INTRODUCTION. Acute kidney injury is characterized by sustained rise in serum creatinine and reduction in urine output. It may also be accompanied by retention of nitrogen products and electrolyte disturbances. The incidence of AKI varies between 36 and 67% among critically ill patients with a mortality rate of 50 to 70%.
OBJECTIVES. We determined the incidence and outcome of acute kidney injury in critical care patients
METHODS. A total of 177 patients, 18 years and older were studied. Data were collected on admission and daily during hospitalization until discharge or death. AKI was defined as:1-2 1) absolute increase in serum creatinine ≥0.3 mg/dL or ≥1.5 times the baseline level, or 2) requirement for renal replacement therapy, or 3) oliguria defined as urine output <400 ml in 24 hours
RESULTS. AKI was observed in 34.3% of our ICU admission, among of whom 4.7% developed AKI during their ICU stay. The mean duration of onset of AKI was 1 (25th to 75th percentile 1-2) days. The overall ICU 30 days mortality was 42.4%, however the 30 days mortality in patients with AKI was 85.5%. Renal replacement therapy was only possible in 36.6% patients. Inotropic support was administered in 59.1% patients with AKI. Factors mitigating against dialysis included proctated hypotension in 63.6%, lack of fund in 18.1%, delayed screening for HIV and Hepatitis B in 18.3%.
CONCLUSION. Acute kidney injury is a common problem in the critically ill patient and is associated with a high mortality rate at our institution.

INTRODUCTION. Acute kidney failure (AKF) is identified in 30-40% of cases in post-operative patients. There is limited literature on the importance and the correlation between peripherical vascular surgeries and the development of AKF.
OBJECTIVES. Analysis of the connection between factors related to AKF or acute-on-chronic-kidney failure (AOCKF) in the ICU during the first 7 days after peripherical vascular surgeries, for example: arterial bypasses, amputations, angioplasties and embolectomies.
METHODS. The definition of AKF is defined by the AKIN: abrupt increase in serum creatinine ≥ 0.3 mg/dL or 50% from the baseline. This study is prospective, observational and non-randomized. Patients on previous dialysis were excluded. Continuous variables were summarized as medians and ranges, and categorical variables as percentages.
RESULTS. A database of 65 patients was evaluated. The data was acquired between April 2018 and March 2019. The median age was 70 (range 22-88 y); 73% were male. 25 patients (38%) had AKF.
The average age in both groups is similar, as well the prevalence of comorbidities (hypertension and DM), distribution of sexes and mortality. 46% of the patients with chronic-kidney disease developed an AOCKF (28% of the AKF group). The frequencies of the following values are bigger in AKF group: Re-surgery, emergency surgery, use of vancomycin, gentamicin or amikacin.
CPK values were different in the two groups (4332 AKF; 2937 no AKF), but our sample was inconclusive to demonstrate a real correlation with AKF. When CPK in the first 24h was divided in three categories (<10.000; 10000-20000 and >20000), it was observed in a Kaplan Meier analyses a correlation between these categories and post-operative hemodialysis.
CONCLUSION. Despite our small sample, CPK when analyzed as a categorical variable, showed a statistical significance in patients submitted to hemodialysis. Despite differences in both groups, as CPK average as well as further factors related to a more serious condition; like patient urgency surgery, re-surgery and the use of antibiotics; our analysis was inconclusive to stablish those factors as predictive

to AKF. The study has several limitations: the number of patients is insufficient for stronger evidences, and it is a single center study. We suggest that a multi-center study can resolve these problems.

Table 1 (abstract 000742). See text for description

Total (65)	AKF (25)	No AKF (40)
Average CPK in first 24h	4332	2937
Mean basal urea	46,8	47,9
Urgency	52%	32%
Contrast use	70%	80%
Nephrotoxic antibiotics	36%	20%
Re-surgery	16%	7%
Mortality	4%	5%
Male	72%	78%
Fem.	28%	22%
Average age	69	68
DM	48%	42%
Chronic renal insufficiency	28%	20%
Hypertension	84%	82%
Tabak consume	35%	55%

