. We use e-ICU software with automatic upload clinical information of ventilator: FiO2,, PaO2/FiO2, PEEP, RSBI(rapid shallow breathing index)Tidal volumeRespiratory rateMinute ventilation, minute Ventilation. We use ventilator associated bundle (VAP) and continuously monitor all the parameters including laboratory results, image findings and vital signs. This is a before and after study aims to detect the effect of implantation of informatics system and care bundle in ICU.

RESULTS. There are 1857 patients who admitted to our ICU during this period (915patients before e-ICU and 942 after). There are 458 (50.1%) patients received intubation with ventilator support and 472 patients (50.1%) after. There is no significant difference in background (APACHE II, gender and age) and mortality rate (33.5% vs 32.9%; p=0.39) between the two groups. The duration of ventilator usage was not significantly different (10.3 days before and 10.1 days after; p=0.46), and 48 hours re-intubation rate reduced from 6.98% (n=32) to 3.39% (n=16) and un-expected extubation reduced from 2.0% (n=9) to 0.2 % (n=1).

CONCLUSION. Implantation of information system (e-ICU) and care bundle in ICU can help reduce unplaned extubation and 48 hours re-intubation rate.

Table 1 (abstract 000495). See text for description

	Before (n=915)	After (n=942)	P value
Male	546 (69.7%)	549(58.2%)	0.40
Age	68.0 ± 0.6	67.5 ± 0.7	0.12
APACHE II	11.9 ± 0.3	11.8 ± 0.3	0.20
Mortality	317 (33.5%)	310(32.9%)	0.39
Patient with ventilator support	458 (50.1%)	472(50.1%)	0.59
Ventilator days	10.3±12.5	10.1±13.6	0.46
Re-intubation with 48 hours	32(6.98%)	16(3.39%)	0.001
Un-expected extubation	9(2.0%)	1(0.2%)	0.007

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000923

INTRODUCTION. Mechanical ventilation (MV) may produce ventilation induced lung injury (VILI). To solve it, protective mechanical ventilation (PMV) appears as TV<8ml/Kg of predicted body weight (PBW) and Plateau pressure <30 cmH2O. Spanish society of intensive critical care and coronary units (SEMYCIUC) have created an indicator to evaluate the adherence to clinical practice guidelines. MV is dynamic, so few manual data collection entails a huge loss of information. Thanks to CIS we can collect MV data every two minutes, and create fully automated and more accurate quality indicators.

OBJECTIVES. Evaluate clinical practice adherence to TV recommendations. Create fully automated and more accurate quality indicators through the data stored into the CIS.

METHODS. Retrospective study of cohorts carried out in a 30-bed polyvalent ICU. Inclusion criteria: patients admitted to ICU (2015-2018) connected to MV. Exclusion criteria: Patient whose height and/or APACHE was not registered and height <140cm. PBW and the % of time in which each patient had a TV> 8ml/Kg PBW (%_OV) was calculated automatically in the ETL (Extract, Transform and Load) process. Cohort was divided into quartiles according to % T_OV (Q1: lower % T_OV and Q4: higher % T_OV) and extreme quartiles were compared based on 24 variables: demographic, clinical, respiratory modality (volume control (VC) or pressure support (SP)) and evolution. A subanalysis of extreme quartiles according to %_OV within the Q4 of % T_OV was carried out using the same methodology. We proposed two indicators: 1) Patients with adequate TV (nº of patients>80%time with TV<8ml/Kg PBW/ total nº of patients with MV x100; proposed standard> 90%), 2) Time of inadequate TV (Total time_OV/ Total time in MV x100, proposed standard <20%). Statistical analysis was performed using R (https://cran.r-project.org/), applying the 'chi2' test for categorical variables and the 'Mann-Whitney U' for continuous ones.

RESULTS. 1071 patients were included. Median age 64 (51-73), 67,3% male, median APACHE 25 (20-31) and median SOFA 7 (4-9). Median TV was 0,53L (0,49-0,58). % of patients with adequate TV was 15,8% and total time of inadequate TV was 63,2% (Q1: 14,9%, Q2: 47,4%, Q3: 76% and Q4: 95,5%). Higher height (and as consequence higher

PBW), males, lower age and lower APACHE II and SOFA values were associated with lower %T_OV. There were also significant differences between respiratory modality, being higher those referred to VC. Overall mortality was 27,7%, without significant differences between Q1 and Q4, neither in MV days nor stay in ICU. In our subanalysis, patients in Q4 of % T_OV with <%OV had shorter ICU stays.
CONCLUSION. CIS are an opportunity to create fully automated and more accurate quality indications to evaluate PMV adherence. Patients with lower TV are taller, with higher PBW. It will be necessary future investigation to adjust the proposed standards.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001010

INTRODUCTION. Early mobilization in intensive care unit (ICU) is a candidate intervention to reduce the incidence and severity of ICU acquired weakness and improve outcomes. Implementing early goal directed mobility (EGDM) was shown to improve duration of mechanical ventilation, ICU stay, long-term functional independence, and possibly mortality. However, it remained challenging issue in daily practice.
OBJECTIVES. The aim of this study is to investigate the impact of early goal directed mobility using novel information system on patients' outcome in intensive care unit
METHODS. All consecutive patients form 2017-2018 in adult ICU were enrolled. The key interventions include novel early rehabilitation*information system* and virtual reality rehabilitation system for critical patients.The patientswere divided into three periods: pre-EDGM system period from Jan to July 2017, EDGM system setting period from August to September 2017 and post-EDGM system period from October 2017 to December 2018.
RESULTS. The early rehabilitationrate improved from 17.1%in pre-EDGM system period, to 20‰ in EDGM system setting period and to 95.1% in post-EDGM system period ($p<0.05$).Average ICU stay decrease from 7.9 days to 6 days after intervention ($p<0.05$).Average ventilator days improved from 5.5 days to 4.9 days in post-EDGM system period ($p<0.05$). The incidence of ventilator-associated pneumonia decreased from 1.3‰to 0.83‰($p<0.05$).
CONCLUSION. The study showed that implementation ofearly goal directed mobility using novel information system could increase early rehabilitation rate, and reduceaverage ICU stay and ventilator days. Furthermore, the incidence of ventilator-associated pneumonia also improved.

Intravenous immunoglobulin therapy is associated with favorable outcome in patients with severe infection having a low level of immunoglobulin G

M. Akatsuka[1], Y. Masuda[1], H. Tatsumi[1], M. Yamakage[2]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001359

INTRODUCTION. Immunoglobulins act as one of host defense systems against microorganisms such as bacteria, virus, and fungi. Severe infection causes sepsis and the related multiple organ failure, resulting in the cause of death in intensive care unit. Recent study shows that serum IgG concentration in sepsis patients is often low and the patients with hypo-IgG have high mortality (1). It is assumed that increased capillary permeability, increased catabolism, and the consuming effect of antigen-antibody reactions can reduce immunoglobulin concentrations. However, the precise mechanisms underlying low IgG in sepsis remains unclear. There have been many studies showing that low IgG level is associated with poor prognosis in sepsis patients. However, the effectiveness of supplementation of intravenous immunoglobulin (IVIG) for improving mortality has not been elucidated.
OBJECTIVES. We conducted this study to determine whether administration of IVIG for patients with a low IgG level can improve the prognosis.
METHODS. This study was conducted retrospectively. Inclusion criteria were the patients with severe infection in whom serum IgG level was determined on admission to the ICU. First, we investigated the prognosis of the patients and drew the Receiver-operating characteristic (ROC) curve. From the ROC curve, we determined the cut off of serum IgG level. Second, we identified the patients with low IgG below the cut off level. Information on patients' characteristics, severity score (APACHE II, SOFA score), IgG level, and the dose of IVIG given was obtained from medical records in the period from January 2013 to August 2018. The primary outcome was set to 28-day mortality.
RESULTS. There were 247 patients with infection in whom serum IgG level was determined on admission to the ICU during the study period. The mortality rate of the patients was 23.9%, and we determined the low IgG level below 663mg/dL from the ROC curve. Sixty-one of those patients had a low IgG level. We divided the

patients into two groups according to administration of IVIG given: non-IVIG group (n=21) and IVIG group (n=40). The 28-day mortality rate in the IVIG group were significantly lower than that in the non-IVIG group (p = 0.024).
CONCLUSION. Our results demonstrated that administration of IVIG for patients with a low IgG level is associated with improvement in mortality. These findings indicate the rationale for performing a prospective study with a large number of patients to investigate the efficacy of IVIG therapy for patients with severe infection with low IgG levels.

Organ Donation Trends in the UK: a Cardio-thoracic Intensive Care Unit Perspective

V. Della Torre[1], A. Rubino[2], D. Walford[3]
[1]Intensive Care, Imperial Healtha, London, UK; [2]Intensive care, Royal Papworth Hospital - Opening April 2019, Cambridge, UK; [3]Intensive care-specialist nurse-organ donation, east organ donation service team, Royal Papworth Hospital - Opening April 2019, Cambridge, UK
Correspondence: V. Della Torre
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001600

INTRODUCTION. The last decade has seen a remarkable change in the landscape of organ donation after brain death (DBD) and circulatory death (DCD) in the UK1. The Organ Donation Taskforce highlighted the urgent need to address the lack of a clear ethical, legal and professional practice framework2, and it has been established that higher referral rates and the presence of a specialist nurse for organ donation (SNOD) lead to higher successful donors3,4.We publish the trends in organ donation of Cardiothoracic (CT) and non-CT Intensive Care Units (ICUs) in the UK, from 1st April 2014 to 31stDecember 2018.
OBJECTIVES. We conducted a retrospective analysis to demonstrate the reasons behind these sustained improvements in number of referrals and organ donations. We identified the differences between CT-transplant and non CT-transplant ICUs.
METHODS. Data analysed were extracted from the NHSBlood&Transplant (NHSBT) potential donor audit, the organ donor register and renal registry. Data collection included all patients deceased at Royal Papworth CT-ICU from April 2014 to December 2018 and we compared these with other CT-ICUs. Variables analysed (Key metrics):

- *Referral*– If suitable patients are not referred, the patient's decision to be an organ donor is not honored.
- *SNOD*- The consent rate in the UK is higher when a SNOD is present.
- *Waiting lists* - The number of patients receiving a life-saving or life-changing organ transplant in the UK is increasing, but patients are still dying while waiting.

RESULTS. In 2007/08 there were 13.4 deceased donors pmp, in total 809 donors. By 2017/18 this has risen to 24.9 pmp (1574 donors). However during 2017/18 there were still 426 deaths waiting for transplant. Transplant CT-ICUs had lower referral rates that non-transplant CT-ICUs.
CONCLUSION.
The reasons why transplant CT-ICUs have lower referral rates have raised questions, as it would seem these units should have a vested interest in the benefits of transplant. Some have postulated that transplant CT-ICUs are more likely to make local decisions that certain patients may not be candidates. Furthermore, transplant centres offers invasive organ support, including extracorporeal life support (ECMO) and mechanical circulatory assist device; therefore withdrawal of patients happens in a later stage. In addition, the issue of confirming death on such devices is contentious5,6,7. Clear definition of key metrics (referral, SNOD and waiting list), that demonstrably change outcome, contributes to improvement in outcome towards the target donor numbers, advocated in the latest NHS Blood & Transplants document "*Taking Organ Transplantation to 2020"4*. Royal Papworth Hospital has tackled this by empowering the "embedded SNODs" in promoting teaching within the staff, and supporting a multidisciplinary team-based approach. This has contributed to increase our referral rates and SNOD involvement from 79.5% and 76% respectively, in 2017, to a 100% in both metrics in 2018. Donation is now considered to be a component of good end of life care. Furthermore, the UK is moving towards deemed consent for organ donation8. An implementing strategy has been used at Royal Papworth in the last year: referrals of all deteriorating patients, at the very early stage of the withdrawal process, identification of potential donors, embedded SNODs, incorporation of organ donation audit into the monthly Morbidity&Mortality Meetings. The results of this strategy have been: increased number of referral to the success of 100% referrals, earlier referrals, and a more efficient multidisciplinary work with Transplant Surgeons.

Conditions for responsible innovation of prognostication in postanoxic coma

M. Boenink[1], M. Mertens[1], M. Weernink[2], J. Van Til[2], J. Hofmeijer[3]
[1]Philosophy, University of Twente / Universiteit Twente, Enschede, Netherlands; [2]Health technology & services research, University of Twente / Universiteit Twente, Enschede, Netherlands; [3]Clinical neurophysiology, University of Twente / Universiteit Twente, Enschede, Netherlands
Correspondence: M. Boenink
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001691

INTRODUCTION. There is increasing evidence that continuous EEG monitoring (cEEG) can reliably predict poor, and possibly also good outcome of patients in postanoxic coma within 24 hours after cardiac arrest (1, 2). As a result, cEEG may soon be included in clinical guidelines for prognostication of these patients. The acceptability of a novel medical technology, however, also hinges on its broader impacts on practices of care and society at large. Responsible innovation implies that possible impacts of a new technology are anticipated and discussed with stakeholders and responded to during its development (3).
OBJECTIVES. To explore the broader impacts of cEEG on practices of care and identify under which conditions cEEG may be a responsible innovation.

METHODS. Ethnographic fieldwork was conducted on 2 Dutch IC's and 1 American IC, all engaged in clinical research with cEEG. Explorative, semi-structured interviews were held with 11 care professionals, 2 surviving patients and 7 relatives of patients who were or had been in postanoxic coma (all Dutch), focusing on what they valued in and were concerned about in relation to prognostic practice and the impacts of cEEG. Additionally, semi-structured interviews were held with 22 Dutch professionals who may become involved in the implementation of cEEG, focusing on enablers and constraints of implementation. Field notes and the first set of interview transcripts were qualitatively analysed, first inductively and then deductively with insights from the ethical literature. The second set of transcripts was analysed deductively, based on well-known determinants of implementation. Findings were discussed with and validated by a panel of representatives of stakeholders.
RESULTS. It was clear to most of our interviewees that cEEG may have added value for prognostication of patients in postanoxic coma, but they also pointed to potential impacts that may be less desirable. The concerns identified centred around: 1. the meaning of cEEG measurements (for example of 'grey' results); 2. the interpretation of measurements (like the tension between ease of use and careful interpretation); and 3. communication about measurements (for example with regard to timing).
CONCLUSION. The concerns identified point to several conditions for the responsible development, design as well as organizational embedding of cEEG, including: more research on long term outcomes, in particular of those with 'grey' cEEG results; an interface that reduces the risk of lay interpretations of measurements; and different communication policies for poor, good and 'grey' results.

Effects after mandatory documentation of therapeutic interventions limiting decisions in Neuro-ICU

H. Novak[1], D. Pavlovic[2]
[1]Neuro Intensive Care Unit, Christian Doppler Klinik, Salzburg, Austria; [2]Neurosurgery intensive care unit, Christian Doppler Klinik, Salzburg, Austria
Correspondence: H. Novak
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001618

INTRODUCTION. Within a six-years-period (2013-2018) 3554 patients were treated ad Neuro-ICU of CDK Salzburg. Average ICU-mortality was 6.7%, average length of stay in ICU (LOS) was 5.4 days.
Average LOS of ICU-survivers was 5.2 days, of ICU-fatalities was 7.9 days.
From 2016 to 2017 we started standardized mandatory documentation of formerly only sporadic decision for limitation of therapeutic interventions (TLD) in order to prevent futile ICU-interventions.
OBJECTIVES. This paper aims to compare ICU-mortality and LOS during first of four years before (2013) to last of two years after (2018) implementation of TLD.
METHODS. ICU-patients-statistics and patients records were reviewed retrospectively for fatalities, LOS and TLD.
RESULTS. Within six years overall ICU-mortality sunk from 7.1% four years before to 4.8% two years after implementation of standardized documentation of TLD. Overall LOS was 6.1 days in 2013 and 5.2 days in 2018, average LOS of deceased patients was 7.9 days, 11.9 days four years before and 5.5 days two years after implementation of TLD.
CONCLUSION. Against opposite apprehensions implementation of TLD decreased average Neuro-ICU-mortality and LOS of deceased patients. As intended but exceeding anticipations, length of futile ICU-treatment could be cut into half.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001441

INTRODUCTION. Major head and neck surgery with flap reconstruction is a frequent treatment option for cancer patients. It may be indicated for primary tumor care (head and neck cancer) or to manage treatment' complications (e.g. osteonecrosis).
This intervention presents a high risk of airway compromise(1) and most patients require post-operative vigilance in an intensive care setting due to their comorbidities, aggressiveness of the surgical procedure and to ensure adequate free flap monitoring perfusion(2).
OBJECTIVES. Understand critical care outcomes of cancer patients submitted to major head and neck surgery with flap reconstruction.
METHODS. Retrospective cohort study of cancer patients admitted to a polyvalent intensive care unit (ICU), between 2015–2018, after major head and neck surgery with flap reconstruction. Exclusion criteria were ICU stay <24h and trauma patients.
RESULTS. During this period, 209 patients were admitted to the ICU after this procedure and 55 fulfilled the enrollment criteria.
The majority of these patients were proposed for surgery as part of their anti-cancer treatment, but 12 were due to osteonecrosis (2 medical and 10 after radiotherapy). Median age was 60 years, most patients were male (72.7%) with an ECOG-PS of 0-1 (94.5%) and a locally advanced disease (52.7%). The median weight at admission was 68Kg (min. 57Kg - max. 76.25Kg).
Median surgery length was 10h30 (min. 7h20 – max. 14h30), 36.4% of patients required intra-operative blood transfusion and intra-operative net fluid balance was positive in the majority of patients (69.1%). Median APACHE and SAPS II scores were 13 and 24, respectively. In the post-operative setting, 67.3% of patients required mechanical ventilation (median duration of 4 days) and 29.1% vasopressor support (median 3.5 days). Flap necrosis was the most common surgical complication (10.9%) and 13 patients (23.6%) required re-intervention. One patient developed bacteremia associated with central venous line. Median ICU length of stay was 4 days (min. 24h - max. 28 days). There were no deaths in the ICU, with a 9% mortality rate at 6 months after discharge.
Weight correlated with the duration of ventilation (r: 0.370; p=0.026) and with the ICU stay (r: 0.305; p=0.025). Longer surgery duration was associated with prolonged ICU stay (>5 days) (p=0.049) on univariate analysis. On multivariate analysis, positive fluid balance was associated with prolonged ICU stay (p=0.049).
CONCLUSION. Patients submitted to major head and neck surgery had good outcomes during ICU stay. Positive net fluid balance

during surgery was significantly associated with prolonged ICU stay in this subset of patients and should be closely monitored.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001669

INTRODUCTION. : Diabetes mellitus (DM) is major risk factor for heart failure (HF) and coronary artery disease (CAD).DM causes structural changes involving the left ventricle (LV) systolic and diastolic function.

OBJECTIVES. To compare diabetic patients who have ischemic cardiomyopathy (ICM) to those with non ischemic cardiomyopathy (NICM) in terms of clinical course, left ventricular (LV) systolic function, diastolic function, in hospital, short term and long term mortality.

METHODS. Sixty diabetic patients with heart failure and left ventricular ejection fraction (LVEF ≤ 35%) admitted to Critical Care Medicine department Cairo University in a period of 16 months divided into two groups based on coronary angiography results group I (ICM) n=32 patients and group II (NICM)n=28 patients.

RESULTS. Results Group I patients had higher mean age (63±7) years, (p=0.004). Hypertension (p ˂0.001) and dyslipidemia (p ˂0.008) was significant in group I compared to group II. No significant differences were found regarding LVEF, global longitudinal strain (GLS), E/A and E/É ratio in both groups. A significant wall motion score index (WMSI) in group I; (1.4±0.4) vs group II;(1.1±0.2),(p= 0.005).

In the study, 4 patients in group I had cardiogenic shock with no documented in hospital mortality. At 6 months a significant mortality difference was found between the two groups, (p= 0.006), while at one year there was no significant mortality difference between the two groups,(p=0.077).In comparison of survived and non survived patients at 6 months the LVEF,GLS were significantly higher in those who survived (41±5.3%) vs (23±6.3%),(p˂0.001) and GLS (-8±2.4%) vs (-4.67±2.7%),(p= 0.027).The E/A and E/É ratio was significantly lower at 6 months in survived patients (1.33±0.91 vs 1.8±0.61),(p 0.037) and E/É (12.12±7.8 vs 21±3.7),(p= 0.016) respectively. At one year, there was a significant difference between survived and non survived; LVEF (39±6.8%) vs (25%), (p= 0.001) and GLS (-8±2.9%C) vs (-5 %),(p= 0.011).The E/A ratio in survived patients was(1.5±0.94 vs 3.3), p= (0.033) while E/É was not significantly different between survived and non survived patients (15±5.2 vs 15),(p= 0.868).

CONCLUSION. The combination of cardiomyopathy and diabetes affects LV systolic and diastolic function. ICM is associated with the worst prognosis.

Risk Analysis of Death in Critically Ill Patients based on China's ICU Medical Quality Survey

L. Su, Y. Long, D. Liu, X. Zhou

[1]Icu, Peking Union Medical College Hospital, Beijing, China

Correspondence: L. Su

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001674

INTRODUCTION. Chinese Critical Care Medicine has developed rapidly in recent years. The uneven level of economic and medical development in different regions lead to differences in treatment efficiency and clinical outcomes.

OBJECTIVES. In order to understand the quality of medical care in Chinese critical Care Medicine, a quality survey on the medical quality of ICUs in China in 2015 was used to explore the risk factors of critically ill patients in the intensive care unit in China.

METHODS. 15 indicators of medical quality of critical care medicine were recommended by the experts' panels of Chines Society of Critical Care Medicine. The database of the National Clinical Improvement System was desinged to collect this information. (https://ncisdc.medidata.cn/login.jsp). The multivariate logistic analysis was performed to identify factors related to mortality in ICU.

RESULTS. Data on 15 indicators of medical quality were collected from ICUs in 1,174 hospitals in China. The indicators were as follows: the proportion of the total inpatients in the ICU (1.83%), proportion of total inpatient bed occupancy accounted for by the ICU (1.44%), proportion of ICU patients with APACHEII scores ≥15 (51.08%), 3-hour Surviving Sepsis Campaign (SSC) bundle compliance (74.37%), 6-hour SSC bundle compliance (76.6%), rate of microbiology detection before the administration of antibiotics (62.93%), proportion of ICU patients administered deep vein thrombosis (DVT) prophylaxis (58.24%), proportion of endotracheal extubations that was unplanned (1.49%), proportion of extubated patients reintubated within 48 h (1.99%), proportion of patients whose transfers to the ICU were unplanned (6.38%), 48-hour ICU readmission rate (1.20%), incidence of ventilator-associated pneumonia (VAP) (1.28 per 1000 ventilator days), incidence of catheter-related bloodstream infections (CRBSI) (3.06 per 1000 catheter days), incidence of catheter-associated urinary tract infections (CAUTI) (3.65 per 1000 catheter days), and in-hospital mortality rate (10.19%). Unplanned transfer to the ICU and higher APACHE II scores are mortality risk factors in Chinese ICUs

(OR=3.798 & OR=4.588, respectively). Treatment in certain regions (Central and North China) and 3-hour SSC bundle compliance may benefit critically ill patients (OR=0.560, OR=0.581 & OR=0.667, respectively).
CONCLUSION. Unplanned transfer to the ICU and higher APACHE II scores are risk factors for higher mortality rates in Chinese ICU. 3-hour SSC bundle compliance and the economic level of the area where the hospital is located maybe benefits. Improving the identification of critically ill patients and the implementation of appropriate and timely treatment interventions are of very important for improving the level of critical care in China.

Hypercapnic exacerbations of COPD carry a high risk of readmission or death independently of the severity

G. Cavalot[1], T. Piraino[2], R. Coudroy[1], F. Damiani[1], N. Philips[1], V. Dounaevskaia[3], O. Smith[1], K. White[2], L. Brochard[1]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001681

INTRODUCTION. Patients with chronic obstructive pulmonary disease(COPD) admitted to the hospital for acute hypercapnic respiratory failure(AHRF) have shown poor outcomes including high readmission rates and mortality at one year.(1) Studies suggested that the use of non-invasive ventilation(NIV) reduces in-hospital mortality but is followed by poorer outcomes after discharge.(2) Recent data also showed that most of these patients have multiple comorbidities often untreated. (3)This study examined 1-year outcomes in COPD patients surviving hospital admission for exacerbation and the impact of the initial severity (respiratory support, intensive care unit(ICU) admission) on readmission and death.
OBJECTIVES. To describe characteristics and evaluate 1-y readmission and mortality rates of COPD patients admitted for exacerbation to one academic hospital in Toronto.
METHODS. We conducted a retrospective study including patients admitted to the emergency department (ED) of St Michael's Hospital in 2017 with AHRF defined on arterial or venous blood gas and presence of respiratory symptoms at admission. We selected COPD patients using appropriate ICD10 codes (J44.0,J44.1). Demographic, clinical and laboratory data, admission to ICU, use of NIV and 1-y readmission rates and mortality were collected. Patients readmitted and not readmitted were compared. We conducted a survival analysis comparing patients who didn't receive any respiratory support,received NIV in the ED or received NIV and were admitted to ICU.
RESULTS. 350 patients met our inclusion criteria for AHRF; among those, 80 patients were labelled as COPD as per ICD10 codes. Most patients were male (59%) with mean age of 67±10years; at admission mean pH was 7.28±0.06, mean pCO2 was 67±12 mmHg. 50% of patients had more than 2 comorbidities. 24 patients (30%) received respiratory support (NIV and/or invasive ventilation), 12 (15%) were admitted to ICU and 3(4%) died. 48 out of 77 patients (62%) were readmitted at least once or died in the follow-up year. No differences were seen between patients readmitted and patients not readmitted in terms of demographics, clinical data and laboratory values. We performed the survival analysis in the three groups: patient that didn't receive any NIV, patients that received NIV only and patients that received NIV and were admitted to ICU. The Kaplan-Meier curves for these three groups (figure) did not differ. The readmission and mortality rate in the following year was 64%(7/11) in patients that received NIV only and 73%(8/11) in patients that received NIV and were admitted to the ICU.
CONCLUSION. All patients that survive an hypercapnic episode of COPD exacerbation are at high risk of hospital readmission or death no matter if they received NIV or were admitted to the ICU during index admission. This whole group should be targeted for prevention of readmissions.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001752

INTRODUCTION. Weaning from mechanical ventilation (MV) is prolonged (>7 days) in 8.7% of all ICU patients (1). Previously, there was no dedicated weaning unit in the Netherlands. In January 2016, a specialized ICU for patients with complex weaning from MV was opened at Radboud University (**Radboudumc Centre of Expertise for Weaning from MV, @NExCOB**) aiming to improve outcome with a better cost efficiency for this group of patients.
METHODS. We use a **multidisciplinary approach** including a **dedicated team** of ICU nurses, physiotherapists, speech therapists,

intensivists, a technical physician, and if indicated other consultants (2). If possible (hygiene) and indicated, patients receive **hydrotherapy** (3). Patients with **difficult or prolonged weaning** are eligible for admission (team decision). **Descriptive analysis** of the first cohort, **3-month outcome data**, derived from **MONITOR-IC** study (4), and **survival data** (population register data) are reported.
RESULTS. From January 2016 to November 2017, 109 patients were admitted. 28% came from other hospitals, 36% had a history of COPD and 15% of cardiac failure. Median duration of MV before admission was 19 days [IQR 12-25]. 61% suffered from delirium, 41% from anxiety, 39% from sleep disturbances. Most patients (75%) were highly motivated for treatment. Median length of stay in our unit was 11 days [IQR 6-20]. Dysphagia was observed frequently resulting in prolonged admission. Survival was 22±1 months (mean±SE, fig. 1).
CONCLUSION. Patients treated at a new dedicated ICU for complex weaning from MV in the Netherlands have a **high rate** of **successful weaning**. Patients were **vulnerable before admission** with increase of frailty at discharge improving modestly after 3 months, while mental health was comparable to before admission. Long-term **survival** in this population was reasonable.

Identification of increased microcirculatory leukocytes using Incident Darkfield imaging in liver resection patients

Z. Uz[1], C. Ince[1], L. Shen[1], B. Ergin[1], M. Heger[2], T. Van Gulik[2]
[1]Translational physiology, Amsterdam UMC, Amsterdam, Netherlands; [2]Surgery, Amsterdam UMC, Amsterdam, Netherlands

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001760

INTRODUCTION. The surgical resection of the liver is the only curative treatment for primary liver cancers.
To reduce blood loss, surgeons will apply the Pringle Manoeuvre which occlude inflow of blood to the liver. However, the application of the Pringle will cause ischemia reperfusion injury (IRI) to the liver, characterized by the infiltration of leukocytes. Leukocytes can be visualized using Incident Darkfield (IDF) imaging. Monitoring the inflammation in the sublingual microcirculation during and 24 hours after liver resection, provides a potential clinical parameter (microcirculatory leukocytes) to monitor critically ill patients whom would benefit from early intervention.
METHODS. 19 patients undergoing major or minor hepatectomy were enrolled. Using Cytocam-IDF imaging, their sublingual microcirculation was measured before skin incision but after the induction of anaesthesia (T0), before skin closure (T1) and 24 hours after surgery (T2). The microcirculatory parameters measured were TVD, PVD, PPV, MFI and PVS. Systemic leukocytes and microcirculatory leukocytes were counted in all time points.
RESULTS. 8 patients of the 19 included patients were analysed. An increase in the number of rolling(r), non-rolling(nr) and total(tl) sublingual leukocytes can be seen from T0 to T1 to T2 (r= 2±1, nr= 5±3, tl= 8±7 to r= 5±6, nr=7±3, tl=4±3 to r=6±5, nr=13±3, tl=12±6, p= 0.62 p=0.309 and p=0.055 respectively). There was also an increase in systemic leukocyte count seen (8±4 to 12±6 to 20±13, p=0.097). There was a significant decrease seen in the MFI from To to T1 to T2 (2.7±0.3 to 2.8±0.0 to 2.3±0.4, p= 0.029).
CONCLUSION. The number of microcirculatory leukocytes increased from T0 to T2 in concordance with the increase in systemic leukocyte count. This study shows that the monitoring of the sublingual microcirculation using IDF imaging identifies non-invasively the level of inflammation and perfusion.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001449

INTRODUCTION. Subarachnoid hemorrhage (SAH) is associated with high morbidity and mortality. Studies have shown that both anemia and red blood cell transfusions (RBCT) are independent risk factors for poor outcome.
OBJECTIVES. To evaluate the role of anemia and RBCT on long-term neurological outcome after SAH.
METHODS. We reviewed our institutional database of adult (>18y) patients admitted to the Department of Intensive Care after non-traumatic SAH over a 5-year period. We recorded hemoglobin (Hb) levels daily for a maximum of 15 days, as well as RBCT (with the pre-RBCT Hb values). We collected unfavorable neurological outcome (UO; i.e. Glasgow Outcome Scale of 1-3) at 3 months.
RESULTS. We collected data from 270 patients (median age 54 years; male 45%); UO was 40%. Hb on admission was 13.4 (12.2-14.3) g/dL; highest and lowest Hb values were 14.3 (12.9-15.2) and 10.3 (8.4-11.9) g/dL, respectively. The patients with UO were more likely to have Hb <11, <10, <9, <8 or <7 g/dL than the others (79 vs. 51% - 63 vs. 32% – 51 vs. 18% - 37 vs. 11% – 20 vs. 5% - respectively; p< 0.05 for all). Patients with UO had consistently lower Hb over the study period, in particular since the second day (p<0.001). More patients with UO received RBCT (15/109, 14% vs. 6/161, 4% - p<0.01); pre-RBCT Hb values were similar in UO and in the other patients (6.9 [6.6-7.1] vs. 7.3 [6.3-8.1] g/dL – p=0.21). In a multivariable analysis, older age, chronic renal failure, neurological status on admission, the use of mechanical ventilation and the development of delayed

cerebral ischemia, but neither Hb nor RBCT were independent predictors of UO.
CONCLUSION. Although anemia is associated with unfavorable neurological outcome after SAH, it does not seem to be an independent prognostic factor.

Use of automated pupillometry to assess autonomic nervous system dysfunction

G. Ponzone, AA. Quispe-Cornejo, J. Creteur, IA. Crippa, JL. Vincent, FS. Taccone
[1]Department of intensive care, Erasme University Hospital, Université libre de Bruxelles, Brussels, Belgium
Correspondence: G. Ponzone
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001485

INTRODUCTION. Autonomic nervous system (ANS) dysfunction is frequently observed in critically ill patients. Heart rate variability (HRV) can provide an estimation of the ANS integrity but requires specific software and expertise. Assessment of pupillary light reflex using automated pupillometry (AP) could also assess ANS dysfunction at the bedside.
OBJECTIVES. To explore whether changes in AP-derived variables correlate with changes in HRV in critically ill patients.
METHODS. We prospectively studied (Nov 2018 - March 2019) 53 adult patients (median age 62 [52-69] years – APACHE II on admission 18 [14-25]), with normal sinus rhythm and an estimated ICU stay > 3 days. Patients with pupillary abnormalities were excluded. Assessment of HRV and AP was performed within the first 24 hours in the ICU (T1) and at least 48 hours thereafter (T2). HRV was assessed for at least a 6-minute period using a specific software (Kubios HRV Premium version 3.2.0) analysing both time-domain and frequency-domain methods of RR intervals. Automated pupillometry (NPi-200 – Neuroptics) was performed with light stimulation three times during the HRV recording on each eye; and mean values were averaged. Changes in HRV and AP-variables were calculated as: (T2-T1)/T2*100.
RESULTS. The 53 patients had an ICU length of stay of 8 [5-13] days and a 28% ICU mortality. There was no significant correlation between changes in AP derived Neurologic Pupil Index and the dilation velocity and changes in HRV. However, changes in pupil size, constriction rate and constriction velocity were significantly correlated with changes in HRV variables, such as root mean square of differences between successive NN intervals (RMSSD), low- and high-frequency power (which captures the magnitude of underlying oscillations in the different HR patterns) and the Poincaré plot standard deviation perpendicular (SD1) or along the line of identity (SD2) parameters. Changes in pupillary latency correlated with changes in other HRV variables, such as the mean R - R interval (mRR), the normalized low-frequency power (FFT-LFnu) and the detrended fluctuation analysis (DFAa1).
CONCLUSION. Automated pupillometry could be used to assess changes in autonomic nervous system dysfunction in critically ill patients.

Acute Stroke Patients in Intensive Care Unit – is it really worth it?

P. Campos[1], G. Videira[2], R. Antunes[1], T. Cardoso[1], R. Felgueiras[2], I. Aragão[1]
[1]Unidade de cuidados intensivos polivalente, Centro Hospitalar e Universitário do Porto, Porto, Portugal, Portugal; [2]Serviço de neurologia, Centro Hospitalar e Universitário do Porto, Porto, Portugal, Portugal
Correspondence: P. Campos
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001505

INTRODUCTION. Stroke is the major cause of disability and the second most common cause of death. The majority of acute strokes are managed on the ward; however, a significant proportion require more specialized care. Neurological impairment with airway or respiratory compromise, seizures, and need for close management of blood pressure and monitoring of post stroke complications are the common indications for Intensive Care Unit (ICU) admission.
OBJECTIVES. This study aims to determine the rate of ICU admission for acute stroke, to analyze and characterize this population, and to determining the functional status at ICU and hospital discharge and at 3 months follow up.
METHODS. Retrospective and observational study conducted at Centro Hospitalar e Universitário do Porto, a tertiary hospital and reference center for thrombolysis and neurosurgery, from January 2013 to December 2016. All patients with acute stroke admitted in the ICU were included. Patients under 18 years of age, stoke due to subarachnoid hemorrhage and due to traumatic etiology and admitted for organ donation were excluded. The functional score was evaluated by Modified Rankin Scale (mRS).
RESULTS. A total of 156 patients, 4.3% of all ICU admission, were included, 78 (50%) for ischemic stroke. The mRS at admission was similar in ischemic and hemorrhagic stroke. The Glasgow Coma Scale (GCS) was lower in hemorrhagic stroke and cardiovascular risk factors were more prevalent for ischemic. SAPS II and SOFA were similar in both groups. The most common locals of occlusion for ischemic stroke were basilar artery and segment M1 of middle cerebral artery. 51% of patients had no infarction in brain computed tomography. Thrombolysis was performed in 35 patients (49%) and 56 (74%) were submitted to thrombectomy. Complete recanalization (TICI 3) was obtained in 12 (21%) of patients and 9 (16%) had no recanalization (TICI 0). Deep hemorrhage was the most common type, being responsible for 41 (53%) of hemorrhagic strokes. Neurosurgical procedure was performed in 62 (80%) of patients with hemorrhagic stroke, being external ventricular shunt the most common procedure. Time to neurosurgical procedure was higher in ischemic stroke (1977 min vs 1089 min). The ICU length of stay was higher in hemorrhagic stroke (12 days vs 6 days). Most of the patients had an mRS score of 5 at ICU and hospital discharge in both types of stroke. Three months after discharge the mortality rate was 44% for ischemic stroke and 40% for hemorrhagic stroke.
CONCLUSION. Despite the incidence of ischemic stroke being higher than hemorrhagic stroke, in our population the rate of admission for both types of stroke was similar. As expected, the cardiovascular risk factors were more frequent in ischemic stroke. Time to neurosurgical procedure was higher in ischemic stroke since it is performed most often due to hemorrhagic complications. Despite the ICU management, the mortality rate and the functional status is poor in the population of patients admitted to ICU.

INTRODUCTION. Severe traumatic brain injury (TBI) is often accompanied by coagulopathy and its presence has been shown to be a poor prognostic factor. Rapid assessment of coagulation status and successful treatment of bleeding disorders are crucial. Standard coagulation tests are usually time consuming and provide information only on the initiation of clot formation. In contrast, thromboelastometry (ROTEM) assess coagulation status within minutes and offer information on clot firmness and clot stability, as well as the initiation of coagulation.

OBJECTIVES. This retrospective study was designed to assess the potential role of ROTEM in patients (pts) with TBI, to identify associated coagulopathy and to correlate these hemostatic disorders with outcome.
METHODS. This retrospective evaluation comprised ICU pts with TBI. Blood samples were obtained on admission, after 12 and after 24-48 hours. ROTEM analysis (EXTEM, INTEM, FIBTEM tests) and standard laboratory coagulation tests (PT, INR, aPTT, platelets count, fibrinogen concentration) were compared. The hemostatic parameters were compared between survivors and non survivors. We evaluated the time course of hemostatic disorders and their relationship with the expansion of hemorrhage, as confirmed by CT-scan. Using standard laboratory tests coagulopathy was defined as one or more of following: INR>1.5, aPTT>35s, fibrinogen<150mg/dL, PLT<100000/μL. Using ROTEM coagulopathy was defined as one or more of the following results: CTextem>80s, CFTextem>159s, MCFextem<50mm, CTintem>240s, CFTintem>110s, MCFintem<50mm, A10fibtem<7mm.
RESULTS. 29 pts with TBI aged 48.31 years were evaluated. 23 pts survived (79.3%) and 6 (20.6%) died. Coagulopathy as defined by both tests were observed in 10 pts (34.48%). In this group 7 pts survived (70%) and 3 (30%) died, while 8 developed expansion of hemorrhage on CT-scan (80%). Out of 29 pts in 19 (65.5%) were observed abnormalities in ROTEM variables, while 9(47.36%) pts of them revealed normal standard coagulation tests. In this group 15 (78.9%) pts survived and 3 died. Remarkably, 16 pts with abnormal ROTEM analysis developed expansion of hemorrhage and 3 did not, which difference is statistically significant ($p<0.05$). Also we observed abnormal CTextem in 18 (62%), CTintem in 8 (27.5%) and A10fibtem in 7 (24.1%). Abnormalities in ROTEM were observed in 15pts (51.7%) on admission, in 13pts (44.8%) after 12h and in 15pts (51.7%) after 24-48h.
CONCLUSION. Coagulopathy is a frequently encountered and highly morbid complication of TBI that has been consistently linked to poor outcomes. ROTEM provides rapid and useful information on the coagulation status of pts with TBI. ROTEM appeared to offer an early signal of life-threatening TBI. Further studies are warranted to confirm these results and to investigate the role of ROTEM in optimizing coagulation therapy.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001537

INTRODUCTION. Aneurysmal subarachnoid hemorrhage (SAH) is an acute and severe cerebrovascular event, with high mortality and morbidity. The moment of aneurysm repair could have an impact on outcomes, but the optimal timing remains controversial.
OBJECTIVES. Our goal is to describe the association of the moment of aneurysm repair procedure with the mortality.
METHODS. This study was conducted in two reference centers – one in Rio de Janeiro and one in Porto Alegre. From July 2015 to March 2019, every adult patient admitted to the ICU with aneurysmal SAH was enrolled in the study. Data were collected prospectively during the hospital stay. Patients were divided into four groups according to the moment of aneurysm repair after bleeding – up to the 3rd day, 4 to 8 days, above eight days and those not repaired. The primary endpoint was mortality at hospital discharge. A multivariate model was made using the group with higher mortality as the reference group (4 to 8 days).
RESULTS. A total of 437 patients were enrolled in the study. Median age was 55 years, mostly female (73%). 31% of patietes had poor-grade SAH (WFNS 4-5), with 22% mortality and 50% poor functional outcome (modified Rankin of 4 to 6). In the multivariate model for mortality (table 1), hydrocephalus, post-procedure neurological worsening, DCI were associated with higher mortality, but late repair (after eight days) was associated with lower mortality (OR 0.4) against aneurysm occlusion between 4 to 8 days, and surgical treatment was associated with lower mortality than endovascular treatment (OR 0.3).
CONCLUSION. Our study shows higher mortality in patients submitted to aneurysm occlusion procedure from day 4 to 8 when compared to a late repair, with higher mortality on patients who underwent endovascular treatment. Still a controversial topic, the timing of aneurysm repair needs more studies to define what would yield the best outcome.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001552

INTRODUCTION. Maintaining blood flow and oxygen transport are of primary importance in neurosurgical patients, avoiding overload and cerebral edema.
OBJECTIVES. We compared 2 fluid therapies in patients undergoing neurosurgery: a restrictive one based on literature data and a goal-directed (GD) one through the evaluation of the stroke volume variation. The primary outcome variable was the hospital length of stay (LOS).