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001365

INTRODUCTION. The withdrawal of respiratory support is key in the evolution of the patient, the identification of the optimal moment to advance in the weaning is fundamental, avoiding the problems associated with both an early and delayed withdrawal with increased morbidity and mortality.
The decision based solely on the clinic has proved unreliable. Weaning predictors offer support for decision making. Among the classic predictors is the combination of two of them, MIP / P0.1, which assesses the capacity of the respiratory musculature and the intensity of the stimulus of the respiratory center.
OBJECTIVES. To assess the predictive capacity of MIP / P0.1 with respect to the classic predictors in patients undergoing prolonged mechanical ventilation.
METHODS. Prospective study including 17 patients submitted to MV due to different causes (TBI, CCV, urgent surgery, respiratory failure). Once criteria for advancing weaning are met, an SBT is made in PSV 5 - 8 cmsH2O over 5 cmsH2O of PEEP, and the following determinations are made: MIP, P0.1, MIP / P0,1, RSBI, FR, Vt. Epidemiological variables are collected, cause of IOT, VM time, weaning failure, mortality.
RESULTS. The average age was 56.12 years +/- 13.95. 70.9% were male. Reason for admission: TBI (29.4%), CCV (29.4%), Urgent Surgery (23.5%). The average duration of MV was 12.76 days +/- 8.82. 64.7% presented weaning failure.
We observe a significant relationship between MIP / P0.1 and weaning failure (Test Chi2 p 0.011). ANOVA was performed, we found a relationship between the variables (F 8.08, p 0.012). We performed a COR curve presenting AUC 0.92 (p 0.005, 95% CI 0.78-1). We found the best cut-off at 0.095 (S 90%, E 83%). If we analyze subgroups (Group 1: MV <10 days, Group 2: MV> 10 days) we did not observe a significant relationship between MIP / P0.1 and failure of weaning
CONCLUSION. - In our sample, MIP / P0.1 is a good predictor of weaning failure in patients undergoing short-term mechanical ventilation, if we compare it with the rest of the classic parameters.
- However, in patients undergoing prolonged mechanical ventilation, their prognostic capacity is limited

INTRODUCTION. EARLY PREDICTORS OF THE DURATION OF MECHANICAL VENTILATION IN THE CRITICAL PATIENT:OXYGENATION AND AGE INDEX
OBJECTIVES. To determine the early predictors of MV duration, with emphasis on age and the inspired oxygen/inspired fraction of oxygen (PaO2/FiO2), in critically ill patients.
METHODS. Descriptive, retrospective study. Sample consisting of 143 patients, ventilated for more than 24 hours. Demographic, clinical and risk factors were studied in relation to time in MV and mortality.
RESULTS. The mean number of days in VM (8,5 +/- 7). (53,4%)remained for less than 5 days in MV and the duration of ventilatory support was shorter in young patients (18-50 years). Patients older than 70 years, with APACHE II>15pts, were associated with higher mortality. There was a linear relationship between age and oxygenation index. PaO2/FiO2 between 101-200, was associated with longer duration in MV and with values of PaO2/FiO2<100, mortality increased. The positive water balance(BH+) was linked to PaO2/FiO2<100. Shock, FiO2>60%, Peep>10cmH20,bronchoaspiration, pneumonia, renal failure, BH+ and use of benzodiazepines were associated with mortality; while the duration of MV was associated with FiO2>60%, shock,bronchoaspiration and hypoalbuminemia. Tracheostomies were performed in (6,9%)patients and general mortality (39,1%)
CONCLUSION. PaO2/FiO2 and age can be considered as determining factors in the duration of MV and mortality in critically ill patients.

PREVENT OR RESCUE? A Review of the Application of Airway Pressure Release Ventilation (APRV) for Patients with Acute Respiratory Distress Syndrome (ARDS) in one District General Hospital (DGH) Intensive Care Unit (ICU)

T. Sanderson[1], T. Samuels[2], R. Kumar[2], A. Falek[2], R. Phelan[2], J. Burns[2], M. Alice[2]
[1]Critical care, East Surrey Hospital, London, United Kingdom; [2]Critical care, East Surrey Hospital, Redhill , United Kingdom