METHODS. For 2 months we included all patients undergoing elective craniotomy for a supratentorial non-vascular lesion, in the IRCCS Neurological Science Institute of Bologna. We excluded all the patients with an age<18 years old, pregnancy, BMI>35, ASA≥4, Revised Cardiac Risk Index≥2, a respiratory disease requiring home oxygen therapy, renal replacement therapy or an increase of more than 50% of the normal values of creatinine. We randomly assigned these patients to the restrictive group (Z Group) or the GD one. In figure 1 we showed the 2 strategies; SVV was measured through the FloTrack/Vigileo (Edwards Lifescience©, Irvine, CA, USA). We recorded demographics, neurosurgery type and indication, intraoperative hemodynamic parameters, postoperative complications, ICU and hospital LOS. We collected neurological status and biochemical data before and after surgery.
RESULTS. We enrolled 20 patients; the mean age was 51.8±7.8 years with a prevalence of female (65%); 45% of the lesions were meningiomas, 20% glial lesions, 20% epileptogenic dysplasia and the remaining 15% brain metastasis or colloidal cysts. The groups didn't show any differences regarding patients basal characteristics (age, ASA, preoperative GCS, Apfel score, biochemical data), mean surgical duration (283±88.6vs273± 94.7,p>0.05) and types of crystalloids. In the GD group we infused a less amount of crystalloids (1862±757mlvs2254±851.6ml,p>0.05); this data reaches the statistical significance when we translate it in terms of perioperative fluid balance (-319.2±634.7ml for the GD group vs 107± 229.4ml for the Z group,p=0.04). Arterial pH was more close to the physiological value in the GD group (7.4±0.04 vs 7.36±0.05, p=0.005); other markers of perfusion and homeostasis such as arterial lactate and base excess tended to approach more physiological values in this group (lactate:1.75±1.3 vs 2.02±0.6,BE: 2.97±3.4vs -1.99±2.5,p>0.05). We didn't find any other differences in terms of neurological evaluation (GCS/RASS), postoperative complications (NRS, nausea/vomit), hydroelectrolytic status and inflammations. While the ICU-LOS is similar, the hospital one tends to be shorter in the GD group (6.4±1.3days vs 7.4±2.5days, p=0.07).
CONCLUSION. We observed a better preservation of the physiological status of the patient with a GD fluid therapy.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001615

INTRODUCTION. Spontaneous intracerebral hemorrhage (sICH) are responsible for 9-27% of cerebrovascular diseases worldwide, with 37-52 % of mortality at 30 days and 54% a year. Brain injury biomarkers (BIB) have been studied to predict prognosis in this pathologies.
OBJECTIVES. To related BIB with mortality and functional outcome in patients with sICH.
METHODS. We performed a prospective study with patients admitted in ICU with sICH. BIB were determined (Enolase, S-100B, Dimer D/DD, Brain natriuretic peptide/BNP) at admission,1,2, and 3rd day. APACHE II, SOFA, GCS and GRAEB were determined at admission and the modified Rankin Scale (mRS: poor outcome >2) and Glasgow Outcome Scale (GOS: poor outcome <4) at ICU discharge and 6 months after the event. Variables were summarized using %, mean (SD) and median. We used T-Student and $\chi 2$($p < 0.05$) for univariable analysis.
RESULTS. We enrolled 120 patients, 63,3% were men, mean age 63,3 ± 12.6 ys. Global mortality was 30,8%. In the univariable analysis of mortality we obtain an stadistically significance with APACHE II 18,4 ± 5,3 vs 12,4 ± 5,4 (p<0,001), SOFA 6,7 ± 2 vs 3,5 ± 2 (p< 0,001); GCS 8 ± 3 vs 11,8 ±3 (p < 0,001), GRAEB 3,84± 0,56 vs 2,46±0,39 (p 0,05); it was also significantly associated with BNP at admission, 1, 2 and 3rd day (p: 0,005, 0,027, 0,029 and 0,012, respectively) and DD at 1, 2 and 3rd day (p 0,041, 0,005, 0,004 respectively). Otherwise, the univariable analysis of poor outcome with mRS and GOS at ICU discharge were associated with DD at admission, 1, 2 and 3rd day (GOS: p 0,005, 0,05, 0,001, 0,001; mRankin p 0,001, 0,001, <0,001, <0,001; respectively) and S100B at admission, 1, 2 and 3rd day (GOS p: 0,015, 0,003, 0,003, 0,008; mRankin p: 0,016, 0,003, 003 and 0,004; respectively). We obtained a significance association between poor mRS and GOS at 6 months with S100B 2nd day(p 0,003).
CONCLUSION. BIB as BNP (at admission, 1, 2 and 3rd day) and DD (1, 2 and 3rd day) were related to mortality. S-100B and DD (both at admission, 1, 2 and 3rd day) in an early stage were related to worse outcome at ICU discharge. But only S100B 2 day was related to poor outcome at 6 months.

Shift Matters: CT scan Predictors of Diabetes Insipidus in Brain Death

A. Daneshmand, EF. Wijdicks
Neurology, Mayo Clinic Hospital, Saint Marys Campus, Rochester, USA
Correspondence: A. Daneshmand
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001655

INTRODUCTION. Diabetes insipidus (DI) is a known complication of patients with catastrophic brain injury resulting in brain death. The pathophysiology of the DI is not fully understood. The presumed mechanism is the injury of the pituitary gland and stalk from brain tissue shift. In the present study, we reviewed the relationship of brain shift and edema and the appearance of DI.
METHODS. We reviewed a series of patients with near complete loss of brainstem reflexes leading to brain death. Baseline Mean Arterial Pressure (MAP) and baseline demographic information were collected. Effacement of basal cisterns and midline shift were assessed using baseline CT scan and correlated to DI using standard diagnostic criteria of specific gravity, and serum and urine osmolarity.
RESULTS. In our series, 26% of patients developed DI before the diagnosis of brain death. The mean midline shift on baseline CT scan in patients who developed DI was 7.2 mm, comparing to 3.6 mm in patients with no DI. (p=0.005). Effacement of basal cisterns was noted in 84% of patients with DI as opposed to 44% of patients without DI (p<0.05). The MAP was not significantly different between the two groups (p=0.33). 40% of patients with subarachnoid hemorrhage, 32% of patients with intracerebral hemorrhage, 22% of patients with anoxic brain injury and 10% patient with traumatic brain injury developed DI.
CONCLUSION. DI is associated with much more profound brain tissue shift and effacement of the basal cisterns in patients who progress to brain death.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001714

INTRODUCTION. Monitoring and management of intracranial pressure (ICP) and cerebral perfusion pressure (CPP) based on brain trauma foundation guidelines(1)is the standard of care in the management of patients with traumatic brain injury (TBI). However, there is a wide variation in the way CPP is measured.Councils of Neuroanaesthesia and Critical Care Society of Great Britain and Ireland (NACCS) and the Society of British Neurological Surgeons (SBNS) **recommend that in the management of TBI, when calculating CPP, the arterial transducer used to estimate mean arterial pressure (MAP) for the calculation CPP =MAP–ICP should be positioned at the level of the tragus (which is an approximation for middle cranial fossa level)(2).**In a person with 30 degrees head elevation and 30 cm distance between heart(Phlebostatic Axis)and the head,the difference in measured MAP/CPP levels will be 11 mmHg depending on the calibration level.
METHODS. We conducted a retrospective audit of the position of arterial transducer in patients with TBI who had continuous ICP and CPP monitoring with **an aim to ensure correct positioning of transducer at tragus level,**as per national recommendations (2).We implemented continuous teaching sessions for nursing staff and introduced a mandatory drop-down list for arterial transducer position(Figure 1)on our electronic patient observation chart. We re-audited the position of transducer after implementation of above changes. Audits were conducted for a period of 1 month where patients with TBI were observed over a period of 3 days with twice daily recording of the position of the transducer. We excluded patients with non-traumatic brain injury and patients with significant extracranial polytrauma even if they had continuous ICP monitoring.**Figure 1 showing the "drop-down list" of arterial transducer position in our electronic patient observation chart**.
RESULTS. A total of 24 observations were recorded from 4 patients with TBI and continuous ICP and CPP monitoring over their first 3 days of admission, checking the position of transducer twice daily, corresponding to nursing shift changes.**Only on 1(4%)occasion was the transducer positioned correctly (tragus) in the 1st audit. After the implementation of nursing education and change in electronic patient observation chart,on 18(75%) occasions, positioning of transducer was at correct level.**
CONCLUSION. We demonstrated significant improvements in adherence to national recommendations on arterial transducer position in patients with isolated TBI requiring continuous ICP and CPP monitoring, after implementation of changes to our patient observation chart as well as improved nursing education on this topic.We recognise that there is scarcity of evidence of benefit for this practice,in terms of outcomes for this cohort of patients.It is perhaps time to design high quality studies to see if there are benefits,in terms of neurological outcomes,of measuring cerebral perfusion pressure at midbrain level.

INTRODUCTION. Intracranial hypertension (ICH) - the most frequent and terrible complication that occurs in patients with intracranial hemorrhage.One of the main tasks of the intensive care of patients with intracranial hemorrhage is the diagnosticsand correction of ICH.
OBJECTIVES. We evaluated the possibilities of the optic nerve ultrasound in the diagnosticsof ICH.
METHODS. This prospective observational study enrolled 51 adult patients with SAH (n=14) and TBI (n=37) with mean age of 48±14 years.All patients underwent neurological examination, performed CT scan of the brain, invasive monitoring using intracranial pressure sensors and dynamic measurement of the optic nerve sheath diameter (ONSD) and optic nerve diameter (OND) within the first 14 days following the onset of the disease. All patients were operated on. We examined 26 healthy volunteers to determine the normal values of ONSD and OND (n=26).
RESULTS. The normal values of the ONSD according to ultrasound in healthy volunteers were 4,7±0,2mm, OND - 2,3±0,1mm.In patients with SAH the mean ICP initially was 12,4±2,0mmHg, OND - 2,5± 0,1mm, ONSD - 5,1±0,2mm. Further was found a tendency to ICH (average ICP values - 32±9mmHg, OND - 2,5±0,2mm, ONSD - 6,3± 0,2mm), then ICP returned to normal values - 14±1,9mmHg, OND - 2,6±0,2mm, ONSD - 5,5±0,2mm. In patients with TBI ICP initially and during first 5 days was high - 37,6±3,1mmHg, OND - 2,6±0,2mm, ONSD - 6,4±0,1mm, then the level of ICP returned to normal values (mean ICP values 14,1±3,2mmHg, OND - 2,4±0,2mm, ONSD - 4,9± 0,2mm). A strong correlation was found in patients with ICP >= 20mmHg and ONSD compared to healthy volunteers (Spearman N= 803, R=0,3, p<0,001; Kruskal-Wallis p<0,001), the OND in the examined patients and in healthy volunteers did not differ (Spearman N= 829, R=0,0055, p=0,9). The ROC analysis showed the ONSD of 5,9 mm was the best cutoff value with a sensitivity of 91% and a specificity of 86% for identifying ICP ^{3}20mmHg.
CONCLUSION. The use of ultrasound of the optic nerve can serve as an additional screening non-invasive method for diagnostics ICH.

INTRODUCTION. Non-traumatic subarachnoid hemorrhage (SAH) represents a dramatic disease.
OBJECTIVES. To analyze prognostic factors and long-term outcomes of patients with SHA.
METHODS. Descriptive study (2009-2017). We collected: age, sex, Hunt & Hess (HH), Modified Fisher (MF), arteriography results and treatment: endovascular coiling (EVC) or surgical clipping (SC). We recorded the complications during ICU stay and the necessity of invasive procedures as external ventricular drain (EVD), mechanical ventilation (VM) and tracheostomy (TR). The time between diagnosis and treatment was analyzed too. Mortality and Glasgow Outcome Score (GOS) was evaluated at hospital discharge and at 6 months.
RESULTS. For 9 years, 184 patients with SAH were recruited, 58.7% were women, median age was 53 (46-64). HH was I-II in 120 patients (65.5%), III in 24 and IV-V in 39 (21.3%). MF was III-IV in 149 patients (81.4%). Arteriography (180) was positive for aneurysm in 134 cases (72.8%), arteriovenous malformation in 6 patients and negative in 40. The median size of aneurysm was 5 mm (4-7). EVC was performed in 117 patients (64.6%), surgical clipping in 17. The time between diagnosis and treatment was less than 24 hours in 58.8% cases. No spontaneous rebleeding was observed. Complications rates were: hydrocephalus 40.4%, vasospasm 26.9%, hyponatremia 17.1%, seizures 5.7%, myocardial injury 9%, lung injury 3% and infection 23.7% (urinary tract infection 51.1%, pneumonia 25.6% and ventriculitis 11.6%). Sixty-eight patients needed an EVD, 59 MV and 26 TR. The average hospital stay was 21.5 (13-33) days and 9 in the ICU (4-19). At hospital discharge 63.5% of the patients had GOS IV-V (moderate disability - good recovery), 22.6% GOS III (severe disability) and 13.8% GOS I-II (dead - vegetative state). At 6 moths 73.3% patients presented GOS IV-V. The overall mortality at six months was 11.4%. In the univariate analysis HH, MF, aneurysm, treatment, timing for EVC, EVD, hydrocephalus, infection, MV and age were related with worse outcome at hospital discharge (GOS I-III) ($p< 0.05$) (table 1). After the logistic regression analysis, the factors independently associated with worse functional status (GOS I-III) were: HH IV-V, hydrocephalus, necessity of MV and age ($p<0.05$) (table 2).

CONCLUSION. SAH had a high incidence of complications during ICU stay. HH IV-V, hydrocephalus, MV and age were independent risk factors for a worse outcome at hospital discharge. However, we observed a high rate of good-moderate recovery. In our series, no rebleeding was found, probably due to the early treatment.

Table 1 (abstract 001371). See text for description

INTRODUCTION. Mechanical power has been increasingly recognized as the unifying variable that gathers the ventilator associated parameters which are responsible for VILI. Since the assessement of mechanical power is somehow difficult at the bedside, finding an easily available surrogate to estimate the energy delivered to the lung over time could be clinically interesting. Our aim is to evaluate the agreement between the measured mechanical power and two of its possible surrogates that we built up starting from the most available ventilation parameters.
METHODS. We collected experimental data from 78 mechanically ventilated pigs and clinical measurements obtained from 36 ICU patients for a total of 1002 observations. The so called "Peak power" was calculated as the product between peak pressure, tidal volume and respiratory rate. For the "Driving power" we used driving pressure instead of peak pressure.
RESULTS. Peak power overstimate actual mechanical power both in animals and human patients, with a significant positive bias of 7.68 J/min and 3.48 J/min respectively. The proportional error was similar in the two groups, with an increasing difference of 0.27 J/min (animals) and 0.25 J/min (patients) for each J/min increase of mechanical power delivered. The R2 of the linear regression was 0,97 for animals and 0,98 in patients, indicating an almost perfect linear relationship. When driving pressure was used instead of the peak pressure the goodness of fit of the model was reduced with an R2 of 0,65 in animals and 0,66 in patients. Driving power leads to an underestimation of the actual mechanical power of 7.35 J/min (animals) and 5.79 J/min (human patients) Both animals and patients showed a proportional error, with an increasingly negative difference of 0.33 J/min (animals) and 0.45 J/min (patients) for each J/min increase of mechanical power delivered.
CONCLUSION. Between the two surrogates we analyzed, peak power compared to driving power. Peak power overestimate the value of power, but this bias is moderate in the range of ventilation parameters commonly used in clinical practice. Moreover, an overestimation is probably safer than the underestimation provided by driving power which also does not take into account the energy needed to overcome PEEP. This might be relevant not only in the context of VILI prevention, but also in the hemodynamic management of the patients.

INTRODUCTION. Ventilator associated pneumonia (VAP) is usually suspected when a patient develops a new or progressive infiltrate on chest radiograph, leukocytosis, purulent tracheobronchial secretions, and worsening gas exchange evidenced either by increasing oxygen requirements or ventilator demand.
Taken from respiratory samples, endotracheal aspirate (EA) and bronchoalveolar lavage (BAL) play an important role by allowing to know bacteriology, antibiotic sensitivity and epidemiology of different centers. Nevertheless respiratory samples are only one of various components in diagnosing VAP.
OBJECTIVES. Measurement of the impact of respiratory samples (EA and BAL) in diagnosing VAP.
METHODS. A retrospective, single-center observational study over a period of 1 year (2017- 2018) was carried out in 233 respiratory samples of 145 patients with suspected VAP.
RESULTS. Out of the 233 samples in 145 patients with suspected VAP, 52% (122) were EA and 48% (111) BAL. 64% of the patients were men and the average age was 53 years.

The most frequent pathologies were respiratory (38%) neurological (18%) and polytrauma (14%).
Clinical criteria, radiological evidence, alterations in gas exchange and respiratory samples were used to define VAP (as Criteria of centers for the control and prevention of diseases). Only in 18% (27) of the patients did the respiratory samples define an accurate diagnosis of VAP in the context of the suspected criteria.
CONCLUSION. The sole use of the respiratory samples (EA and BAL) for the diagnosis of VAP without taking into account clinical criteria, does not increase the accuracy of the diagnosis and it can lead to error, with an important impact on health costs and inadequate management of antibiotic therapy which generates greater bacterial resistance. Among the population studied with the implementation of international guidelines, in 18% of the patients the respiratory samples concluded a definitive diagnosis of VAP.

INTRODUCTION. ARDS is a heterogeneous disease and its mortality rate is still high in intensive care unit (ICU). Causes of death generally are not only pulmonary pathologies, but concomitant extrapulmonary dysfunction.
OBJECTIVES. To characterize patients who developed ARDS.
METHODS. Retrospective study with data collected from January to December in 2017, performed through the analysis of the medical records of patients admitted to the ICU in the Hospital Universitário do Oeste do Paraná - Brazil. The variables were described by mean, standard deviation and percentage. Variables with normal distribution were compared using the *Student's T-Test,* and the non-normally distributed variables were compared using the *Man Whitney* tests. All analyzes were performed at 5% significance.
RESULTS. The sample consisted of 36 patients who developed ARDS, 22 survivors (SG) and 14 deaths (DG). The variables comparing were SG *vs* DG: age in years (45.6 ± 21.8 *vs* 52.7 ± 26.8; p=0.55), male (63% *vs* 50%), non-neuro clinical causes of admission (29.16 *vs* 50%), severe traumatic brain injury (29.16% *vs* 21.42%), APACHE II (29.90 ± 7.13 *vs* 34.92 ± 7.42; p=0.05), SOFA (10.90 ± 3.03 *vs* 15.28 ± 3.02; p= 0.0002), higher FiO2 (57.5 ± 17.30 *vs* 53.21 ± 12.95; p=0,48), worst plateau pressure (19.13 ± 6.95 *vs* 21.5 ± 4.20; p=0.55), worst static complacency (31.40 ± 8.16 *vs* 32.78 ± 9.93; p=0.66), worst PaO2/FiO2 (155.54 ± 59.85 *vs* 142.92 ± 62.07; p=0.55), tidal volume ml/kg (6.90 ± 0.52 *vs* 6.57 ± 0.64; p=0.08), higher PEEP (12.40 ± 4.15 *vs* 12.85 ± 2.87; p=0.70), drive pressure (12.07 ± 3.02 *vs* 11.86 ± 4.45; p=0.85). The SG had an ICU length of stay of (24.04 ± 24.04) days, time of sedation in hours (253.10 ± 164.21), and time of the mechanical ventilation in hours (398 ± 338.29). The death group had an ICU length of stay of 14 ± 16 days. The alveolar recruitment maneuver was used in all patients and the prone position was used in 27% SG and 79% DG.
CONCLUSION. Patients with ARDS who died had the higher APACHE II and SOFA scores.

INTRODUCTION. Mechanically ventilated (MV) patients may present airway inflammation and elevated secretion production. However, it is not known whether total protein counts in bronchial samples may be useful to evaluate the clinical condition of patients and bronchial sampling for such purposes is not yet standardized.
OBJECTIVES. We aimed to evaluate bronchial secretions, with or without cells, in terms of differential total protein count obtained by mechanical ventilated critical care patients using different methods of sampling
METHODS. This study took place in the Intensive Care Unit of a tertiary Greek hospital during a six-month period. Patients were included if they were under MV for less than 24 hours and required bronchoscopy. Furthermore, non-mechanically ventilated subjects who underwent a single bronchoscopy, were assessed as controls. In all patients, aspiration of bronchial lining fluid (BLF) was performed, Bonchoalveolar lavage (BAL)and two types of Bronchial Washings (BW40 and BW5) were performed with the instillation of normal saline (ml) 150, 40, 5, while visible bronchial secretions were obtained via bronchoscopy (VBS) and blinded, via a common catheter for tracheobronchial aspiration (AC). Samples were divided in two and one of them was homogenized in a Heidolph Silent Crusher S and total protein was measured using the Bradford method after treatment with Lysis buffer (20 mM Tris-Cl pH 8.0, 150 mM NaCl, 1% Triton X-100, 1 mM dithiothreitol, 100 mg/mL-1 PMSF). Cell extracts were cleared by centrifugation (1000g, 20min, 4°C) and optical density was measured photometrically in samples with or without cells.
RESULTS. Twenty-five patients and six controls were evaluated. Mean (SE) age was 65.9 (3.0) and APACHE II 18.5(1.5). Ten patients were admitted due to surgical problems. Protein concentration was elevated in homogenized samples [14.98(1.45) µg/ml] compared to non-homogenized ones [13.69(2.25) µg/ml, *p<0.05]. Regarding the sampling technique, AC and VBS appear to be no different, while protein concentrations were elevated in VBS compared to BAL and BW samples (*p,0.05). There appeared to be no differences in samples with or without cells.
CONCLUSION. Both the sampling technique chosen and the homogenization of the sample, but not the presence of cells in the sample, can affect protein concentration in both MV patients and controls. These results show that total protein concentration in bronchial secretions could represent a potential inflammation biomarker.

INTRODUCTION. The single cell gel electrophoresis (comet assay) is a sensitive technique for the detection of DNA damage which could serve as an index of cellular stress in the lung during mechanical ventilation (MV).
OBJECTIVES. DNA damage caused in lung parenchyma and bronchi in mini-bronchoalveolar lavage (mini-BAL) and bronchial washing (BW) samples obtained from patients under mechanical ventilation, was presently assessed.
METHODS. This prospective study took place in the Intensive Care Unit of a tertiary Greek hospital during a six-month period. Patients were included if they were under MV and required two bronchoscopy sessions; a. within the first 48 hours and b. at the 7th MV-day. Non-mechanically ventilated subjects who underwent a single bronchoscopy, were assessed as controls, as well. In all patients mini-BAL and BW were performed with the instillation of 40 ml and 5 ml of normal saline, respectively. Cellular stress response was assessed by the comet assay in which the fragmented DNA migrates out of the nucleus forming a tail, known as a "comet". Damage was quantified using the parameter %DNA in the comet's tail, which represents the percentage of total DNA migrated in the tail and is calculated as ratio of total intensity of the tail and total intensity of the comet.
RESULTS. Nine patients were assessed. Mean±SE age was 66.4±3.4 and APACHE II 18±1.8. Five patients were admitted due to medical problems (three of them with respiratory failure). Mean % DNA in the comet's tail were 9.84±3.1 and 6.3±2.7 in BW and mini-BAL, respectively; 7.6±2.0, 5.2±1.5 and 12.9±7.0, 7.6±3.3 in the first and second week, respectively, whereas % DNA damage in control samples was lower (1.10±0.3).
CONCLUSION. The comet assay may be useful in the evaluation of the cellular stress response in the lung due to mechanical stress of MV. A larger study will help to assess separately the role of various insults that can affect the lung during MV.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001263

INTRODUCTION. The optimal hemoglobin threshold to trigger transfusion of packed red blood cells (PRBCs) in critically ill adults with acute respiratory distress syndrome (ARDS) is unknown. While several guidelines recommend to maintain the hemoglobin concentration within normal ranges, a restrictive transfusion strategy has been proven safe in many other clinical settings. However, the outcome of different hemoglobin thresholds that trigger blood transfusions in patients with ARDS has not been evaluated.
OBJECTIVES. To assess the effect of different transfusion thresholds on short-term outcome in patients with ARDS. We hypothesized that short-term outcome in patients transfused at lower hemoglobin thresholds is not inferior compared to patients transfused at higher hemoglobin thresholds.
METHODS. This retrospective observational study was conducted in a tertiary ARDS referral center. Patients admitted with an ARDS between January 2007 and December 2018 that received at least one PRBC transfusion were included into the study. For each patient, the hemoglobin concentration prior to each PRBC transfusion was identified and then the average over the number of PRBC transfusions was calculated. According to this individual hemoglobin threshold, patients were assigned to 5 different groups (<7 g/dl, 7-8 g/dl, 8-9 g/dl, 9-10 g/dl, 10-13 g/dl). In each group, a transfusion was not given until the hemoglobin concentration dropped into the group specific range. The primary endpoint was ICU mortality. Cox proportional hazards regression was used to estimate the risk of mortality in each group and to control for between-group differences of prognostic determinants in ARDS. (Ethical approval: Charité - Universitätsmedizin Berlin, No. EA2/018/19).
RESULTS. A total of 1042 ARDS patients were screened and 904 (86.8%) patients receiving overall 17.197 PRBC units were included in the analysis. The main cause for ARDS was pneumonia (64.6%). Most patients were graded with severe ARDS (84.8%) and 569 (62.9%) patients were treated with an extracorporeal lung assist device (ELAD). A total of 42 (18; 101) [median (25%; 75% quartiles)] hemoglobin values per patient were screened to calculate the individual hemoglobin threshold for each patient, resulting in 67 patients transfused at <7 g/dl, 275 patients at 7-8 g/dl, 309 patients at 8-9 g/dl, 147 patients at 9-10 g/dl, and 106 patients at 10-13 g/dl, respectively. After adjusting for confounders of mortality in ARDS, the risk for ICU mortality was not higher in patients transfused at lower hemoglobin thresholds (<7 g/dl and 7-8 g/dl) compared to patients transfused at higher hemoglobin thresholds (8-9 g/dl, 9-10 g/dl, and 10-13 g/dl). This finding was concordant with the results found in the subgroup of patients with ARDS and therapy with an ELAD.
CONCLUSION. In critically ill ARDS patients, the risk of death in the ICU is not higher when a restrictive transfusion strategy is applied compared to a liberal approach.

Diaphragm Dysfunction from Phrenic Nerve Injuries during Cardiac Procedures: The Evolving Positive Role of Diaphragm Pacing to Improve Nerve and Diaphragm Function

R. Onders[1], H. R.[2], M. Elmo[1]
[1]Surgery, University Hospitals Cleveland Medical Center, Cleveland, USA; [2]Pulmonary, University Hospitals Cleveland Medical Center, Cleveland, USA
Correspondence: R. Onders
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001274

INTRODUCTION. Phrenic nerve damage from cardiac surgery occurs in 1 to 60% of cases depending on the procedure and methods of diaphragm evaluation. During atrial fibrillation ablation procedures it occurs in up to 20% of patients. Phrenic injures can results in symptoms of mild dyspnea, dependency on non-invasive ventilation (NIV) and failure to wean off mechanical ventilation (MV) with associated morbidity and mortality. Data on spontaneous recovery post injury is sparse and historically nerve recover can take up to 18 months.

OBJECTIVES. Report on the use of diaphragm pacing (DP) as a modality to improve diaphragm function post phrenic nerve injury.
METHODS. This is a retrospective review of a compassionate off label use of an FDA approved humanitarian use device under IRB approval (#02-10-18). Patients with diaphragm dysfunction (DD) from phrenic nerve injury underwent laparoscopic direct evaluation of the diaphragm. If the diaphragm was stimulateable, two intramuscular electrodes were placed in each diaphragm and electrical stimulation was begun to facilitate diaphragm strengthening and phrenic nerve recovery. Electrical stimulation therapy to strengthen the diaphragm ensued. Serial diaphragmatic electromyography (dEMG) through the implanted electrodes, chest radiographs (CXR), ventilation use and patient reported symptoms were obtained.
RESULTS. Twenty-three of 115 patients in the database had DD post cardiac procedure. Three developed DD post ablation and 1 after pericardial effusion procedure. Nineteen had median sternotomies: 3 left ventricular assist devices, 3 heart transplants, 2 atrial myxoma resections and 9 valve or coronary bypass isolated or combined cases. Nine were dependent on invasive MV with 8 tracheostomis. Nine used NIV with 5 continuous full-time NIV. Average age was 66.7 years (47-85). Time from insult to implant was 2 weeks to 15.5 years(median 2 months). Eight of the nine MV were weaned with five tracheostomy decannulations. Complete weaning averaged between 1 to 35 days (13.45 average). Initial dEMG data, available for 19, showed minimal to no activity on the affected side. Seventeen had significant improvement in dEMG. Overall survival is 23.6 months(2 weeks-7.5 years) with 6 deaths. Twenty patients had demonstrated diaphragm and phrenic nerve improvement (86.9%).
CONCLUSION. Patients requiring prolonged MV post cardiac procedure have significant morbidity with only a 30% one year survival. Reported spontaneous improvement of diaphragm paralysis is less than 45%. In this report DP showed improvement in 86.9% of patients utilizing diaphragm electrical stimulation as physical therapy to overcome the atrophied diaphragm and help nerve recovery. Early use of DP can help prevent the elevated diaphragm from paradoxical movement that can lead to lung collapse which would increase pneumonia risk. Early use may decrease the morbidity of tracheostomies. Future randomized trials will elucidate the role of early diaphragm pacing in preventing prolonged MV.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001630

INTRODUCTION. Neurally adjusted ventilatory assist (NAVA) is a mode that delivers proportional ventilation using esophageal probe to detect the electrical activity of the diaphragm (EAdi).
Difficulty in weaning is partly associated with the presence of asynchronies between the patient and the ventilator ,which occurs when either the initiation and/or termination of mechanical breath is not in time agreement with the neural inspiration, or if the magnitude of mechanical assist does not respond to the patient's respiratory demands.
OBJECTIVES. To evaluate role of NAVA mode in reducing asynchrony versus PSV mode
METHODS. A prospective, randomized, interventional, single-center study, which was approved by the IEthics and Research Committee in both Cairo University and Suez Canal Authority. Before inclusion, patients and/or families (next of kin) gave their consent about participation after information on the aim of this study.The study was conducted in the service of the ICU of Suez Canal Authority Hospital over a period of 14 months (from June 2017 till August 2018)
Inclusion criteria:
Invasively ventilated patients with predictive criteria of difficult weaning
Exclusion criteria:

- Contraindication to EAdi catheter placement

Patients who met the inclusion criteria and give their or their families consent about participation were successively ventilated for 24 h using PSV and then they were ventilated for another 24 h in the NAVA. dysynchronies were recorded and calculated .
RESULTS. Fifteen critically ill invasively ventilated patients were included in this study after fulfilling the inclusion criteria and giving their or their families consents.
CONCLUSION.

- Using NAVA mode was helpful in reducing patient ventilator desynchronies significantly when compared to PSV (which allow more patient comfort).
- There were significant increase in oxygenation index during NAVA than during PSV

Transpulmonary pressure guided ventilation in ECMO eligible obese severe ARDS patients

S. Jog, P. Kalyani, D. Pradip, R. Prasad
[1]Intensive care medicine, Deenanath Mangeshkar Hospital and Research Center, Pune, India
Correspondence: S. Jog
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001663

INTRODUCTION. Transpulmonary Pressure(TPP) measurement is a promising tool used for ventilatory adjustments in ARDS patients. Its

usefulness and application in the management of severe ARDS remains unclear.
OBJECTIVES. 1) Does TPP measurement help in ventilatory adjustments in severe ARDS patients?
2)Do TPP guided ventilator strategies improve gas exchange?
3) Does TPP guided PEEP adjustment increases incidence of barotraumas?
METHODS. Prospective observational study. TPP measured by an esophageal balloon catheter(Nutrivent, Sidam, Italy) and a suitable ventilator(Hamilton G5, Switzerland)
Inclusion criteria – Adult patients with Body Mass Index > 25, Severe ARDS (PO2/FiO2 ratio < 100) having set PEEP ≥ 15 cm, Airway plateau pressure > 30 cm and under deep sedation with neuromuscular blockade and at least one 16 hour prone position trial instituted.
Exclusion Criteria – 1)Patients receiving ECMO 2) Patients in whom position of esophageal balloon and measurement of TPP could not be confirmed by cardiac oscillation and abdominal pressure technique. Ventilatory parameters and blood gas parameters were documented before measuring TPP and after measuring TPP. Ventilatory setting adjustments done after TPP measurements were – i)increasing PEEP in hypoxic patients(SpO2 < 88 %) till oxygen saturation remained > 90% provided plateau TPP remained < 23 cm and end expiratory TPP remained > 0 cm ii)Increasing tidal volume(> 6 ml / KG) in hypercapnoeic acidotic patients (pH< 7.20 and PCO2> 80mm Hg) provided plateau TPP remained < 25 cm.
RESULTS. Consecutive 18 patients who met inclusion criteria were screened only 10 patients included in the study. All 10 of our study patients were eligible for ECMO. However ECMO therapy could not be offered to these patients due to resource limitations. Average weigh of these patients was 88.3 ± 20.3 with BMI 30.8 ± 6.8 . Average PEEP set was 15.1 ±2.1 cm of H2O prior TPP measurement. Post intervention PEEP was 20.5 ± 3.1 cm of H2O. (p = 0.000043). The mean PO2/FiO2 ratio before intervention was 85.5 ± 24.41 and after intervention it was 103.4 ± 20.9 . The difference in PO2/FiO2 ratio before and after intervention was significant, 68.7 ± 14.34 versus 81 ± 12.28 (p = 0.0473). None of these 10 patients developed pneumothorax even at average PEEP of 20.5 ± 3.1 cm and average airway plateau pressure of 41.2 ± 4.2 cm. 6 out of 10 patients survived till hospital discharge and 4 patients died due to sepsis and MODS.
CONCLUSION. TPP measurement is useful in setting appropriate PEEP and tidal volume in severe ARDS patients without increasing the risk of barotrauma. TPP guided ventilation strategy in ECMO eligible severe ARDS patients , can improve outcome in resource limited settings.

PEEP effect of tracheotomy high-flow oxygen therapy in patients with severe head injury

P. Xu[1], H. Ge[2]
[1]Sir Run Run Show Hospital, School of Medicine, Zhejiang University, Hangzhou, China; [2]Respiratory care, Sir Run Run Show Hospital, School of Medicine, Zhejiang University, Hangzhou, China

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001664

INTRODUCTION. The current research is mostly focused on nasal high-flow oxygen therapy (NHFO). Whether the high-flow oxygen therapy has the same physiological effect through tracheotomy catheter is still unknown(THFO) , and there are certain doubts in the clinic.
OBJECTIVES. Investigate the physiological role of tracheotomy high-flow oxygen therapy in the patients with severe craniocerebral injury after tracheotomy.
METHODS. From July 1st to December 31st, 2018, we entered the emergency department of our hospital with craniocerebral injury (GCS ≤ 8) and underwent tracheotomy. Patients who successfully detached from the ventilator for 24 hours were followed up by themselves. Give venturi mask gas mask (MO) and tracheotomy high flow oxygenation (THFO), high flow rate from 30L / min, 45L / min to 60L / min in turn, each method lasted for 30 minutes. The main observation was the measurement of end-tidal lung volume (△EELI) during the different oxygenation modes of patients by electrical impedance tomography (EIT). Secondary observations included different oxygenation methods for vital signs, oxygenation and the impact of gas exchange.
RESULTS. Total of 20 patients with severe craniocerebral injury were included in the study. The end-expiratory lung volume (EELI) decreased significantly with the increase of flow rate after high-flow oxygen therapy ($p<0.05$), mainly in the non-gravity lung. The decline in lung volume in the dependent area. The oxygenation index and carbon dioxide partial pressure were significantly improved compared with the oxygen absorption in the venturi, which were $p<0.01$ and $p<0.05$, respectively. However, the oxygen concentration did not increase significantly with the increase of THFO flow, $p = 0.234$, and the change of PaCO2 did not cause a significant change in blood pH ($p = 0.298$). The patient's respiratory rate was lower at high flow oxygen therapy ($p < 0.05$), but the increase in the THTO flow did not decrease further ($p = 0.554$). Other vital signs such as tidal volume, heart rate, blood pressure, and mean arterial pressure were not statistically different between high-flow oxygen therapy and venturi.
CONCLUSION. Tracheotomy high flow oxygen therapy can reduce the respiratory rate, end-tidal and arterial blood carbon dioxide partial pressure in patients with severe craniocerebral injury, and improve the patient's oxygen and without affecting other vital signs. THFO does not produce PEEP effect, and the end-expiratory lung volume even has a tendency to decline. The specific reasons need further study.

INTRODUCTION. Prone ventilation (PV) is a standard of care for severe ARDS . Factors associated with outcome of PV are not well studied.
OBJECTIVES. This retrospective analysis aims at finding the factors associated with survival as an outcome in patients who received PV in severe ARDS.
METHODS. Single center retrospective observational study. Patients with severe ARDS who received lung protective ventilation as per the ARDSnet protocol and received prone ventilation(PV) were considered for the analysis. Inclusion criteria - 1)PO2/FiO2 ratio < 100 2)Plateau Pressure > 28 cm 3)PEEP > 12 cm 4) Received at least 1 session of PV for consecutive 14 hours. Exclusion criteria –i)Patients who received ECMO or ECCO2R Extended prone session was defined as a prone ventilation session continued for more than 24 hours consecutively. Multivariable regression analysis used as a statistical method.
RESULTS.
Data of 44 patients was analysed. Mortality was 54.44%(24/44).Average days of mechanical ventilation were 14.84 days.ICU length of stay was 18.72 days. Average days of mechanical ventilation were 14.84 days.ICU length of stay was 18.72 days .In univariate analysis, we analysed 32 clinical, organ function, gas exchange and lung mechanics parameters of each patient. Survival as an outcome was significantly associated with Extended Prone Session (P<0.005) and number of Extended Prone Sessions (P < 0.05) while following factors were significantly associated with death as an outcome:
1)pH < 7.15 at the end of first prone session (P = 0.000) 2)Presence of shock needing vasopressors (OR 9.86 ; CI 1.07 to 90.7) 3)Need for Renal Replacement Therapy (OR 5.4;CI 1 to 28.93) 4)PCO2 > 55 mm Hg at the end of first prone session (OR 4.46; CI 1.24 to 17.41) In multiple regression analysis, 2 factors were independently associated with outcome. pH < 7.15 at the end of first prone session(1.25 ± 0.57;P=0.03) was associated with Mortality and number of extended prone position sessions (0.10 ± 0.04;P=0.02) was associated with Survival
CONCLUSION. Extended sessions of prone position are associated with survival and persistent respiratory acidosis at the end of first prone session is associated with death in patients of severe ARDS treated with prone position.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001668

INTRODUCTION. Neurally adjusted ventilatory assist (NAVA) is a mode that delivers proportional ventilation using esophageal probe to detect the electrical activity of the diaphragm (EAdi).Difficulty in weaning is partly associated with the presence of asynchroniesbetween the patient and the ventilator ,using Proportional modes vs traditianoal PSV in weaning appears to reduce dyssynchrony and aid weaning(1)
OBJECTIVES. To evaluate the role of NAVA compared to PSV in patient with difficult weaning
METHODS. This is a prospective randomized control study conducted on 30 critically ill, invasively ventilated patients with predictive criteria of difficult weaning(2) admitted during the period from June 2017 till August 2018 ,the patients were evaluated for readiness criteria and presence of weaning indices then they were randomly divided into two groups: group A include fifteen patients were ventilated in PSV (as a weaning mode) and evaluated for successful weaning and group B: including Fifteen patients were NAVA was used as a weaning mode for 24 hours.Research and Ethics comittee approval was taken prior to performing the study and a written consent from each patient and or his next of kin before participating in the study.
RESULTS. There was no difference between both groups regarding demographics ,baseline charecteristics and initial cause of venilation or initial ventilatory support.
There was no significant difference between both groups regarding length of mechanical ventilation ,susessful weaning, length of hospital stay.see ***table(1)***
The assyncrony index was lower in group B using NAVA while the oxygenation index was significantly higher in same group compared to group A using PSV during weaning .
CONCLUSION. Using NAVA during sponteneous breathing trial in difficult weaning patients reduced Assynchrony index and improved oxygenation index but this did not affect the sucess of weaning nor the outcome of patients(mortality LOS nor LOV).

INTRODUCTION. Activation and assembly of the NLRP3 inflammasome is dependent on interaction between NLRP3 and the intermediate filament protein vimentin in ARDS model.
OBJECTIVES. The roles of vimentin in the process of ARDS were further investigated.
METHODS. The human fetal lung (HFL-1) fibroblasts with vimentin transfergene or knockout were treated with LPS intervention. The oxidative stress damage, inflammation and cytokines, apoptosis, autophagy, and pyroptosis were measured and analyzed the relevant mechanism.
RESULTS. We demonstrated that vimentin expression less in the HFL-1 cells with vimentin knockout in response to LPS. Specifically, an increase of oxidative stress, a decrease of mitochondrial membrane potential, and an increase of calcium ion permeability resulted in an increase in the level of fibroblast apoptosis. As the same time, inflammatory response of vimentin knocked out were also upregulated, including the higher levels of TNF-a, IL-1ß, IL-6, and IL-10. Importantly, the mechanism of suppression of vimentin in lung fibroblasts was caused by a decrease in autophagy, a decrease in mitochondrial membrane protein, and a decrease in mitochondrial function, which might contribute to the augmented cellular injury in response to LPS exposure.
CONCLUSION. This study provided insights into that vimentin may interfere inflammatory cascade by activating the mitochondrial autophagy pathway of lung fibroblasts in the early stage of acute lung injury.