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000182

INTRODUCTION. Trial evidence suggests that early application of APRV is associated with better oxygenation and shorter length of stay in ICU (1). Animal studies suggest early APRV may improve oxygenation, minimise histological lung damage and even prevent ARDS development entirely (2, 3). However, the use of APRV is inconsistent and not widespread (4).
OBJECTIVES. To review the use of APRV within our ICU and describe the course of ARDS and clinical outcomes in those patients.
METHODS. A protocol for intital settings, weaning and trouble-shooting APRV is in place in our 16 bed mixed medical and surgical ICU. Data were collected between 09/2018-03/2019 on patients receiving APRV for management of ARDS (using the Berlin definition) (5). Nursing charts were reviewed to retrieve PaO2 & FiO2 values. PaO2:FiO2 ratios (PF) were calculated for admission, initiation of APRV, and 6 & 24 hours post initiation. Electronic patient records were reviewed to find mortality rates at 28 and 90 days.
RESULTS. 9 patients were initiated on APRV for management of ARDS. On admission to ICU, 5 were classified severe, 2 moderate. Mean time between the point where the patient first met the ARDS criteria on ICU (T0) and initiation of APRV was 12 hours (range: 0-47 hours). PF deteriorated in 5 patients from T0 to APRV initiation by 12-50%; by which point 7 patients were severe, and 2 moderate ARDS. 3 of the 4 patients who died were noted to have the most significant drop in PF (31%, 38% and 50%). In 2 cases APRV was used within 2 hours of T0 and PF was not observed to deteriorate. In the remaining 2 cases, PF improved between T0 and APRV initiation by 13% & 28%. 4 patients were discussed with ECMO, and 2 transferred. 1 was lost to follow up as they were transferred within 4 hours of APRV initiation. PF improved on APRV by 16-342% at 6 hours (with one patient's PF ratio dropping by 41%), 4-364% at 24 hours, and 49-321% at point of APRV termination. 7 of the remaining 8 patients still met the criteria for ARDS on APRV cessation (4 = Moderate, 3 = Mild). Mortality was 44% at 28 days (unchanged at 90 days).
CONCLUSION. In this small study, most patients were admitted to ICU with already well-established ARDS, suggesting that it may not have been possible for them to achieve the benefits of early APRV. In addition, further delay before initiation of APRV was associated with deterioration in PF in 5 out of 9 patients. The most significant deterioration in PF was seen in 3 of the 4 patients who died. There was variation in the apparent indication to start APRV (with no obvious PF threshold) implying inconsistency with the practice of APRV. In addition many patients with ARDS will have undergone prone positioning instead of APRV, as there is little evidence to guide which patients will respond optimally to each technique. Further work is needed to clarify optimal timing of APRV use and the role of earlier ICU admission, in order to reduce ARDS progression, and to guide where APRV may be more appropriately used than prone positioning.

Use of inverse ratio ventilation in prehospital emergency medicine

G. Jansen; N. Kappelhoff, R. Borgstedt; S. Rehberg
Anaesthesiology, Prostestant Hosiptal of the Bethel Foundation, Bielefeld, Germany
Correspondence: G. Jansen
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000230

INTRODUCTION. The increasing availability of modern emergency respirators, allows for differentiated ventilation strategies, such as Inverse ratio ventilation (IRV) also in the pre-hospital emergency care setting. While there are detailed guidelines for preclinical airway management , recommendations for preclinical ventilation are just based on guidelines for in-hospital intensive care. The present survey was designed to determine the use of IRV in the prehospital setting by German emergency physicians (GEP).
METHODS. An anonymous web-based questionnaire encompassing 7 questions was sent to GEP from September to December of 2018. They were asked to specify their medical specialty; their education level, their experience in intensive and prehospital emergency care, their average number of assignments per month, their used ventilator model and ventilation mode.
RESULTS. 60 % of the questionnaires were completed (157/261). 95 % of participants had preclinical access to respirators with the ability to perform IRV. 9.9% of respondents (male 11, female 4) stated that they were already performing preclinical IRV (I:E 1.5=1; I:E 2:1 = 1). The proportion of consultants in the IRV group was higher than in the non-IRV group. The proportion of experience in intensive care medicine and the number of assignments per month differed significantly between both groups. The corresponding group characteristics are shown in tables 1 and 2.
CONCLUSION. Approximately 10% of the surveyed GEP employ IRV in the pre-hospital setting. Compared to their colleagues not using

IRV, IRV using GEP had a longer experience in intensive care and a higher rate of monthly missions. These results suggest, that , training in differentiated ventilation strategies such as IRV should be integrated into the training of GEP.