Quality control targets (SpO2≠100%, PaCO2≮40mmHg, Pmean ≯10cmH2O) on Outcome Among Patients in ICU

L. Su[1], P. Pan[2], D. Liu[1], X. Wang[1]
[1]ICU, Peking Union Medical College Hospital, Beijing, China; [2]Icu, Beijing Tiantan Hospital, Beijing, China
Correspondence: L. Su
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001678

INTRODUCTION. A series of quality control (QC) targets (SpO2≠100%, PaCO2≮40mmHg, Pmean ≯10cmH2O) was put forwarded and widely used in a single intensive care unit (ICU) setting.
OBJECTIVES. The aim of this study is to assess whether these QC targets could improve outcomes of the critically ill patients.
METHODS. The real-time clinical data of patients with mechanical ventilation at ICU admission between May 2013 to May 2017 in the Department of Critical Care Medicine of Peking Union Medical College Hospital were collected and analysed.
RESULTS. A total of 7,670 patients (mean age, 58 years; 3,943 [51.5%] male) were divided into QC before (n = 3,936) or QC after (n = 3,734) group. QC targets (SpO2, PaCO2, Pmean) and respiratory parameters (FiO2%, PaO2, PEEP, tidal volume, respiratory rate) within 72-hour ICU admission, primary outcome (ICU mortality, 28-day, 60-day, and 90 day mortality) and secondary outcomes (against advise discharge, ICU admission days, mechanical ventilation times, and central venous pressure) were calculated and made the comparisons between QC before and after.72-hour averaged SpO2, Pmean, FiO2%, PaO2, and VT were significantly lower and PaCO2 was higher after QC (*P<0.05*). Lower 90-day mortality, less against advise discharge, ICU admission days and mechanical ventilation times were found after QC (*P<0.05*). Interestingly, CVP significantly decreased accordingly in the QC after group (*P<0.05*).
CONCLUSION. The QC targets (SpO2≠100%, PaCO2≮40mmHg, Pmean ≯10cmH2O) contributed to avoid the high oxygen hazards, protect the lung injury, and improve the circulatory function, which resulted in better prognosis of critically ill patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001171

INTRODUCTION. The imbalance between organ demand and organ availability has led to the development of new strategies to increase the donor pool. The ACCORD-Spain project, carried out in 68 Spanish hospitals between November 2014-April 2015, evaluated the number of patients deceased after a devastating brain injury (DBI) and not admitted to intensive care (ICU) due to their bad neurological prognosis, that could have become potential donors. This project laid the grounds for what it is known as intensive care to facilitate organ donation (ICOD).
OBJECTIVES. To evaluate the impact of a new protocol aimed at promoting ICOD in patients with a DBI once active treatment (medical and/or surgical) has been deemed futile.
METHODS. Retrospective descriptive study (January 2016-December 2018) carried out in a Spanish tertiary hospital with a transplantation program that performs all transplants except small bowel and pancreas. The new protocol for ICOD comprehended the elaboration of a banner explaining which patients could be eligible for ICOD together with informative talks in the Emergency, Neurology, Neurosurgery and Internal Medicine Departments. We reviewed all patients notified to the Transplant Coordination Team and data were recovered from their database. Evaluation and analysis of all notifications were carried out.
RESULTS. During the period evaluated, 27 cases were notified; 21 (77%) out of the Emergency Department, four (15%) out of the neurology ward and two (8%) were ICU patients admitted after a DBI secondary to complications of an endovascular neurointervention. Mean age: 84.5 years with 21 (77%) females. The most frequent cause of DBI was intracranial hemorrhage (n= 18; 66%) followed by severe traumatic brain injury (n=6; 22%), stroke (n=2; 8%) and acute subarachnoid hemorrhage (n=1; 4%). Eleven (40%) out of the 27 patients were admitted to ICU with five (18.5%) of them becoming effective organ donors. An average of 2 organs were retrieved from each donor, with a total of 10 organs being implanted (1 bilateral and 1 single lung, 4 livers and 4 kidneys). This accounted for 7% of our total annual donor pool. Reasons for discarding the other six (21.5%) patients as donors were: absence of progression to brain death (n=2), new diagnosis of a neoplastic process, hemodynamic instability, medical contraindication and dismissal by the National Organ & Tissue Transplantation Organization due to lack of recipient (one case each).
Sixteen patients (60%) were not eligible for ICOD because of: age above 90 years plus comorbidities (n=5); clinical and radiological criteria that oriented to a low probability of evolving towards brain death (n=3); family refusal for ICOD (n=3) and absence of free ICU beds (n=2). Hemodynamic instability, the impossibility of correctly studying a neoplastic process at the time of admission and reasons not detailed in the clinical history constituted the three remaining cases.
CONCLUSION. ICOD represents a good and feasible option to increase the organ donor pool. For this reason, we believe all patients with a DBI in which treatment has been deemed futile should be evaluated by the Transplant Coordination Team.
ICOD will only be possible after efforts have been made to raise awareness towards organ donation across different hospital departments.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001272

INTRODUCTION.*Do-not-resuscitate* (DNR) orders apply to the decision to withhold *cardiopulmonary resuscitation* (CPR) and should not impact on other diagnostic or therapeutic measures. When there is *limitation of life-sustaining therapies* (LT), DNR is frequently the only or the first therapy to be limited and to many physicians a pre-requisite for other limitations.
OBJECTIVES. To evaluate the use of DNR orders worldwide and how they are related to LT.
METHODS. ICUs worldwide were invited to participate in Ethicus-2 through their country societies. Consecutively admitted patients who died or had LT during a 6 month period from 1.9.2015 to 30.9.2016 were prospectively studied. Regions included *North, Central and Southern Europe* (NE, CE, SE), *North and Latin America* (NA, LA), *Asia* (As), *Australia/New Zealand* (Au/NZ) and *Africa* (Af). Previous *end-of-life practices* (EOLP) definitions (1) were used.
RESULTS. 199 ICUs in 36 countries participated, enrolling 12850 patients. Decisions to LT, either *withholding* (WH) or *withdrawing* (WD) or to *actively shortening the dying process* (SDP) for the different regions were (WH %,WD %, SDP %): Af (20;13;0); As (41;39;0); NE (38;53;0.2); CE (47; 37; 1); SE (41;25;1); LA (60;6;0); NA (54;36;1); Au/NZ (45;46;0). The % of use of DNR orders in patients with LT for region was: Af (8); As (80); NE (92); CE (85); SE (50); LA (41); NA (95); Au/NZ (97). DNR orders are common when a decision to WH, WD or SDP is taken in Asia, NE and CE, NA and Au/NZ, but not in Af, SE and LA.
CONCLUSION. DNR orders are used differently with other limitations of LT around the world.

Moral distress in organ donation decisions in ICU

U. St Ledger[1], DF. Mc Auley[2], J. Reid[3], L. Prior[4], B. Blackwood[2]
[1]{street_address}, Belfast, UK; [2]Centre for experimental medicine, Queen's University Belfast, Belfast, UK; [3]School of nursing & midwifery, Queen's University Belfast, Belfast, UK; [4]Centre of excellence for public health, Queen's University Belfast, Belfast, UK

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001580

INTRODUCTION. Moral distress, a powerful and detrimental psychological response experienced when moral action is constrained (Jameton, 2008) has been reported in end-of-life care (Hamric and Blackhall, 2007). Increasingly intensive care unit (ICU) end-of-life decisions were expected to involve approaches for organ donation and opt in opt out approaches to organ donation high on international political agendas. However, organ donation related moral distress and the impact on clinicians and patients' relatives was under-investigated.
OBJECTIVES. To explore the triggers for moral distress and the consequences for physicians, nurses and relatives involved in approaches for organ donation in end-of-life decisions.
METHODS. This qualitative narrative inquiry thematic analysis was undertaken, in a large 19-bedded ICU in Northern Ireland, from August 2012-November 2013. Twenty bereaved relatives and 45 nurses and physicians involved in 21 end-of-life patient cases were purposively recruited and interviewed using in-depth digitally recorded methods.
RESULTS. The timing and sensitivity of the organ donation approach was important for supporting relatives to make morally comfortable decisions. Physicians and nurses roles of carer versus broker for organs created moral conflict. Physicians perceived pressure to challenge relatives' decisions not to donate. Such challenge was morally distressing for relatives and nurses, jeopardising autonomy, integrity and relationships. Rapid therapy withdrawal in donation after circulatory death clashed with notions of 'a good death'. Lengthy delays in organ retrieval threatened relatives' fulfilment of culturally important after-death rituals and obligations and risked withdrawal of consent to donate. Moral distress impacted negatively on the grieving process, well-being and attitudes about organ donation and positively on quests to promote organ donation.
CONCLUSION. Organ donation decisions can generate considerable moral distress. Findings have important implications for: (a) the educational preparation and support of ICU clinicians to recognise and manage the ethical challenges and sensitivities of organ donation approaches and processes; (b) timely organ retrieval supportive of important familial and cultural obligations and beliefs; and (c) for organ donation opt in-opt out policies and legislation and organ donation consent rates.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001558

INTRODUCTION. Hypertensive derangements, preeclampia included, complicate 8-10% of pregnancies worldwide and represent a major cause of maternal and foetal morbidity and mortality. Preeclamptic patients are often hypovolemic and oedematous with increased systemic vascular resistances (SVR), low cardiac output (CO) and variable degree of left ventricular hypertrophy and dysfunction. In these patients the haemodynamic variations induced by loco-regional anesthesia (LRA) during caesarean section (CS), despite common, may be unpredictable and risky.
OBJECTIVES. This observational study aimed to minutely evaluate the haemodynamic effects of LRA in preeclamptic and hypertensive patients, compared to healthy controls.
METHODS. Pregnant(18-40 y) and informed women, single fetus, gestational age> 31weeks, ASA II or ASA III, elective or urgent CS under LRA. Used monitoring system: Clear-sight finger cuff (Edwards Lifescience). Recorded hemodynamic parameters were: CO, cardiac index (CI), systolic, diastolic and mean arterial pressure (SAP,DAP,-MAP) and heart rate (HR), stroke volume (SV), stroke volume index (SVI), stroke volume variation (SVV). Precise chosen waypoints were: baseline,left lateral decubitus, LRA, skin incision, fetal extraction, afterbirth.
RESULTS. 10 preeclamptic patients (PE, 5 early and 5 late preeclampsia), 5 hypertensive patients (HT) and 22 controls (CN). No statistically significant differences for preoperative data (age, weight, height, comorbidities, chronic therapy) were found, except hypertension and hypertensive drugs. Hemodynamic parameters varied during surgery within all groups, being pathological from the beginning in PE and HT patients; pressure followed physiological and LRA-induced changes, PE and HT pts maintained higher PAM values than controls; CI downward variation was higher in preeclamptic patients than in hypertensive ones, with a 25% increase in CN and HT patients after LRA nadir; non compensatory HR increase was witnessed in PE patients; SVI variation pattern was group specific after LRA maximal effect. Fig.1-2.
CONCLUSION. Pathological pregnancy is characterized by a heterogenous response to LRA. Preeclampsia may not be treated as hypertension.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001566

INTRODUCTION. Emergence delirium is defined as a cognitive disturbance during emergence from general anesthesia resulting in hallucinations, delusions and confusion manifested by agitation, restlessness, involuntary physical movement and extreme flailing in bed. Postoperative emergence delirium develops in 12% to 18% of al children undergoing general anesthesia for surgery. This postanesthetic phenomenon changes cognitive and psychomotor behavior, and puts pediatric patients and health care personnel at risk of injury.
OBJECTIVES. To describe a single-institution pilot study regarding prevalence and risk factors for delirium in children after maxillofacial surgery.
METHODS. A ptospective observational pilot study was made, from Jenuary to March 2019 in the pediatric operating room (maxillofacial surgery) at an urban academic medical center. Thirty consecutive patients, aged 28 to 185 months were enrolled. When the patients were awake (Richmond Agitation and Sedation Score > -3), two trained investigators conducted the Paediatric Assessment of Emergent Delirium (PAED) and the pediatric Confusion Assessment Method for the Intensive Care Unit (pCAM-ICU) three times: basal (at the preliminary anesthetic visit, before surgery), 30 minutes after the end of general anesthesia and 6 h later.
RESULTS. All children have been accopanied to operating room by their caregivers. Only 6% recived an oral premedication before surgery. 86% received opioids during anesthesia. Pediatric delirium was present on 2% patient at awake time, 12 % after 30 min and 3% 6 h late. Both pediatric delirium scales was similar in recognizing the presence of delirium. All of this children with delirium received opioids during induction and/or general anestehesia. Only 1 of this patients had a IV cannula at the operating room admission. No one of them received a premedication before surgery. The children who developed delirium were the youngest.
CONCLUSION. In our institution, pediatric delirium is a prevalent problem, with identifiable risk factors (opioids during anesthesia, no premedication before surgery, smal age). Some have a short-lasting course, which underlines the need for early screening. The pCAM-ICU scale, usually used in the intensive care unit to recognize pediatric delirium, could be used in other departments than in intensive care setting, as demonstrated. Our findings support the view of delirium as a continuum of acute neurocognitive disorder. Further research is needed to investigate prophylactic and treatment approaches for postoperative pediatric delirium.

INTRODUCTION. Guidelines published suggested appropriate management of pain, agitation and delirium (PAD) is crucial in improving patient outcomes. However, the practice of PAD assessment and management in community hospitals is unclear and the mechanisms contributing to the potential care gap are unknown. Because of this, we want to know their perception in our ICUs
OBJECTIVES. To describe the perception of the management of PAD in ICU by its professionals in 4 ICUs in Northern Spain.
METHODS. Multicenter descriptive study on the management of PAD in 4 ICUs of 4 Medical centers: Complexo Hospitalario Universitario de Ourense (CHUO), Hospital Álvaro Cunqueiro de Vigo (HAC), Hospital Montecelo de Pontevedra (CHOP) and Clínica Mompía de Cantabria (CMC).
An anonymous survey was conducted from December 2018 to March 2019 to the ICUs staff (physicians and nurses). We ask about demographic variables and different characteristics of PAD assessment and management in the 4 ICUs.
RESULTS. They answered 152 surveys (CHUO 41.4%, HAC 36.8%, CHOP 15.1% and CMC 6.6%). The 74.3% were nurses with age between 31-45 years (56.6%). 45.4% were permanent staff and 36.8% had more than 10 years of experience. Only 1 center had a PAD protocol.
The pain scales used were: VAS and NRS in communicative patients (95.8%) and ESCID in non-communicative (61.8%). The most used analgesic drugs were acetaminophen (64.5%) and fentanyl (32.9%). Preemptive analgesia before nursing procedures was ocassional. The 46.7% of the staff thought that patients had pain. The 50.7% believed that the response to treatment was satisfactory.
97.4% used RASS as a sedation scale. Light sedation strategy was the most used (59.9%). The preferred sedatives were midazolam (83.6%) and propofol (72.4%). The combination of midazolam and fentanyl was the most popular (88.2%). The sedation degree was uneven: 33.3% poor, 36.2% correct and 27% over sedated. Physicians subgroup consider that patients were overstated (71.8%).
Delirium evaluation was uncertain: occasional (52.6%). Among those who used a diagnostic tool, CAM-ICU was preferred (74.3%). Our results indicated that delirium was underdiagnosed (66%) and oversedation contributed to its appearance (75.7%).
Non-pharmacological measures were used in 69.1%. The preferred by our surveyed were: light control (32.2%) and family support (47.3%). Only 1 of the ICUs had an open visits schedule more than 6 hours. Haloperidol is the most commonly drug used in treatment (78.9%)
CONCLUSION.

- The global use of scales is high.
- Despite of the Guidelines recommendations, benzodiazepines (midazolam) use is elevated.
- Exist a different perception in sedation degree between nurses and physicians.
- It is necessary to implement protocols to optimize and standardize the handling of PAD.

INTRODUCTION. Exist a large number of scientific publications that describe the importance of delirium in terms of outcomes (mortality, days of hospital stay and sequelae), but the association with the alterations in the quality of life and executive function is not well understood1,2.
OBJECTIVES. Evaluating the impact of delirium in the decline of cognitive and executive functions, quality of life and survival of the critically ill.
METHODS. A nested case-control study in a cohort of six months. The prevalence of delirium, mortality, cognitive and executive disorders, and the quality of life in survivors in a period greater than three months after discharge from the ICU were evaluated. The CAM - ICU for delirium screening was performed daily for all patients to find the cases, defined as a positive score, and a homogeneous sample with a negative score was considered as a control group3. For the follow-up, the scales of quality of life in health (SF-36), instrumental activities of daily life (PGC - IADL) and minimental test (MMSE) were carried out.
RESULTS. 457 patients were hospitalized between April and September of 2018. 81 patients were evaluated after three months of discharge from the ICU, with a mean of 61.3 ± 18 years. Of this group, 43 subjects had delirium and 38 did not. We found differences with statistical significance in the cognitive functions ($p < 0.01$), with greater affectation of the domains of the orientation, the calculation and the language / praxis ($p < 0.05$) and deterioration in the quality of life (QoL) in the subscales of social function ($p < 0.006$), emotional role ($p < 0.04$) and mental health ($p < 0.04$) in cases. Although the executive functions were not affected by the presence of delirium in the hospitalization, it was diminished in both groups.
CONCLUSION. Cognitive capacity, social function, emotional role, and mental health were affected with statistical significance in the group of patients who had delirium during the stay in ICU for any reason when compared with a control group not exposed to this factor, but with similar socio-demographic characteristics.

INTRODUCTION. In patients undergoing surgical procedures, the type of surgical procedure and the perioperative sampling time may influence the correlation between the standard laboratory tests (SLT) and their equivalent ROTEM parameters.
OBJECTIVES. Prospective study (ABCD study, NCT:026552897) funded by Carlos III Institute (PI15/00512), aimed at investigating the correlation between prothrombin time (PT) *vs*. clotting time of ex-TEM (CT-exTEM), and between plasmatic Clauss fibrinogen level (pFBN) *vs*. maximum clotting firmness (MCF-fibTEM), in patients undergoing procedures with high (glioblastoma multiforme resection: GBR) or moderate (colon cancer resection, by laparoscopy: CCR) degree of surgical injury, at different perioperative time-points.
METHODS. ExTEM clotting-time (CT-exTEM) and FibTEM maximum clot firmness (MCF-fibTEM), as measured by ROTEM, were correlated with prothrombin time (PT) and plasma fibrinogen (pFBN, Clauss method), as measured at SLTs, in GBR (N=60) and CCR (N=40) patients. Blood samples for SLTs and ROTEM assessments were drawn simultaneously within 24-hours before surgery (baseline) and 2, 24 and 48-hours after surgery. Correlations between ROTEM parameters and SLTs values assessing similar coagulation profile were evaluated by Spearman r rank-order. Receiver-Operator Characteristic (ROC) curves were performed in order to screening the efficiency of best CT-exTEM and MCF-fibTEM cut-offs for detecting prolonged PT (>15 s) and low pFBN values (<2 g/L), respectively.
RESULTS. The correlations between PT and CT-exTEM and between pFBN and MCF-fibTEM were weak ($r < 0.40$) or moderate ($r \approx 0.40 – 0.65$), respectively, and remained unchanged over the studied perioperative period in both groups. Recommended cut-offs for CT-exTEM (>75 s) and MCF-fibTEM (<10 mm) had poor sensitivity (% [95% confidence interval]) for identifying a prolonged prothrombin time (17 % [8, 31]) or a low pFBN (46 % [32, 62]).
CONCLUSION. As SLTs and their ROTEM equivalents parameters are poorly related, they should not be used interchangeably in patients undergoing GBR or CCR. Neither the type of surgery nor the perioperative timing significantly influenced these correlations.

INTRODUCTION. Critically ill, mechanically ventilated patients in intensive care units generally require sedation treatment to relieve anxiety and agitation. But long-term mono-sedative use is associated with some adverse effects. Different sedatives sequentially used after meeting the sequential criteria may reduce these adverse effects, leading to patient faster recovery, earlier extubation and better outcome.
OBJECTIVES. This study aimed to evaluate the factors influencing ventilator weaning time in sequential sedation patients.
METHODS. A total of 216 ventilated patients who received sequential sedation and completed sequential sedation protocol were enrolled to this analysis. The primary endpoint in this study was patient weaning time defined as duration of mechanical ventilation after patients met the sequential criteria. Sequential criteria indicated patients passed spontaneous breathing trial (SBT) safety screen, but failed the 30-minute SBT. Univariate and multivariate Cox proportional hazards regressions were used to predict factors influencing weaning time.
RESULTS. In this analysis, older age (RR=0.984, 95%CL 0.974-0.993, p=0.001), longer time from meeting the sequential criteria to stopping sedation (RR=0.968, 95%CL 0.959-0.977, p<0.001), more accumulated dose of fentanyl after patients met the sequential criteria for extubation (RR=0.891, 95%CL 0.801-0.993, p=0.036), and faster rapid shallow breathing index (RSBI) when patients undergoing SBT trial (RR=0.992, 95%CL 0.985-0.998, p=0.008) were independent risk factors for prolonging patient weaning time. Non-smokers (RR=2.456, 95%CL 1.489-4.053, p<0.001), lighter average sedation depth (RR=1.221, 95%CL 1.053-1.416, p=0.008), sequential sedation with propofol (RR=2.612, 95%CL 1.796-3.800, p<0.001), and sequential sedation with dexmedetomidine (RR=2.543, 95CL% 1.727-3.744, p<0.001) after patients met the sequential criteria were associated with earlier ventilator weaning.
CONCLUSION. In sequential sedation patients, older age, longer time from meeting the sequential criteria to stopping sedation, more accumulated dose of fentanyl after patients met the sequential criteria for extubation and faster RSBI were independent risk factors for delaying ventilator weaning. However, non-smokers comparing with current smokers, lighter average sedation depth, sequential sedation with propofol or dexmedetomidine after patients met the sequential criteria could shorten patient weaning time.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001647

INTRODUCTION. Lung protective ventilation improves survival in ARDS1. It's role in elective major abdominal surgery is controversial2. Peritonitis patients undergo laparotomy and often develop ARDS.
OBJECTIVES. To identify whether use of lung protective ventilation during laparotomy in abdominal sepsis patients affect mortality and morbidity.
METHODS. After Institutional ethics committee clearance and informed written consent, 100 adult patients undergoing emergency laparotomy for peritonitis were randomized in to two groups. In Group1: Vt 6-8ml/kg, PEEP 6-8cmH2O and recruitment maneuver every 30min and in Group 2 Vt 10-12ml/kg, no PEEP and no recruitment were used. All the patients were followed up till death/discharge.
RESULTS. All the patients received allocated treatment. Follow up was lost for six patients and data from 94 patients (45 patients in Group1 & 49 patients in Group2) were analyzed.
Demographic & laboratory parameters were comparable in two groups. In-hospital mortality was 26.7% in Group1 versus 26.5% in Group2 (risk difference 0.14%, 95% CI -17.7- 18.0; p=0.98, Chi- square test). Kaplan Mayer survival analysis confirmed similar in-hospital mortality in two groups (p=0.79, log-rank test). Duration of hospital stay [median (IQR) 13(9-18) days in Group1 versus 13(8-21) days in Group2; p=0.82] & duration of ICU stay [median (IQR) 7(4-10) days versus 6(3-12) days; p=0.88] were also similar. Postoperative pulmonary complications (POPC) during hospital stay were also similar [median (95% CI) of POPC grade in Group1 was 2(1-4) versus 3(1-4) in Group2; p=0.45].
CONCLUSION. Intraoperative lung protective ventilation does not provide mortality benefit in peritonitis patients undergoing emergency laparotomy.

Relationship between thromboelastography and conventional clotting tests values with the severe bleeding in critically ill patients with coagulopathy

M. Casado-Mendez, A. Diaz-Martin, V. Arellano-Orden, A. Pastor, R. Dusseck, D. Cuenca-Apolo, S. Leal-Noval
I.c.u., H.U. Virgen del Rocio, Seville, Spain

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001648

INTRODUCTION. Certain groups of critically ill patients are archetypally at high risk of coagulopathy and severe bleeding. Detection and correction of coagulopathy frequently relies on standard laboratory tests (SLTs). The viscoelastic tests (VET) offers an alternative approach to assess coagulation alterations, offering faster turn-around-time and performing a more global assessment of coagulation.
OBJECTIVES. This study aimed to ascertain the relationship between thromboelastography (TEG®) and standard laboratory tests (SLTs) values with the presence of bleeding in critically ill patients with known coagulopathy.
METHODS. Consecutive coagulopathic patients with hepatic failure, postoperative period of prolonged cardiac surgery or complex abdominal surgery with sepsis, were prospectively included in this study. On intensive care unit (ICU) admission, patients were stratified into two groups according to whether yes or not they had major bleeding (MB) [whether evident overt bleeding, important bleeding apparent on image studies and/or need of moderate-massive blood transfusion and hemodynamic instability]. Blood samples were drawn for SLTs [international normalized ratio (INR), activated partial thromboplastin time (aPTT), platelets count and fibrinogen level (Clauss)] and TEG (R, reaction time; MA, maximal amplitude and Ly30, clot lysis at 30 min.). Receiver-Operator Characteristic (ROC) curves analysis were performed in order to screening the efficiency of TEG and SLTs in detecting bleeding. Correlation between SLTs and TEG parameters assessing similar coagulation profile was evaluated by Spearman rank-order.
RESULTS. Eighty-tree patients were included and bleeding was confirmed in 45 (54%). Fibrinogen level demonstrated the best accuracy, even low, for detecting bleeding with an area under curve and 95% confidence intervals (AUC (95% CI)): 0.74 (0.63-0.85) for a best cut-off ≤ 2 g/L. Regarding to TEG-MA, values for an optimal cut-off ≤ 51 mm were AUC: 0.68 (0.56-0.80).
CONCLUSION. Both conventional clotting tests and TEG values were poorly associated with bleeding in this critically ill cohort patients with coagulopathy.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001658

INTRODUCTION. Cardiovascular complications due to ischemic injury of the myocardium after major non-cardiac surgery are frequent and cause a considerable amount of morbidity and mortality in patients undergoing noncardiac surgery. Major Cardiovascular and Cerebrovascular Events (MACCE), are the most common causes of serious postoperative complications. Current risk stratification systems have limited sensitivity and specificity in identifying patients at risk of MACCE and postoperative symptoms and clinical signs of myocardial injury are often diffuse or lacking. Endothelin-1, a potent vasoconstrictor considered to have an important pathophysiological role in cardiovascular dysfunction, is proposed as a promising biomarker in predicting adverse cardiovascular events.
OBJECTIVES. The purpose of this study is to identify if ECG-changes and levels of C-terminal pro-endothelin-1, CT-proET1 can predict MACCE in patients undergoing major abdominal surgery.
METHODS. We conducted a multicenter prospective study including 387 surgical patients. This was a preplanned substudy of the MINSS study (NCT03436238). Perioperative blood samples and ECGs were obtained at five sample points: pre-surgery, immediately post-surgery, and on Days 1,2,3 after surgery. We analysed plasma levels

of CT-proET-1 and hsTnT levels, as well as ECG-changes and tested for their association with MACCE within one month of surgery.
RESULTS. Perioperative plasma levels of CT-proET-1 were significantly higher in patients affected by MACCE and the prognostic value exceeded that of cTnT, the number one cardiac biomarker used today, in all analyses. The number of ECGs interpreted at the end of this study was not sufficient to run statistical analyses, however, the distribution of ECG-changes did not seem to be a predictor of MACCE.
CONCLUSION. Our analysis suggests that increased perioperative CT-proET-1 levels significantly identify patients at risk of MACCE in the ensuing month following major abdominal surgery and the prognostic value exceeded that of cTnT.

The relationship between near infrared spectroscopy (NIRS) and carotid blood flow as an indicator of cerebral blood flow

U. Borg
[1]Medical affairs, Medtronic Surgical Solutions, Boulder, USA
Correspondence: U. Borg
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001671

INTRODUCTION. NIRS is frequently used in cardiac surgery to assess adequacy of cerebral oxygenation (rSO2). Current NIRS devices are categorized as oxygen saturation monitors although there are possibly additional benefits to NIRS monitoring. This study was performed to investigate the ability of NIRS monitoring to detect changes in cerebral blood flow during hypovolemia and resuscitation.
OBJECTIVES. To investigate the ability of the INVOS 5100C system (Medtronic, Boulder USA) to detect changes in cerebral blood flow during hypovolemic shock and resuscitation.
METHODS. In an animal study approved by the local animal use committee we anesthetized, intubated and ventilated 19 pigs. Hypovolemic shock was accomplished by removing 50% of the animal's blood volume over a 20-minute period in 3 steps. Resuscitation by blood returned to the animal over a 20-minute period in 3 steps. 30-minutes allowed between end of blood removal and start of resuscitation. Blood pressure, heart rate, arterial oxygen saturation, internal carotid blood flow (CBF), rSO2 and end-tidal carbon dioxide was measured continuously. Normocapnia was maintained in all animals.
RESULTS. CBF and rSO2 correlated during bleeding (r2 0.88). Bleeding resulted in a final CBF of 66 ml/min a decrease of 58% while rSO2 fell by 31% (Fig 1).
During resuscitation CBF and rSO2 correlated during the first infusion of 10% of the shed volume increasing the CBF from 115 ml/min to 176 ml/min and rSO2 from 46% to 55%. The second and third infusion increased CBF to 207 ml/min without a major change in rSO2 (59%) (Fig 2).
CONCLUSION. During blood loss rSO2 may be an indicator of cerebral blood flow since fall in rSO2 and decrease in CBF correlated. Allowing 30 minutes for stabilization after final blood removal resulted in recovery of CBF due to peripheral vasoconstriction. Increased CBF did not result in increased rSO2 probably because of increased cerebral oxygen extraction. Infusion of the first 10% of shed volume led to rSO2 correlation with increase in CBF. Further infusionsion did not result in increased rSO2 despite increase in CBF. During resuscitation there may be very limited correlation between rSO2 and cerebral blood flow due to compensatory oxygen extraction and vasoactive behavior because of prior ischemia during shock.

Therapeutic plasma exchange in critical care: a 5-year review

M. Toscano[1], P. Valério[2], LF. Frade[3], FC. C.[4], I. Botelho[3], A. Ramos[3]
[1]Internal medicine, Hospital de Cascais, Alcabideche, Portugal; [2]Nephrology, Centro Hospitalar De Setúbal E.P.E., Setúbal, Portugal; [3]Intensive Care Unit, Hospital de Cascais, Alcabideche, Portugal; [4]Oncology, IPO, Lisboa, Portugal

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001721

INTRODUCTION. Therapeutic plasma exchange (TPE) is an extracorporeal treatment used in the removal of high molecular weight particles causing acute toxicity, whose applications have been undergoing constant development.
OBJECTIVES. Retrospective analysis of patients undergoing TPE and respective outcomes
METHODS. Review of the clinical files of patients who underwent TPE since 2014
RESULTS. Between January 2014 and April 2019, 15 patients underwent TPE. The most frequent indication was hypertriglyceridemic pancreatitis, in 7 cases. All were young male patients, most commonly with favorable response after a single session. We highlight the occurrence of 2 deaths due to necrohemorrhagic pancreatitis and multiorgan dysfunction. There were 3 cases of thrombotic microangiopathy. In 2 of these (HELLP syndrome in a 41-year-old puerperal patient and atypical hemolytic-uremic syndrome in a 31-year-old patient), there was resolution of hemolysis and complete recovery of renal function. In a case of thrombotic thrombocytopenic purpura in a 66-year-old patient, refractory shock and death was observed. There was only 1 case of dialysis-dependent ANCA+/PR3 vasculitis with diffuse alveolar hemorrhage in a 79-year-old patient, with unfavourable outcome. In 2 cases of myasthenic crisis submitted to short cycles of TPE, along with immunosuppressive therapy, significant symptomatic improvement and reduction of fatigability were observed. Finally, in 2 patients diagnosed with autoimmune encephalitis, who underwent prolonged cycles of TPE, response varied, with ad integrum recovery in a 19-year-old patient with anti-NMDAr encephalitis, and persistence of neurological deficits and development of hydrocephalus in a 51-year-old patient. Complications included pneumothorax associated with placement of central venous catheter, transient hemodynamic instability and electrolyte imbalance.
CONCLUSION. TPE has a proven benefit, and is sometimes a life-saving therapy. This is the case of thrombotic microangiopathy and myasthenic crisis, where we also observed the most favorable results. On the other hand, its role is not established in hypertriglyceridemic pancreatitis as well as in autoimmune encephalitis (except for anti-NMDAr), where it remains a reasonable alternative, to be considered in cases of immunosuppressive therapy failure. Complications are rare and generally related to central venous access catheterization, need for anticoagulation or associated with the replacement fluid used.
In sum, TPE is a useful treatment in a wide range of diseases observed in the critical patient.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001728

INTRODUCTION. Recombinant activated Factor VII (rVIIa) enhances haemostasis with action limited to areas of injury. It is approved for use only in haemophilia and presence of clotting factor inhibitors. We sought to audit its use outside these recommendations and evaluate its efficacy in improving outcome.
OBJECTIVES. To observe efficacy of Factor VII (rVIIa) outside its prescribed indications and monitor its outcome.
METHODS. We performed a retrospective observational study of all patients who received factor rVIIa in two tertiary care hospitals between January 2008-December 2012 for persistent haemorrhage refractory to conventional treatment. Efficacy of factor rVIIa was assessed by mortality and blood product requirements.
RESULTS. Total of 42 patients were given factor rVIIa. Indications included cardiac surgery (26%), haematological disorders (21%), intracerebral haemorrhage (14%), obstetric bleeding (9.5%), abdominal surgeries (7.1%), sepsis (7.1%), trauma (7.1%), liver diseases (4.7%) and dengue (2.3%). The median of units of packed red blood cell (PRBC), platelets, fresh frozen plasma (FFP) and cryoprecipitate requirement before and after factor rVIIa administration in medical patients were 4,3,5,2 and 1.5,0,0.5,0 respectively. In surgical patients requirements of PRBC, platelets, FFP and cryoprecipitate before and after use of rVIIa were 6,3.5,5,6 and 3,0,2,1 respectively. Mortality was 28% among medical patients and 46% among surgical patients. There was no documented thromboembolic phenomenon in the study patients.
CONCLUSION. Recombinant Factor rVIIa is widely used beyond conventional recommendations. It appears to be effective in reducing further need for blood product transfusions in medical patients but not in surgical patients. Higher mortality in surgical patients receiving factor rVIIa may be contributed by inadequate source control of the bleeding. Cost effectiveness of rVIIa therapy needs to be factored in prior to use in all patients.

INTRODUCTION. The continuous techniques of renal clearance in patients admitted to the intensive care units (ICU) continue to be used up to 20%, in which anticoagulation of the extracorporeal circuit is mandatory. The regional anticoagulation with citrate has been used in recent years to prevent circuit coagulation, maintain filter performance and reduce the risk of bleeding.
OBJECTIVES. To determine the prevalence of filter consumption according to the use of anticoagulation with unfractionated heparin in relation to the regional anticoagulation with citrate.

METHODS. Retrospective observational study, performed on patients admitted to the intensive care unit with renal clearance in the period from 2016 - 2018 at the University Hospital of Bellvitge.
RESULTS. We analyzed 186 patients admitted to the ICU which required renal clearance techniques, 41 patients of them received anticoagulation with unfractionated heparin, 15 ± patients with citrate anticoagulation and 115 of the patients did not receive anticoagulation.
The average of the days that required techniques of renal clearance with unfractionated heparin was 7.6 ± 7.9, that of regional citrate anticoagulation was 8.4 ± 7.9; the average daily use of filters was 0.8 ± 0.6, in patients with anticoagulation of unfractionated heparin, 0.7 ± 0.8 in patients with regional citrate anticoagulation and 0.8 ± 0.6 in patients who did not receive anticoagulation. The mean number of filters used with unfractionated heparin was 4.8 ± 4.6 and 4.6 ± 4.7 for citrate anticoagulation.
CONCLUSION. No significant differences were found between the consumption of filters of patients who received anticoagulation with fractionated heparin in relation to patients who received anticoagulation with citrate. It was difficult to find significant difference due to a small population.

Predictors of post-traumatic AKI in the ICU

M. dlela, T. Olfa, T. Amal, M. Bahloul, M. Bouaziz
[1]Intensive care unit, Habib bourguiba university hospital, Sfax, Tunisia
Correspondence: M. dlela
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001560

INTRODUCTION. The occurrence of acute kidney injury (AKI) in trauma patients is a problem that has been little studied to date. Its presence has been shown to be associated with an increased risk of morbidity and mortality in affected individuals.
OBJECTIVES. To determine the incidence of post-traumatic AKI and identify its predictive risk factors that could be eventually prevented.
METHODS. This is a ten-month long prospective cohort-study, conducted in the department of emergencies and intensive care unit (ICU) of a university hospital, including trauma patients with a minimum ICU stay of 7 days. Renal failure was defined based on the new KDIGO classification. Predictors of AKI were identified using univariate and then multivariate analysis.
RESULTS. One hundred thirty patients were admitted during the study period for the management of post-traumatic injuries, among which 86 patients were included. The incidence of AKI in the studied population was 53% (46 cases) with 26 (56%) diagnosed with stage one, ten (22%) with stage two and ten (22%) with stage three.
On univariate analysis, older age and medical history of diabetes or hypertension were predictors of AKI. Injury assessment found traumatic brain injury (AIS>3), Glasgow (GCS) on admission, and the diagnosis of fat embolism to be associated to post-traumatic AKI. Moreover, hemodynamic instability on admission and during ICU stay, shock-index on admission, the amount of fluid administered the use of vaso-active drugs, sepsis, hyperbilirubinemia, P/F ratio and acute respiratory distress syndrome (ARDS) were also associated to post-traumatic AKI.
Among these factors, ARDS (p = 0.001, OR = 9 , CI: 6-100), fat embolism (p = 0.028, OR = 2, CI: 1.6-2.5), Shock index (p = 0.02, OR = 15.2, CI: 2.2-105), and bilirubin levels (p = 0.006, OR = 1.035, CI: 1.01-1.06) were identified as independent predictors of post-traumatic AKI on multi-variate analysis.
Besides, according to our analysis, the following variables were predictive of stage3 AKI, including bilirubin levels on the day of AKI diagnosis (p = 0.026, OR = 1.032, CI: 1.004-1.061), transfusions (p = 0.02, OR = 1.5, CI: 1.1-1.9), fat embolism (p = 0.015, OR = 11.3, CI: 1.6-75), and diuretics' administration (p = 0.004, OR = 10.4, CI: 1.8-57).
CONCLUSION. Post-traumatic AKI could be associated with significant morbi-mortality in the ICU. The identification of predictors from the initial onset of trauma could be valuable to guide its management.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001636

INTRODUCTION. Sepsis-associated acute kidney injury is the most common syndrome in ICU. CRRT may be useful during sepsis, but definitive recommendations are lacking. Early and appropriate antibiotic therapy is the mainstay to successfully treat sepsis, but no comprehensive guidelines exist that provide antibiotic dosing recommendations for adult patients receiving CRRT.
The factors that need to be considered when dosing patients on RRT are related to the drug being used, type of RRT, and patient status. Particularly, the type of membrane plays a major role in drug removal. New synthetic and biocompatible membranes have high adsorptive affinity to proteins, endotoxins, inflammatory mediators, but also drugs. Two antibiotics, Vancomycin (VAN) and Teicoplanin (TEC), are frequently used in critically ill adult patients receiving CRRT to treat Gram-positive infections, especially sustained by methicillin-resistant Staphylococcus aureus.
OBJECTIVES. The aim of this study was to evaluate, in an in vitro system simulating the in-vivo permeability drugs, the convective and adsorptive drug clearance of VAN and TEC during CVVH with polymethylmethacrylate filter.
METHODS. VAN (1448 Da) and TEC (1885 Da) clearance was assessed in vitro in blood from healthy donors, spiked with one antibiotic under investigation. Closed circuit simulating CVVH was performed using PMMA filter at 10 ml/min ultrafiltrate and 50 ml/min blood flow rates. The duration of the experiment was of 360 min. Samples were collected at 5, 10, 30, 60, 120, 240 and 360 minutes from in-flow, out-flow and ultrafiltrate line; antibiotic concentrations were measured with biochemistry analyzer. Convective clearance was evaluated in terms of sieving coefficient, and adsorptive clearance was calculated using mass balance analysis.
RESULTS. The target initial VAN and TEC plasma concentrations set in this study were respectively 100 and 130 mg/L. Although the initial VAN concentration was 99.7 mg/L, after 360 minutes of CVVH, VAN concentration slightly decreased to 90.7 mg/L, with a total estimated adsorbed mass per surface area of 10.86 mg/m2. The blood SC ranged from 0.84 to 0.87. The initial TEC concentration was of 129 mg/L. After two hours, the concentration decreased of 25% and of 44% at the end of simulation, with a total estimated adsorbed mass per surface area of 65.12 mg/m2. The blood SC ranged from 0 to 0.19.
CONCLUSION. Our findings suggest that VAN prescription should take into account the elevated SC with PMMA membrane and dosage should be adjusted proportionally with ultrafiltration flow. Otherwise, TEC is largely adsorbed by PMMA membrane; a loading dose should be considered at the beginning of each treatment to balance the adsorptive phenomenon.

Acute Kidney Injury Requiring Renal Replacement Therapy In Patients With Septic Shock

F. Sadaka, D. Bhargavi, G. Justin, N. Organti, D. Tannehill, J. O'brien
[1]Critical Care Medicine, Mercy Hospital St. Louis, St. Louis, USA
Correspondence: F. Sadaka
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001679

INTRODUCTION. Acute Kidney Injury (AKI) occurs frequently among patients with septic shock (SS) and is associated with worse prognosis, particularly if renal replacement therapy (RRT) is required. International guidelines recommend rapid recognition and initiation of treatment of SS.
OBJECTIVES. We examined the characteristics and outcomes of patients with SS who developed AKI requiring RRT.
METHODS. Data on 53 SS patients (requiring vasopressors - VP) were collected from acute physiologic and chronic health evaluation (APACHE) Outcome database and medical records. Data included age, gender, APACHE III score, APS (acute physiologic score), Sequential Organ Failure Assessment (SOFA) score at time of VP initiation (T0) and at 72 hours (T72), Delta SOFA (SOFA T0 - SOFA T72), lactic acid at T0, serum creatinine (Cr) at T0, duration of vasopressors in days, Input/Output (I/O in cc) at 6 hours and 24 hours, hospital length of stay (LOS in days), and hospital mortality. AKI was diagnosed based on Kidney Disease Improving Global Outcomes (KDIGO) criteria.
RESULTS. Of the 53 patients with SS, AKI occurred in 24 patients (65%) of which 16 patients (67% of AKI cases) required RRT. Overall, the prevalence of AKI requiring RRT among SS patients was 30%. The SS-RRT group (16) and the SS without RRT group (37) were comparable on age (65 ± 12 vs 66 ± 15, p = 0.8), gender (male, 63 % vs 65 %, p = 0.9), APACHE III scores (114 ± 26 vs 99 ± 36, p = 0.2), SOFA T0 (13.4± 3.6 vs 11.6 ± 3.8, p = 0.1), lactic acid (4.9 ± 1.9 vs 5.9± 4.2, p = 0.3), I/O at 6 hrs (2200 ± 1800 vs 2100 ± 2100, p = 0.9), I/O at 24 hrs (6900 ± 4000 vs 5900 ± 3300, p = 0.4), and hospital mortality (38% vs 48%, p = 0.5). The SS-RRT group had higher APS (102 ± 24 vs 84 ± 33, p = 0.05), higher SOFA T72 (11.6 ± 3.8 vs 9.2 ± 4.4, p = 0.05), less Delta SOFA (1.8 ± 5.0 vs 4.4 ± 5.9, p = 0.03), higher Cr (3.7 ± 1.5 vs 2.2 ± 1.3, p < 0.001), longer duration of VP (6.0 ± 3.5 vs 3.3 ± 2.3, p < 0.01), and longer hospital LOS (24 ± 13 vs 14 ± 12, p < 0.01).
CONCLUSION. AKI and AKI requiring RRT are prevalent among patients with septic shock. Patients who developed AKI requiring RRT during septic shock have a significantly higher acute physiologic derangements, worsening organ failures, higher creatinine, longer duration of vasopressors, and longer hospital LOS than those without.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001697

INTRODUCTION. Currently, there are no reliable predictors of risk of development and severity of acute kidney injury (AKI) in septic patients. In the prospective study, we sought to determine plasma surfactant protein D (SP-D) levels and *SP-D*polymorphisms rs721917C/T and rs2243639A/G of septic patients with AKI(defined with KDIGO criterion) *versus*those without AKI. The association between *SP-D*polymorphisms and plasma SP-D level and subsequent development and severity of AKI were analyzed.
METHODS. The study enrolled septic and septic shock patients admitted to the Department of Critical Care Department of two tertiary care hospitals. *SP-D*rs721917C/T and rs2243639A/G polymorphisms were determined using the PCR-SSP method. Furthermore, plasma SP-D and urine NGAL contents were examined using commercially available ELISA kits.
RESULTS. Totally 330 septic patients including 121 patients with septic shock were included. Their mean SOFA scores were 12 ± 3 (range 8-21). Septic patients with AKI (n=156) had significantly higher plasma SP-D levels (median: 150 ng/mL, range: 138-160 ng/mL) than those without AKI (median: 101 ng/mL, range: 82-111 ng/mL;*P*= 0.01).Plasma SP-D levelsof septic AKI patients were correlated with urine NGAL contents(*r*=0.596) and duration for CRRT(*r*=0.448). Septic patients with AKI had a significantly higher rate of rs721917 CC genotype (AKI: 35% *vs.* non-AKI:20%; *P* = 0.012), but a significantly lower rate of TT genotype (AKI: 19%*vs.*non-AKI: 26%; *P*= 0.005). Our multivariate analysis showed that SP-D rs721917 CC genotype was a significant independent predictor of AKI (*P*= 0.044) and mortality (*P*= 0.014) of septic patients.
CONCLUSION. Our study showed that septic patients with AKI had significantly higher plasma SP-D levels *versus*those without AKISP-D rs721917CC genotype is an independent and significant predictor of AKI development and mortality of septic patients. SP-D rs721917C/T polymorphisms should be further studied as a diagnostic and prognostic biomarker to facilitate early recognition of AKI so that treatment can be instituted promptly.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000446

INTRODUCTION. Cardiogenic shock occurs in 2-6% of patients undergoing cardiac surgery. One percent will require mechanical support using VA ECMO. Acute Kidney Injury (AKI) is one of the most frequent complications in patients undergoing ECMO support and is associated with mortality.
OBJECTIVES. The aims of our study were to 1/ describe the epidemiology and 2/ identify the risk factors of AKI in adult patients assisted by VA ECMO in perioperative of cardiac surgery.
METHODS. We conducted an observational, retrospective and monocentric study in the Surgical Intensive Care Unit of the Cardiology Institute of La Pitié-Salpêtrière University Hospital in Paris, France. All patients hospitalized in the department between January 1, 2013 and December 31, 2016 on a cardiac surgical peri-operative basis and assisted by VA ECMO for more than 48 hours were included in the study. A multivariate statistical analysis identified the risk factors for severe AKI in this cohort.
RESULTS. Of the 319 patients included, 211 (66%) developed severe AKI (KDIGO 3 stage), for an overall 30-day mortality of 48%, increased to 59% in patients undergoing renal replacement therapy (86% of patients with AKI). Risk factors for AKI werehigh preoperative LVEF

(OR 1.02 CI 95%[1.01-1.04], p=0.006); maximumperoperative adrenaline dose (OR 1.04 CI 95%[0.75-1.45], p=0.002); presence of right ventricular dysfunction (OR 2.20 CI 95%[1.14-4.23], p=0.009); arterial lactate level (OR 1.07 CI95%[0.97-1.18], p=0.009), bilirubinemia (OR 1.01 CI95%[1.004-1.020], p<0.001) and creatinine level (OR 1.01 CI 95%[1.01-1.02],p=0.001) on the day of VA ECMO implantation. The implantation of VA ECMO percardiotomy (OR 0.51 CI 95%[0.28-0.94], p=0.02) and high protidemia (OR 0.96 CI95%[0.92-0.99], p=0.04) were protective factors for AKI. Several risk factors ofday 30 mortality have been identified: chronic arteriopathy (OR 3.59 CI 95%[1.42-9.10], p=0.01); biventricular failure (OR 1.77 CI 95%[1.00-3.11], p=0.048) and high arterial lactate level (OR 1.17 CI 95%[1.07-1.28], p<0.001) at VA ECMO implantation. Heart transplantation was a protective factor of mortality compared to other types of surgery (OR 0.34 CI 95%[0.14-0.80], p=0.01). In this cohort, AKI was not associated with increased mortality.