Vitamins use in septic shock in a polivalent ICU of a third level hospital

D. Robaglia, A. Vidal, L. Polanco, JJ. Paez Vargas, VA. Hortigüela Martín, JM. Milicua, A. Tejero, CC. Perez
ICU, Hospital Universitario Fundación Jiménez Díaz, Madrid, Spain
Correspondence: D. Robaglia
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001348

INTRODUCTION. Septic shock is a severe pathology in ICUs, with high cost for the society. There is a recent interest about vitamins therapy in septic shock patients in our unity as much as in the critical medical literature.
OBJECTIVES. Describes epidemiological, clinical data and treatments dispended (vitamins and hemodynamic) of all patients admitted with septic shock in our ICU of a third level hospital.
METHODS. Retrospectively, all patients diagnosed with septic shock according to SOFA criteria between January 2018 and November 2018 were analyzed. Epidemiological characteristics, gravity scores, admission causes, treatment dispended (vitamins and steroids), complications (acute renal failure, acute liver failure, acute myocardial failure, ARDS and multiorgan failure) and outcome like ICU stay and mortality were collected. We also analyzed hemodynamic data (type of monitoring, need of noradrenalin, use of second vasopressor and use of ionotropic support).
RESULTS. A total of 39 patients were analyzed (63.2% ± 2.59% males), the average age was 63.23±2.59 years, the SAPPS II gravity score at admission was 47 ± 2.81, SOFA was 9 ± 1.58 and PCR was 34 ± 14.3. Lactate peak of the first 72 hours was 52.53 ±6.14.
The ICU admission most frequent causes were septic shock (65.8%), post operatory (15.8%) and low conscience level (5.6%).
55.3% of the patients receive surgical treatment, 44.75% emergently. 65.8% had acute renal failure (ARF), 39.5% receive extra renal depuration therapy (ERDT), 15.8% develop an acute liver failure (ALF), 13.2% an ARDS, 26.7% an acute myocardial failure (AMF) and 36.8 % a multiorgan failure (MOF). Use of noradrenalin in 94.7% and in 44.7% of theses case in higher concentration than 0.5 5 µg/kg/min, use of a second vasopressor in 7.9%, dobubutamin was receive in 39.5% and second ionotropic agent in 5.3%.
55.3% of the patients receive thiamine (Vitamin B1), the same percentage steroids and 21.1% vitamin C. The use of vitamin B1 is statistically related with use of steroids (p=0.001) and vitamin C (p=0.018), develop ARDS (p=0.003) and need to ERDT (p=0.037). The use of vitamin C is statistically related with use of steroids (p=0.039) and vitamin B1 (p=0.032), develop ALF (p=0.012), need a second vasopressor (p=0.006) and need to ERDT (p=0.039).
Mortality at hospital discharge was 36.1% in which 46.13% was for multiorgan failure and the same percentage for limitation of effort.
CONCLUSION. Vitamin B1 is use more frequently than vitamin C, more than half of the patients with septic shock receive it. Both of them are use in a refractory septic shock with the same indication that we use steroids. Vitamin C is dispended in a few desperate cases with data of high severity like acute liver failure or use of second vasopressor. It is, in our unit a compassionate treatment.

Usefulness of blood gas analysis as predictor of hospital mortality in patients with septic shock: Cohort study

OE. Palacios Calderon, P. Palacios Moguel, JE. Monter Vigueras, CA. Rojas Gomez, R. Carbajal Serrano, J. Franco Granillo, G. Camarena Alejo, J. Aguirre Sánchez, A. Aisa Alvarez
Intensive care unit, The American British Cowdray Medical Center, Mexico City, Mexico
Correspondence: O.E. Palacios Calderon
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001136

INTRODUCTION. Blood gas analysis is probably the most common diagnostic tool used in intensive care. A proper understanding and use of arterial and pulmonary/central venous blood gas analysis makes it possible to correctly interpret most of the respiratory, circulatory and metabolic derangements which may occur in septic shock patients1.
OBJECTIVES. To assess the effectiveness of arterial and venous blood analysis in predicting mortality of patients with septic shock.
METHODS. Prolective cohort study conducted in two general intensive care units, between June 2018–April 2019. Adults >18yo with septic shock diagnosis based on SEPSIS-3 criteria were included. Time 0 when diagnosis was made. All patients monitored from admission to hospital discharge. Simultaneously, blood gas analysis were carried out to obtain: PaO2/FiO2, ScvO2, Qs/Qt, P(v-a)CO2, C(a-v)O2, P(v-a)CO2/C(a-v)O2, O2ER. Primary outcome was usefulness of arterial and pulmonary/central venous blood analysis as mortality predictor. Standard deviation and medians with interquartile ranges for quantitative variables. Frequencies and percentages for qualitative variables. Student´s t-distribution or Mann-Whitney U-test for groups comparison depending on distribution. Binary logistic regression to control for confoundings. Pearson test for correlation analysis between two quantitative variables. Multiple linear regression analysis to generate an equation with the significant variables of the model.
RESULTS. 66 patients with mean age of 66.5 ± 17 years, 35 (53%) men, 16 (24%) diabetics and 27 (40%) with hypertension. SAPS II 41.5 (12 – 97) and SOFA 8.4 ± 3.2. 13 (19.7%) patients died. Patients who died had CKD (30 vs 8; $p = 0.05$), higher BMI (29.14 ± 10.53 vs 24.92 ± 5.6; $p = 0.05$) and lower PaO2/FiO2 (139.51 ± 48.48 vs 218.48 ± 98.07; $p = 0.04$). Logistic regression analysis showed that PaO2/FiO2 in time 0 was associated with mortality