CONCLUSION. AKI in patients assisted with VA ECMO undergoing cardiac surgery is frequent and associated with significant mortality. Several risk factors for AKI are identified. The implantation of VA ECMO in per cardiotomy is a protective factor.

Correlation among Pseudomonas Aeruginosa and nursing, severity and outcome indexes in ICU patients

A. Vakalos, M. Piperidou
[1]Icu, Xanthi General Hospital, Xanthi, Greece
Correspondence: A. Vakalos
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000136

INTRODUCTION. The ability of Pseudomonas Aeruginosa strains to cause infection is complex, because not only they provide strong infection ability, but because invade the tissues with discretion as well. Spreading of these strains may lead in developing severe infections in critically ill ICU patients.

OBJECTIVES. The aim of our observation retrospective study was to test the hypothesis that a statistical significant correlation exists among nursing, severity and outcome indexes and percentage of Pseudomonas Aeruginosa positive cultures in severely ill patients in our both medical and surgical ICU served in community hospital.

METHODS. From January 2006 to December 2017, 1107 patients admitted to our ICU. Mean age 66 years, mean length of stay (LOS) 12.2 days, mean APACHE II score on admission 21.5, predicted mortality 39.5 %, actual mortality 29.3 %, Standardized mortality ratio (SMR) 0.74. From our database we looked for percent of total of Pseudomonas Aeruginosa positive cultures and nursing (number of patients, number of patients ventilated, length of stay, hospitalization days, ventilation days per patient ventilated, percentage of ventilated patients, plentitude, mechanical ventilation days), severity (age, APACHE II score, predicted mortality) and outcome (actual mortality, Standardized mortality ratio) indexes per year from 2006 to 2017 (mean values). Using linear correlation method, we looked for linear slope, correlation coefficient (r), and coefficient of determination (r2), and by linear regression method using ANOVA test we looked for p value, according Pseudomonas Aeruginosa % and ICU indexes.

RESULTS.

CONCLUSION. According to our data, there was no statistical significant correlation detected among all severity, all outcome and all of the nursing indexes and the percentage of Pseudomonas Aeruginosa positive cultures. Our data suggest that in our study, the impact of the incidence of Pseudomonas Aeruginosa infection was not statistical significant or not strong enough to influence the length of stay or the outcome.

INTRODUCTION. Advanced age is associated with higher mortality and adverse outcomes in ICUs

OBJECTIVES. The aim of this study was to evaluate the possible effect of age correlated to apache II score, co morbidities and reason for admission for the final outcome.

METHODS. Our study included 280 patients aged 18 and older that were admitted in the ICU from January 2016 till March 2019. Demographic parameters, apache score II, admission diagnosis, underling diseases, ICU length of stay and finally outcome were recorded.

RESULTS. We enrolled 280 patients, 156 males and 124 females with mean age 55±37 years. The main reasons for ICU admission were: post operative (after elective operation), trauma, acute respiratory failure and sepsis. Out of 280 patients the 171 had co morbid medical illness (e.g. ischemic heart disease, arterial hypertension, diabetes mellitus, COPD, chronic renal failure). The mean length of stay was 22 days but it ranged from 1 to 72 days. 196 patients were discharged from the ICU and 84 patients died. Apache II score ranged from 6 to 39, higher values were correlated with longer hospitalization and worse outcome. Post operative patients independently from the age and co morbidities had the best outcome. There were not differences in the outcome as far as the gender was concerned.

CONCLUSION. Reasons for mortality appears to be multifactorial. High age alone is not a factor to predict morbidity. Previous health state, co morbidities, high apache II score and the reason of admission in the ICU play a very important role for the final outcome.

Table 1 (abstract 000843). See text for descriptio

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000864

INTRODUCTION. In the past, quality and improvement in healthcare have focused on what proffesionals think should be valued and have been less interested in what serve userd felt was important. In the Intensive Care Unit, the patient's perspective, as well as their relatives', is central to quality improvement.
OBJECTIVES. To evaluate the level of technical and structural human quality of an Intensive Care Unit (ICU) from the perspective of patients and their relatives.
METHODS. Information was collected from June to September 2018 through a survey adapted to patients and family members. The questionnaire included a 7-score Likert scale conformed by different items aimed at assessing the quality of the service provided to patients in the ICU.
Based on the work of Mora Lourido (2015), we took the dimensions created to measure the technical and structural human quality in the ICU, and we conducted an analysis of means using the student's T, to check the differences in the perceived quality by patients and relatives.
RESULTS. The measurement scale was consisted of 7 dimensions, whose average values are shown in the attached table.
CONCLUSION. We may conclude that the relatives' group is more critical when evaluating the technical and structural human quality of the ICU. Statistically significant differences were found in the valuation of all the dimensions, excepto for "food" and "facilities, available resources and environmental atmosphere", being able to explain why there are dimensions where aspects in which the human factor does not intervene are valued. On the other hand, "waiting room" was punctuated only by relatives, since this ítem was not included in the patient's questionnaire.The human dimension and professionalism in patient care were the aspects that were best valued by both patients and relatives. On the other hand, the dimension referring to visits has been the worst evaluated by both groups, so an improvement should be considered in the future.

INTRODUCTION. Potassium is one of the body's major ions, 98% of the body's potassium is intracellular. It is important for generating action potentials. Disturbance in potassium homeostasis common in critically ill patients s it can induces lethal arrhythmias and result in cardiac dysfunction
OBJECTIVES. We determined the incidence of potassium abnormalities in critically ill patients.
METHODS. The stduy was conduct at a University Teaching Hospital between June 2018 and December 2018. changes in potassium concentration in adult critically ill patients was studied. The serum potassium was measured on admission and dialy for seven days.
Normal range: for potaasium described as 3.5 -5.0, Mild Hypokalemia as 3.0-3.4 and severe: as potassium <3.0. Mild Hyperkalemia defined as potassium > 5.0 -6.0 and severe potassium >6.0
RESULTS. A total of 120 patients were studied. The median age 36 years, the meadian duration of ICU admission was 5 days. Hypokalemia was observed n 61.6%, In patients with hypokalemia; mild hypokalemia observed in 37.3% and severe hypokalemia was observed in 24.3%. Hyperkalemia in 17.6% of patients. Mild hyperkalemia in 12.7% and severe hyperkalemia in 4.9% of patients. The median duration of onset of hypokalemia and hyperkalemia was 2 days. While the median duration of hypokalemia and hyperkalemia were 2 and 2.5 days respectively.
CONCLUSION. Potassium derangement is not uncommon in critically ill patients at our institution.

Use of APACHE II score for predicting prognosis in elderly patients admitted to emergency department

K. B.ismail, N. Zaouek, Y. Yahia, K. Zaouch, R. Boubaker, R. Baccouche, H. Maghraoui, K. Mejd
Urgences, Hospital Rabta, Tunis, Tunisia
Correspondence: I.K. Ben
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001649

INTRODUCTION. Emergency departments receive an increasing number of elderly patients in often critical condition. The APACHE II score usually calculated at intensive care unit admission could be useful to determine the prognosis in elderly patients admitted to emergency department.
OBJECTIVES. The aim of this study is to evaluate the ability of APACHE II score to predict prognosis in elderly patients hospitalized at emergency department (ED).
METHODS. This is a retrospective study conducted in all old patients (≥65years) admitted to ED between September 2018 and March 2019. Data of all patients were collected and the APACHE II score was calculated at admission. The main study endpoints were the use of mechanical ventilation or vasoactive drugs and inpatient mortality.
RESULTS. •A total of 257 elderly patients were included.The mean age was 75±7 years.
• 134 (52%) were females and 123 (48%) were males. Patients had an history of hypertension (56%), diabete (56%) and coronary disease (29,6%).
• Diagnosis of hospitalization were: diabetic ketoacidosis (29%), acute coronary syndrom (16%), acute heart failure (9%), meningoencephalitis (9%), sepsis (8%), hypoxemic pneumonia (8%), acute exacerbation of chronic obstructive pulmonary disease (6%), hemorrhagic syndrome (6%), stroke (4%).
•ventilation was performed in 24% of patients and vasoactive drugs were used in 13%.
•35% were discharged, 45% were transferred to other services including 5% to intensive care unit.
•The mean duration of stay was 35,7±7hours.
• In hospital mortality rate was 20% and mean score of APACHE II was 18±23.
•The APACHE II score was significantly correlated with using mechanical ventilation (p=0,000) and vasoactive drugs (p=0,04) but not with inhospital mortality (p=0,99).
CONCLUSION. The APACHE II score wasn't useful for predicting inhospital mortality in elderly patients admitted to ED but it was significantly correlated to the use of mechanical ventilation or vasoactive drugs.
Further studies seem necessary to confirm these results.

Correspondence: S. Cunha,
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001745

INTRODUCTION. Pregnancy involves many physiologic adaptations and sometimes physiopathological changes also ensue.
Per year, around 200-700/100.000 pregnant women are admitted into an Intensive Care Unit (ICU). The admission reasons are diverse, involving obstetric and also non obstetric causes. Thereafter, this population is frequently a challenge when in the ICU.
OBJECTIVES. This study's aim is to describe the demographic, clinical data and outcomes of patients admitted in the ICU of Cascais' Hospital for obstetric reasons.
METHODS. We conducted a retrospective descriptive analysis of patients admitted to the ICU with the following inclusion criteria: pregnant or puerpera women admitted for obstetric reasons, either in the antepartum, postpartum period or late puerperium. The statistical analysis of epidemiological and clinical data was performed with the software SPSS®. The study period comprised between June 1st 2017 to 31th December 2018.
RESULTS. During the study period, 31 patients were admitted to the ICU for obstetric reasons: 14.8% with the antenatal period, 11.1% on the vaginal pospartum period and 70.4% post-cesarean section. The medium age of this sample was 33 years (SD=6), the median of the gestational age at admission was 34 weeks (IQR 10) and 81,5% had a surveilled pregnancy. The main reason of admission was pre-eclampsia (18.5%), followed by hemorrhage and HELLP syndrome, both accounting 14.8% of admissions. In our sample, the mortality rate was 0%, nevertheless 29.6% required ventilatory support, 14.8% vasopressor/inotropes and 7.4% renal replacement therapy. The median duration of stay in the ICU was 3 days (IQR 3).
CONCLUSION. Despite the low incidence of admissions in ICU among pregnant women, the higher maternal age and increasing cesarean deliveries, are contributing to the increasing physiopathological changes and potentially fatal disorders, such as hypertensive disorders of pregnancy (pre-eclampsia, eclampsia and HELLP syndrome) and post-partum hemorrhage.
The authors highlight the importance of the prompt diagnosis and multidisciplinary approach (involving obstetricians, neonatology and ICU) of this obstetric disorders, aiming for the best maternal and neonatal outcome.

Multiple boluses of intravenous tranexamic acid to reduce hidden blood loss and the inflammatory response following major surgery after severe traumatic injury: a randomised clinical trial

D. Dmytriiev
Grushevskogo 21/15, Vinnytsia, Ukraine
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000011

INTRODUCTION. The aim of this study was to examine the efficacy and safety of multiple boluses of intravenous (IV) tranexamic acid (TXA) on the hidden blood loss (HBL) and inflammatory response following **major surgery after severe traumatic injury** (STI).
METHODS. A total of 102 patients were allocated randomly to receive a single bolus of 20 mg/kg IV TXA before the incision (group A), a single bolus followed by a second bolus of 1 g IV-TXA three hours later (group B) or a single bolus followed by two boluses of 1 g IV-TXA three and six hours later (group C). All patients were treated using a standard perioperative enhanced recovery protocol. Primary outcomes were HBL and the level of haemoglobin (Hb) as well as the levels of C-reactive protein (CRP) and interleukin-6 (IL-6) as markers of inflammation. Secondary outcomes included the length of stay in hospital and the incidence of venous thromboembolism (VTE).
RESULTS. The mean HBL was significantly lower in group C (244.14 ml standard deviation (sd) 125.97) than group A (464.23 ml sd 198.23, $p < 0.001$) or B (334.12 ml sd 193.26, $p = 0.012$). The decrease in the level of Hb between the pre-operative baseline and the level on the third post-operative day was 29.32 g/L (sd 5.84 g/L) in group A, 30.16 g/L (sd 6.44) in group B and 29.94 g/L (sd 4.32) in group C. This decrease differed significantly among the three groups

($p < 0.01$). The mean level of CRP was significantly lower in group C than in the other two groups on the second ($p \leq 0.030$) and third post-operative days ($p \leq 0.010$). The levels of IL-6 were significantly lower in group C than group A on the first three post-operative days ($p = 0.020$). The mean length of stay was significantly lower in group C than group A ($p = 0.024$). No VTE or other adverse events occurred.

CONCLUSION. Anterior rectus sheath blocks using local anesthetics and steroids are safe and long-term successful in more than one-third of children suffering from abdominal pain due to anterior cutaneous nerve entrapment syndrome after laparoscopic oncology surgery.

Perception of discomfort in the ICU by caregivers and patients: a qualitative study

S. Ashkenazy[1], F. DeKeyser Ganz[2]
[1]Hadassah medical center, Hebrew University, Jerusalem, Israel; [2]School of nursing, Hadassah Hebrew University, Jerusalem, Israel
Correspondence: S. Ashkenazy
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001147

INTRODUCTION. Being hospitalized in the Intensive Care Unit (ICU) can lead to unpleasant experiences that involve pain and discomfort for most patients. Sedation and analgesia have become common treatments for alleviation of these symptoms, especially for those receiving mechanical ventilation. As a result, patient – caregivers communication is impaired, leading to caregivers' decreased ability to distinguish between pain and other sources for discomfort. Since patient behaviour might look the same whether the patient is in pain agitated or just uncomfortable. Caregivers may fail to recognize sources for discomfort as opposed to pain. This in turn lead to inappropriate treatment when the patient is uncomfortable but not in pain

OBJECTIVES. The present study is aimed at exploring and understanding caregivers and patients' perception of discomfort in the ICU.

METHODS. This is a descriptive qualitative study using content analysis. Caregivers (n=25, nurses and physicians) and patients (n=12), treated in the ICU for more than 48h and receiving mechanical ventilation, were interviewed after ICU discharged using a semi-structed interview.

RESULTS. Two main categories (physical and emotional discomfort) and other sub-themes categories emerged from this analysis. Differences and similarities were found in the perception of discomfort in the ICU discomfort as described by patients and caregivers. Caregivers described both objective and subjective ways to differentiate between discomfort pain and agitation.

CONCLUSION. Patients experienced discomfort in the ICU. In order to improve quality of care it is important, that caregivers be aware of other sources of discomfort other than pain, while caring for the ICU patients. Strategies to identify discomfort where described.

Intensive care unit: nosocomial acinetobacter spp. multi-drug-resistant strain monobacteremia

D. Adukauskiene[1], D. Valanciene[2], G. Kasputyte[3]
[1]Intensive care unit, Lithuanian University of Health Sciences, Kaunas, Lithuania; [2]Anesthesiology and intensive care department, Klaipeda Seamen's Hospital, Klaipėda, Lithuania; [3]Department of anesthesiology, Lithuanian University of Health Sciences, Kaunas, Lithuania
Correspondence: D. Valanciene
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000521

INTRODUCTION. Patients in Intensive Care Units (ICU) are at higher predisposition to acquire nosocomial infection with high mortality rates. Vast majority of bacteremias in ICU is caused by Gram-negative rods. The rate and resistance of nosocomial infections is increasing in hospitals all over the world.

OBJECTIVES. The aim of study was to analyze sensitivity of multi-drug-resistant (MDR) Acinetobacter spp. strains of nosocomial monobacteremia and associating factors for primary bacteremia and mortality in ICU.

METHODS. Ongoing work: the retrospective data analysis of patients treated in Kaunas Clinic's ICU with positive blood culture of nosocomial MDR Acinetobacter spp. strain during past 10yrs period was carried out. Bacteremia was defined as nosocomial, if positive blood culture was taken after 72hrs of hospitalisation. Strain was defined as MDR, if resistant to ≥ 3 classes of antibiotics.

RESULTS. There were recorded 79 cases of nosocomial MDR Acinetobacter spp. strain monobacteremia with sensitivity to antimicrobial drugs: imipenem and colistin (n=79, 100%, P=0.001), meropenem (n=71, 89.9%, P=0.03), amikacin (n=36, 45.6%), ciprofloxacin (n=18, 22.8%), piperacillin/tazobactam (n=14, 17.7%), gentamicin (n=13, 16.5%), piperacillin (n=12, 15.2%), cefuroxim (n=10, 12.7%), ampicillin and ampicillin/sulbactam (n=2, 2.5%). For patients with primary origin of nosocomial MDR Acinetobacter spp. monobacteremia (n=58, 73.4%, P=0.02, OR=2.06, CI95%=2.67-14.98) invasive procedures (n=62, 78.5%, P=0.01, OR=2.75, CI95%=1.67-15.87) and abdominal surgery were performed (n=56, 70.9%, P=0.02, OR=3.66 CI95%=4.76-11.65), previous hospitalization recorded (n=48, 60.8%, P=0.04, OR=1.48 CI95%=3.56-7.86), treatment with wide-spectrum antibiotics during previous 30 days was used (n=45, 57.0%, P=0.04, OR=1.77, CI95%=4.67-8.67). Lethal outcome (n=68, 86.1%) was found in patients with mechanical ventilation (n=68, 100%, P=0.001, OR=1.73, CI95%=2.56-7.89), septic shock (n=62, 91.2%, P=0.001, OR=1.15 CI95%=3.78-9.64), primary bacteremia (n=58, 85.3%, P=0.03, OR=2.08, CI95%=2.56-7.56), inadequate empiric antimicrobial treatment (n=58, 85.3%, P=0.03, OR=2.08, CI95%=2.56-7.56), SOFA score ^{3}13 (n=55, 80.9%, P=0.02, OR=2.06 CI95%=4.78-11.67), ^{3}3 co-morbidities (n=41, 60.3%, P=0.04, OR=1.39 CI95%=3.65-9.65), elderly (n=35, 51.5%, P=0.04, RR=16.5).

CONCLUSION. Acinetobacter spp. MDR strains of nosocomial bacteremia were found to be sensitive to imipenem and colistin. Primary bacteremia was associated with invasive procedures, abdominal surgery, previous treatment in hospital and use of wide spectrum antibiotics during 30 days before bacteremia. Nosocomial MDR Acinetobacter spp. monobacteremia was characterized by high mortality rate of 86% and associated with mechanical ventilation, septic shock, primary bacteremia, inadequate antibacterial treatment, high SOFA score, comorbidities and elderly.

Carbapenem resistant bacteria infections in a general ICU

C. Cardoso, F. Faria, R. Cavaco, A. Graça, L. Bento
Unidade de urgência médica, São José Hospital, Lisboa, Portugal
Correspondence: C. Cardoso
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001727

INTRODUCTION. Carbapenem resistant bacteria (CRB) infection is currently one of the most common causes of high mortality in ICU with very few antibiotic options.

No studies have been published about epidemiology, antibiotic susceptibility patterns and treatment outcome related to these infections in portuguese ICU's.