[OR 0.95 (IC95% 0.90 to 0.99); p = 0.04]. There is correlation of PaO2FiO2 with SvcO2 (r 0.3; p = 0.013) and Qs/Qt (r 0.6; p < 0.001), by these results we generate the following equation with a multiple linear regression analysis: **PaO2/FiO2 = 84,748 + 3.136 (SvcO2) - 4.411 (Qs/Qt) [r2 0.45;*p*< 0.001]**.
CONCLUSION. We found association of PaO2/FiO2 with mortality in patients with septic shock. There is correlation of PaO2/FiO2 with SvcO2 and Qs/Qt, so we believe that this should be adjusted to these variables. To increase statistical power, a larger sample size is required.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000210

INTRODUCTION. In recent years, several papers reported that renal dysfunction caused by contrast media is less frequent than previously reported in critically ill patients(1). However, it remains unclear whether the administration of contrast media for critically ill is harmful, as previous studies focused on specific subpopulations in the ICU(2) or were conducted in a single center(3-5).
OBJECTIVES. To assess the risk of contrast media administration by examining the renal function and prognosis of patients with or without receiving contrast media in critically ill patients.
METHODS. This was a post-hoc analysis of the Japan AKI Database study, which was a prospective cohort study on acute kidney injury (AKI) conducted in the 13 mixed ICUs in Japan from July through December in 2016(6). Adult patients who stayed for >24 hours in the ICU were consecutively registered. Patients were divided into Group C, who received contrast media within 48 hours before the ICU admission and Group NC, who did not receive contrast media. The primary outcome was deterioration of renal function (DRF) defined as elevation of serum creatinine level (>0.3mg/dL or 1.5-fold from baseline) or decreased urine output (<0.5ml/kg/hr for 6 hours). ICU mortality and hospital mortality were also assessed as the secondary outcomes. The effects of contrast media on the outcomes were analyzed using propensity score matched analysis.
RESULTS. A total of 2246 patients were eligible to the study. Of which, 606 patients were given contrast media within 48 hours before the ICU admission. After propensity score matching, the proportions of DRF were similar between group C and group NC (35.9 vs 33.8%, P= 0.706). As for secondary outcomes, ICU and hospital mortality (4.0 vs 2.8%, P =0.623 and 13.8 vs 9.3%, P =0.159, respectively) were similar between two groups.
CONCLUSION. The effect of contrast media on the deterioration of renal function was not evident in critically ill patients.

INTRODUCTION. Renal replacement therapy (RRT), as a cornerstone of supportive treatment, has long been performed in critically ill patients with acute kidney injury (AKI). However, the majority of studies may have neglected the effect of the duration of RRT on the outcome of AKI patients. To explore the effect of the long duration of RRT on the outcome of critically ill patients with AKI
METHODS. This retrospective study was conducted by using the Multiparameter Intelligent Monitoring in Intensive Care II (MIMIC-II) database, which is a publicly available clinical database developed by the Massachusetts Institute of Technology (MIT), Phillips Healthcare, and Beth Israel Deaconess Medical Center (BIDMC). This database contains data from more than 32,000 critically ill patients who were treated in the ICUs at BIDMC from 2001 to 2008.The primary outcome measure of this study was the survival rate at 28 days, 60 days and 90 days in the long-duration RRT group and the non-long-duration RRT group. The secondary outcomes assessed the difference

in clinical outcome in these two groups. Lastly, the effect of the duration of RRT on mortality in AKI patients was determined as the third outcome.