OBJECTIVES. Analyze epidemiology and treatment outcomes of CRB infections in a portuguese general ICU
METHODS. Retrospective study on patients who were admitted or developed CRB infections in a general ICU in a two year period
RESULTS. Forty four infections were identified : thirty nine due to *Klebsiella pneumoniae* and five due to *Pseudomonas aeruginosa*. Eleven pneumonias, thirty bloodstream infections, one urinary tract , one abdominal and one soft tissue infection. Main admission diagnosis was sepsis and thirteen patients had hematologic malignancies. Mean days of hospitalization for infection development was 22,2 days.
Half of patients presented with septic shock. All patients were initially treated with dual antibiotic therapy; Colistin and Tigecycline being the most used combination. Ceftazidime Avibactam was used in nine patients, three of them due to persistent bacteremia. Ceftolozane Tazobactam was prescribed in three patients due to multidrug resistant *Pseudomonas aeruginosa*. With these newer antibiotics all patients survived, except one. Mortality for all causes was high (52,3%), especially in hematologic patients. In a significant proportion it was not possible to determine outcome since some were transferred to other hospitals with contact loss or were under life-support interventions limitation at the time of antibiotic treatment.
CONCLUSION. In a portuguese general ICU, CRB infections are related to high mortality especially in groups such as hematologic patients. Susceptibility rates are high to Colistin so it still seems to be an adequate treatment combined to another antibiotic. Ceftazidime Avibactam and Ceftolozane Tazobactam achieve good results regarding outcome but more studies are needed to determine which patients might benefit from their prescription.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000816

INTRODUCTION. Community-acquired pneumonia is a pathology with an important impact on public health. The term community-severe pneumonia identifies the group of patients with pneumonia who require admission to the intensive care units.
OBJECTIVES. Our goal is to study the pneumonia acquired in our community. The incidence of each microorganism, bacteria or virus. The need of mechanical ventilation of the pathology itself and by etiological group.
METHODS. A retrospective, observational study was performed with all the patients who required admission to the Intensive Care Service in a Tertiary and University Hospital with the diagnosis of Community acquired pneumonia (CAP) from March 2015 to February 2019.
RESULTS. A total of 141 patients were collected. The characteristics of the patients were: Age 59.6 ± 13.9, SOFA 7.36 ± 3.9, APACHE II 18.5 ± 8.7, SAPS II 40.4 ± 17.5, Sex (Male) 60 , 6%, Diabetes Mellitus 26.8%, Arterial hypertension 39.4, Cardiovascular pathology 22.5%, Chronic lung disease 43.7%, Cirrhosis 4.2%, Need for vasoactive drugs 69.7%, Need for mechanical ventilation 55.6%, Our sample shows a mortality rate of 5.6%.
Viral microorganisms were isolated in 46 patients, whereas in 62 cases, the isolation was bacterial. The two microorganisms most frequently isolated were Streptococcus pneumoniae (41) and Influenza virus (32), followed by Staphilococcus Aureus (8). In the comparative analysis of CAP due to influenza virus and streptococcus pneumoniae and eliminating co-infections, we found that viral pneumonia presents a higher need of mechanical ventilation (82% vs 58%;P = 0.05). Bacterial pneumonia presents higher renal failure (61.2% vs 30%; P = 0.024). No statistically significant differences were found in terms of mortality (0% vs 6.4%; P = 0.325) or previous personal history.
CONCLUSION. CAP is a very common pathology in the ICU. Although the most frequent cause is bacterial, community viral pneumonia plays an important role, being the Influenza virus the second most frequently isolated microorganism. In our sample, viral pneumonia was associated in a statistically significant way with the need of mechanical ventilation.

Correspondence: C. Kaymak
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000793

INTRODUCTION. Ventilator associated pneumonia (VAP) is a significant cause of morbidity and mortality in critically unwell patients within the intensive care unit (ICU). Implementation of protective measures for VAP and early diagnosis can reduce mortality and reduce the development of multidrug resistant organisms.
OBJECTIVES. The aim of this study was to evaluate the VAP rate, ventilator use rate and causative microorganisms isolated in VAP cases in a five year study period.
METHODS. This study was conducted in the 25-bed anesthesiology and reanimation intensive care unit (AR-ICU) between 2014 and 2018. VAP rate per 1000 mechanical ventilator-days, device utilization ratio for mechanical ventilator and pathogens isolated in patients with VAP were evaluated retrospectively (VAP Rate = VAP Number / Ventilator Day x 1000). Hospital acquired infection definitions are made according to the US Centers for Disease Control and Prevention (*CDC*) criteria.
RESULTS. Results: During the study period totally 2944 patients were followed in the AR-ICU for 37402 bed days. In 2014, the VAP rate was 14.5 per 1000 mechanical ventilator days and the ventilator use rate was 55%, whereas the VAP rate was 5.7 per 1000 mechanical ventilator days and the ventilator use was 55% in 2018. Between 2015-2017, the VAP rate and the ventilator use rate were 13.6, 8.8, 9.5 and 58%, 62%, 52%, respectively. The number of VAP was 44, 44, 47, 43 and 27 in years of 2014-2018, respectively. Generally during the five-year study period, the mostly isolated pathogens of VAP were Acinetobacter baumannii (42.6 %) and Pseudomonas aeruginosa (25.5 %). The rate of Acinetobacter baumannii in VAP patients was decreased form 55.7% in 2014 to 27.3% in 2018.

CONCLUSION. In the AR-ICU, the VIP rate decreased gradually in the last 5 years, while the ventilator usage rate was generally similar. We think that infection control measures as well as early diagnosis and appropriate treatment of VAP can be effective in reducing the VAP rate.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001412

INTRODUCTION. Infections caused by Klebsiela pneumoniae carbapenemase-producing (KPC-p)has become a worldwide emergent health problem considering the difficulty involved in the treatment of these multi resistant organisms and the highmortality rates. Despite the severity from this disease, treatments are divergent in medical literature.
OBJECTIVES. This study aims to analyze the characteristics of patients infected by KPC-p in a single center, in a cohort retrospective analyzing mortality, treatment options and site infections during a period from January 1st 2014 until December 31th2016.
METHODS. This study was conducted in a surgical intensive care unit from a tertiaryhospital in Brazil. KPC-p was observed in 41 patients, with a total of 42 positivecultures for KPC-p. The site infections were distributed between bloodstream(40,47%), respiratory tract (23,80%), abdominal (19,04%), urinary tract (9,52%)and soft tissues (7,14%). Average of SAPS 3 score at the day of admission at ICU was 63,23 (estimated mortality of 41,2%) and average of SOFA score atthe day of the culture was 9,30 (estimated mortality of 35%).The average of patients age was 59,5 years old, and sex distribution was 65,85% male, 34,35% female. All the patients received vasoactive drugs during the stay in the ICU and 56,07% of them required hemodialysis. A total of 12,19% of patients did notreceive any specific treatment against KPC-p infection, 12,19% receivedmonotherapy treatment, 36,58% double therapy and 39,02% three or moredrugs directed to the KPC-p treatment. The drugs considered as specific treatment to KPC-c were carbapenems and tigecycline combined with another drug; polymyxins and aminoglycosides combined or in monotherapy.
RESULTS. General mortality was 80,48% in our sample and the mortality when compared initial antibiotherapy containing a specific treatment to KPC-p or not was,respectively, 84,6% and 80,6%.The mortality when analyzed the stablished treatment after results from cultures was 100%, 82,3% and 76,4% respectively in mono, double and triple therapy. Comparing infection sites as mortality predictor, this outcome was observed in 89,4%, 85%, 81%, 75% and 33%respectively in bloodstream, abdominal, respiratory, urinary and soft tissues infections.
CONCLUSION. This study has several limitations. The higher mortality ratio in all groups canoverestimate the importance from some variables and our sample wasinsufficient to stablish differences statistically significance. Despite this,differences of mortality in monotherapy vs. double therapy vs. triple therapy,can indicate a better option to treat patients infected by KPC-p. Differences ratios between site of infections and mortality can be useful as a predictormortality in future models. Studies with increase in number of patients are necessary to stablish better recommendations in treatment.

INTRODUCTION. The treatment of infective endocarditis (IE) has been widely discussed in order to decide which patients are going to benefit from a surgical approach.
Surgical indication should be established with caution due to its technical difficulties and potential postoperative complications.
OBJECTIVES. Describe the clinical and evolutionary characteristics of patients with infective endocarditis both in native or prosthetic valves undergoing cardiac surgery.
METHODS. Retrospective study in patients operated of IE between 2010 and 2018, at Fundación Jiménez Díaz and Rey Juan Carlos Hospitals.
Demographic variables (sex, age), affected valve (native, prosthetic), microorganism (blood cultures, valve or explanted prosthesis), type of intervention, postoperative complications, lenght of ICU and hospitalization stay were collected.
In January 2019, the status and functional status (NYHA) of the survivors was assessed by telephone call or review of the medical record.
RESULTS. 91 patients were operated (67% males) with a mean age of 65.1 years. 58 (63.7%) had native valve endocarditis. The average EuroSCORE II was 18.3. There was mitral involvement in 38 patients (41.8%), aortic in 33 (36.2%) and both in 18 (19.8%). In the mitral group 23 were native and 15 prosthetic; 25 bioprostheses and 12 mechanics were implanted. In the aortic group 24 were native and 9 prosthetic; 30 bioprostheses and 3 mechanics were implanted. In the mitral-aortic group 66.6% were pure native and the rest had at least one previous prosthesis.
The microorganisms isolated in blood cultures (BC) were: 39.5% Staphylococcus, 25.2% Streptococcus, 16.4% Enterococcus and 2% fungi. In 7.6% BC were negative.
The postoperative complications were: renal failure (16.4%), atrial fibrillation (9.8%), bleeding (5.4%), pneumonia (5.4%), polyneuropathy (5.4%) and stroke (4, 3%). The mechanical ventilation time (MV) was lower than 72 hours in 71.4% of the patients. 12% required tracheostomy. 9.8% required a definitive pacemaker (55% within the mitral-aortic group). 4% of patients were re-admitted to the ICU after being discharged to the ward. There was a hospital mortality of 13 patients (14.3%).
At the time of follow-up, 13 patients had died, 3 were hospitalized and the rest (62, 68.1%) were functional grade I (45.1%), II (56.4%) and III (3.2%), of NYHA respectively.
CONCLUSION. The surgery of the IE has a very good vital and functional prognosis, with a low mortality, although it is not free of post-operative complications. There are no major differences in relation to the native valve affected. The bioprostheses are the most

used. Patients with bivalvular infection have a higher incidence of permanent pacemaker due to affectation of the auriculo-ventricular conduction zone.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001576

INTRODUCTION. Acute acalculus cholecystitis (AAC) is a serious complication of critical illness.
However, up until now there are no specific criteria to diagnose AAC in intensive care units (ICU).
OBJECTIVES. The aim of this study was to evaluate the underlying diseases, clinical and diagnostic features, and outcome of operatively treated AAC among ICU population.
METHODS. We conducted a retrospective study, over a five-year period, between September 1st, 2013 and august 31st, 2018, including the patients admitted to our ICU, who undergone surgery for suspected AAC during their ICU stay.
AAC group was defined as the group of patients with confirmed AAC based on operative findings and anatomopathological examination.
RESULTS. Fourty-eight patients underwent open cholecystectomy for AAC during the study's period. Traumatic injury was the most common admission diagnosis (66.7%), followed by acute respiratory failure (12.5%), hemorrhagic stroke (8.3%) and cardiac surgery (4.2%). The mean Sequential Organ Failure Assessment (SOFA) score was 5.8. On admission, 12 (50%) patients presented with shock and 4 (16.7%) with acute respiratory distress syndrome (ARDS).
According to operative findings and anatomopathological exam, thirty patients had confirmed AAC (65%). The mean length of ICU stay before AAC was suspected was 16.7 days, and the mean delay of surgical treatment was 2.6 days.
Ultrasonographic (US) abnormalities included gallbladder distension (66.7%), thickened gallbladder wall (66.7%), ultrasonographic Murphy's sign (12.5%) and pericholecystic fluid (50%).
On the day of cholecystectomy, average SOFA score was 5, twenty patients presented with positive blood cultures including klebsiella pneumonia in ten cases, pseudomonas in four cases, stenotrophomonas maltophilia in two cases and candidemia in four cases.
According to our analysis risk factors associated to AAC were trauma, cardiac surgery, diabetes and blood transfusions. On the day of diagnosis, hyperglycemia, increased gastric residual volume and jaundice were predictive of AAC. Moreover the delay to AAC was also predictive of the diagnosis with a best cut-off at 12.5 days (AUC ROC =0.77, Se=86% ,Sp=73%).
The mean total length of ICU stay was 31.9 days, and overall mortality was 17%. Subjects with confirmed AAC had higher mortality rates (21%). Our study showed that compared to the survivors, nonsurvivors had higher SOFA scoring on the day of cholecystectomy (p= 0.001, OR= 1.5, CI= 1.2-2). Intraoperative bleeding was also predictive of mortality (p= 0.001, OR= 4, CI= 2.5-7.8).
CONCLUSION. Acute acalculous cholecystitis is associated with multiple organ failure, long ICU stay and death. The diagnosis of AAC remains challenging and should be suspected especially in critically ill patient with traumatic injuries or cardiac surgery and jaundice.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001645

INTRODUCTION. Patients admitted to ICU are prone to various nosocomial infections (NI) due to various reasons. Gram negative bacteria (GNB) are often the most important causative organisms for the same. Of these, multi-drug resistant (MDR) GNB lead to difficulty in treatment, increase length of ICU stay, cost of treatment and increase morbidity and mortality.
OBJECTIVES. a) To investigate the trends of NI in our ICU over the period from 2011 to 2018. b) To study the trends in NI caused by MDR-GNB in that period.
METHODS. A retrospective observational study design. Charts were reviewed of all patients admitted in ICU in the 12 months of 2011 and 2018. Patients developing NI (defined as new onset infection developing after 48 hours of ICU admission) were included in the study. Data was collected regarding socio-demographic factors, cause of ICU admission, type of infection (organ system involved, type of bacteria, sensitivity pattern on culture, etc.), outcomes [ICU length of stay (LOS), mortality].Variables were characterised by number and percentage and were compared by applying Pearson's Chi-square with Fisher's exact test. Trends over time were determined by the Cochran–Armitage trend test and linear regression.
RESULTS. The results are shown in Table no 1.Of the organisms causing NI, 20% were found to be MDR in 2011 as compared to 40% in 2018 ($p<0.05$). The average ICU LOS was 16.5 and 17.4 days (p= NS) in 2011 and 2018 respectively, and mortality was 25.3 and 28.4% (p=0.06) in 2011 and 2018 respectively.
CONCLUSION. There was a significant increase in occurrence of NI. Though there was a reduction in Respiratory tract infections over the period of the study, there was an increase in Urinary tract infections as well as Skin & soft tissue infections. The number of MDR organisms isolated also saw a significant increase. There was an increase in ICU LOS and mortality though not statistically significant.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001700

INTRODUCTION. Carbapenem-resistant Enterobacteriaceae (CRE) infections are associated with poor patient outcomes. Data on risk factors and molecular epidemiology of CRE in complicated intra-abdominal infections (cIAI) are limited.
METHODS. In this retrospective analysis, we identified cIAI patients hospitalized during a period from 1 January 2013 to 31 October 2018 in 14 hospitals in China. 30 CRE isolates were genotyped.
RESULTS. *Escherichia coli* (34.5%)and *Klebsiella pneumoniae* (21.2%) were the leading pathogens. Patients with hospital-acquired (HA)-cIAIhad lower rate of *E. coli*(26.0% vs. 49.1%; p<0.001) and highercarbapenem-resistant Gram-negative bacteria (31.7% vs. 18.8%; p=0.002)than patients with community-acquired (CA)-cIAI. 16.0% of the *Enterobacteriaceae*isolates and 23.4% of the *K. pneumoniae* isolates were resistant to carbapenem.The 28-day mortality was 12.2% and 9.0% in patients with CRE-cIAI versus non-CRE-cIAI(p <0.001). In-hospital mortality was 4.7-fold higher for carbapenemase-producing(CP)-CRE versus non-CP-CRE infection (p= 0.049), which was regardless of carbapenem-containing combinations.The risk factors for 28-day mortality in patients with CRE-cIAIincluded sepsis or septic shock,antibiotic exposure during the preceding 30 days,and comorbidities.
CONCLUSION.*Klebsiella pneumoniae*is the highest prevalence in CRE-cIAI. Infection with CRE, and CP-CRE in particular, is associated with increased mortality in cIAI.

INTRODUCTION. Moderate therapeutic hypothermia (MTH) is currently recommended to improve neurological outcomes in adults with persistent coma after resuscitated out-of-hospital cardiac arrest (OHCA). However, the effectiveness of MTH in patients with non-shockable rhythms (asystole or pulseless electrical activity) is debated. We tested the effectiveness of MTH at 33°C in patients with non-shockable in- or out-of-hospital cardiac arrest (CA).

METHODS. HYPERION was a randomized controlled trial comparing MTH (33°C) to targeted normothermia (37°C) in comatose patients admitted to 25 intensive care units after non-shockable CA. Outcome assessment was blinded. The primary outcome was neurological recovery assessed on post-randomization day 90 using the Cerebral Performance Categories (CPC) scale, with CPC 1 and 2 defining a good outcome.

RESULTS. Between February 2014 and November 2017, 584 patients were randomized and 581 were included in a modified intention-to-treat analysis (3 patients withdrew consent). On day 90, 29 (10.2% [95% confidence interval, 6.7%;13.7%] of the 284 MTH patients were CPC 1 or 2, compared to 17 (5.7% [3.1;8.4%]) of the 297 normothermia patients (OR, 1.87 [1.01;3.50]; P=0.048). Day-90 mortality did not differ between groups (MTH: 81.3% [76.8%;85.9%]; normothermia: 83.2% [78.9;87.4%]; P=0.81). Pre-specified adverse events were not different between the groups.

CONCLUSION. Neurological outcomes after non-shockable CA are poor. Compared to normothermia, MTH at 33°C improved neurological recovery in survivors but had no effect on mortality.

INTRODUCTION. Most patients admitted to intensive care are discharged to a general ward in the same hospital, but some patients require transfer to another hospital. Indications for inter-hospital transfers (IHT) include referral for specialist treatment, lack of intensive care beds at the referring ICU and repatriation to ICU in home hospital [1].
OBJECTIVES. To review mortality of ICU-patients undergoing IHT and analyse whether different indications for transfer render different mortalities.
METHODS. Retrospective cohort register study using the Swedish Intensive Care Registry (SIR) during 2016-2018. The SIR collects data from 98.8% of Swedish ICUs including data on discharge from ICUs to other hospitals/ICUs. Transfers were divided into three categories: transfer due to medical reasons, lack of ICU beds or repatriation to ICU in home hospital. We analysed odds ratios (ORs) for dying within 30 days after discharge from ICU using risk adjusted (SAPS3 score) multi-level mixed effect logistic regression with ICUs as random effect.
RESULTS. We identified 12,356 patients who were discharged to another ICU and hospital, i.e. inter-hospital transfers. The unadjusted mortality 30 days after IHT was 17.2 % compared to 12.4 % if discharged to ward in the same hospital. Mortality after IHT varied with the cause of discharge (Figure).Main diagnoses for transfer due to specialist treatment were subarachnoid haemorrhage, head injury and multi-trauma whilst for lack of ICU beds post cardiac arrest, respiratory failure and pneumonia dominated. Risk adjusted analysis showed a significantly increased risk of dying after discharge due to lack of ICU-beds in comparison with other reasons for IHTs
CONCLUSION. The adjusted risk of dying within 30 days after inter-hospital transfer was greater among critically ill patients when the transfer was due to lack of beds in the referring ICU. The increased mortality lingered for at least 6 months underlining the importance to identify causes and intervene to avoid unnecessary loss of life.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001556

INTRODUCTION. Influenza virus epidemics can cause complications resulting in severe illness and are associated with significant mortality each year worldwide. Up to one third of adults hospitalized with influenza require admission to an intensive care unit (ICU) and up to 80% are mechanically ventilated (MV), due to viral pneumonia

and acute distress respiratory syndrome (ARDS), with a resultant mortality rate of up to 30%.
OBJECTIVES. To determine if early oseltamivir treatment (within 48 hours of symptom onset) compared to no treatment and late treatment is associated with decreased ICU-mortality among patients with severe influenza infection.
METHODS. Prospective, observational study including subjects with confirmed influenza infection admitted to 184 ICUs in Spain. Patients with missing data on antiviral therapy or on outcome were excluded. The primary outcomes were to investigate the impact on ICU-mortality of antiviral therapy (All treated [AT], early therapy [ET], and late therapy [LT]) compared to untreated (UT) patients and the effect of ET vs LT. To evaluate endpoints, Cox proportional hazards regression models were made. Propensity Score Matching (PSM) Competing Risks analysis (CRA) were used to control bias.
RESULTS. Between June 2009 and April 2018, 4175 patients were enrolled. 3537 patients met the inclusion criteria. AT patients (n= 3439) were compared to UT group (n=98). After adjusting for severity of illness, AT patients had higher survival compared to UT patients (HR 0·64; p=0·022). Afterwards, 149 patients were excluded for timing of oseltamivir study, remaining 3388 patients (ET, n=807 and LT, n=2581). Most of patients developed influenza pneumonia (84·7%). Overall ICU-mortality was higher in LT group (23·1% vs 19·8%; p=0·05). In the multivariable analysis, ET with oseltamivir was associated with lower ICU-mortality rate (OR 0·7; p=0·004). PSM was applied performing the new matched cohort (ET, n=790 vs LT, 2522). ET with oseltamivir was associated with lower ICU-mortality over time (HR 0·77; p=0·005) compared to LT and this result remained firm after CRA (sHR 0·80; p<0·05).
CONCLUSION. In patients with confirmed severe influenza infection, ET with oseltamivir is associated with better survival rates.