RESULTS. We selected 1,020 patients in total who received RRT treatment according to the MIMIC-IIdatabase. According to the inclusion and exclusion criteria, we finally selected 506 patients with AKI: 286 AKI patients in the non-long-duration RRT group and 220 in the long-duration RRT group. After 28 days, there was a significant difference in all-cause mortality between the long-duration RRT group and the non-long-duration RRT group (p=0.001). However, the difference disappeared after 60 days and 90 days (p=0.803 and p=0.925, respectively). The length of ICU stay, length of hospital stay and duration of mechanical ventilation were significantly longer in the long-duration RRT group than those in the non-long-duration RRT group. Considering 28-day mortality, the longer duration of RRT was shown to be a protective factor (HR=0.995, 95% CI 0.993-0.997, p< 0.0001),while 60-day and 90-day mortality were not correlated with improved protection.

CONCLUSION. The long duration of RRT can improve the short-term prognosis of AKI patients, but it does not affect the long-term prognosis of these patients. Prognosis is determined by the severity of the illness itself. This suggests that RRT can protect AKI patients through the most critical time, however, the final outcome cannot be altered.

Rising GGT during ICU admission protects against acute kidney injury and is associated with lower hospital mortality

G. Jansma, P. Freire Jorge, M. Nijsten
Department of critical care, University Medical Center Groningen, Groningen, Netherlands
Correspondence: G. Jansma

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000246

INTRODUCTION. It has been demonstrated in various ICU patient populations that an elevated gamma-glutamyl transpeptidase (GGT) between the 6th and 14th ICU day is associated with a better outcome [1-3]. Whether a relatively high GGT also confers a lowered risk for acute kidney injury (AKI) has not been investigated. In this study we examined the dynamics of GGT during the first ICU week and its relation with AKI and outcome.

METHODS. A cohort of patients previously studied for the glucose/lactate interaction with liver and renal function was analyzed [4]. Daily creatinine levels were used for the assessment of the development of AKI during the first ICU week. GGT levels were determined frequently. We selected patients with initially normal GGT (i.e. <55 IU/L). GGT levels were compared between AKI and no AKI and hospital survivors and hospital non-survivors. We also analyzed the relation of GGT with AKI in the group of survivors.

RESULTS. The cohort existed of 9074 patients (63% male; median age 64 years) and a hospital mortality of 11%. The incidence of AKI in the cohort was 21% (n=1877) and was significantly lower in the group hospital survivors compared to the group hospital non-

survivors (17 vs 51%, p<0.001). After selecting patients with a normal GGT at ICU day 1 (n = 5399), median [IQR] GGT levels were significantly higher in the group AKI vs no AKI on the first 2 days of ICU admission (26 [17-37] vs 22 [15-32] p=0.02 resp 27 [17-37] vs 24 [16-34] p<0.001). On ICU day 6 GGT was significantly higher in the patients with no AKI vs AKI (80 [45-154] vs 70 [39-119] p<.01). On the first 2 days of ICU admission GGT was also significantly higher in the group non-survivors (29 [19-40] vs 22 [15-33] p<0.001 resp 28 [19-38] vs 24 [16-34] p<0.001) and on day 6 GGT was higher in the group survivors compared to non-survivors (79 [44-148] vs 66 [38-103] p<0.01). Also when only survivors were analyzed, higher GGT at ICU day day 6 was associated with lower risk of AKI (p=0.04).

CONCLUSION. In patients with a normal GGT level at day 1 of ICU admission, higher GGT on the first 2 days of ICU admission were associated with a higher incidence of AKI and hospital mortality. However, during ICU admission overall GGT levels progressively increased and higher GGT levels on day 6 of ICU admission were associated with a lower incidence of AKI and hospital mortality. This suggests a protective role of GGT itself or that elevated GGT may be a marker of regeneration and recovery of the liver or kidneys.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000292

INTRODUCTION. Serum creatinine (Screat) may overestimate renal function at discharge from the intensive care unit (ICU). The objective was to evaluate the association between biomarkers of kidney function and injury at ICU discharge and one -year survival.

METHODS. Ancillary study of the FROG-ICU cohort, a prospective observational cohort in 21 ICUs in France and Belgium, including ICU patients receiving mechanical ventilation and/or hemodynamic support, with one-year follow-up. Kidney biomarkers were measured at ICU discharge among ICU survivors (plasma Cystatin C (pCystc); plasma and urinary Neutrophil gelatinase associated lipocalin (pNGAL and uNGAL); plasma proenkephalin (penKid®)). A Sub-group analyses were performed in the sub-group of patients with discharge serum creatinine < 1.5-fold of baseline.

RESULTS. Among 1207 ICU survivors with complete biomarker assessment and follow-up, 231 died during the year following ICU discharge (19.4%). One-year non-survivors had higher discharge biomarkers level (79 (56.5 to 113.5) vs. 63 (50 to 86) mmol/L for Screat, 91.9 (31.6 to 266.9) vs. 47.7 (23.1 to 141.2) ng/mL for uNGAL, 201 (106 to 350.8) vs. 115 (71 to 189.2) ng/mL for pNGAL, 1.6 (1.2 to 2.4) vs. 1.1 (0.9 to 1.6) 1 mg/L for pCystC and 80.7 (53.3 to 132.9) vs. 55 (40.7 to 82.9) ng/mL for penKid, all p<0.0001). Un-adjusted and adjusted (i.e. on prognostic factors previously identified in the FROG cohort: Age, Charlson comorbidity score, vascular disease, severe valvular disease, chronic kidney diseases, cancer, loss of autonomy, systolic blood pressure, body temperature, total protein and platelet counts, and white blood cell count at ICU discharge, red blood cell transfusion and prolonged ICU length) odds ratios showing association between kidney biomarkers and one-year mortality are presented in Table 1.

CONCLUSION. Kidney biomarkers measured at ICU discharge are associated with one-year outcome, including patients with low serum creatinine at ICU discharge. These results suggest that patients with sub-clinical acute kidney injury at discharge are identified using these biomarkers.

Table 1 (abstract 000292). Adjusted OR and 95% confidence interval for one-year mortality in all ICU survivors, as well as in the subgroup of patients with low serum creatinine at discharge (i.e. <1.5 fold baseline)

	All patients	Screat <1.5 baseline at discharge
sCreat	1.79 [1.17 - 2.73]	1.68 [1.04 - 2.69]
eGFR	2.06 [1.30 - 3.27]	1.94 [1.15 - 3.29]
uNGAL	2.08 [1.35 - 3.21]	1.99 [1.23 - 3.21]
pNGAL	2.61 [1.71 - 3.97]	2.63 [1.61 - 4.27]
pCystC	3.11 [1.88 - 5.16]	2.84 [1.67 - 4.83]
penKid	2.20 [1.44 - 3.38]	2.08 [1.29 - 3.37]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000325

INTRODUCTION. It is unclear as to whether intensivist coverage has an effect on improving outcomes of patients postoperatively admitted to the surgical ICU.

OBJECTIVES. This study aimed to assess the effect of intensivist coverage on the incidence rate of postoperative acute kidney injury (AKI) and postoperative ventilator time among patients postoperatively admitted to the ICU

METHODS. Adult patients postoperatively admitted to the ICU between January 2012 and December 2017 were retrospectively enrolled. The incidence rate of AKI within 72 hours after surgery and the

postoperative ventilator time were compared between the intensivist coverage group and the non-intensivist coverage group.
RESULTS. In total, 5,494 subjects were included in the final analysis (2,747 subjects in each group). The incidence rate of AKI was significantly higher in the non-intensivist coverage group than that in the intensivist coverage group (22.8% vs 20.2%; *P*=.017). Moreover, logistic regression analysis showed that the incidence rate of postoperative AKI in the non-intensivist coverage group has increased by 17% compared to that in the intensivist coverage group (odds ratio: 1.17, 95% confidence interval: 1.03-1.33; *P*=.017). Lastly, the median time of ventilator use in the non-intensivist coverage group was significantly longer than that in the intensivist coverage group [7.8 hours [interquartile range, IQR: 2.7-13.5] vs 5.5 hours [IQR: 2.1-8.5]; *P*<.001).
CONCLUSION. High-intensity intensivist coverage is associated with lower risk of postoperative AKI and shorter postoperative ventilator time, indicating the need for full-time intensivist coverage at the surgical ICU.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000348

INTRODUCTION. The Kidney Disease Improving Global Outcomes (KDIGO) guidelines recommend using regional citrate anticoagulation for continuous renal replacement therapy (RRT) in critically ill patients with acute kidney injury. We introduced citrate RRT in May 2017 in our intensive care unit.
OBJECTIVES. To assess the effect of citrate RRT on filter usage, RRT days, and filter downtime in critically ill patients in a district general hospital.
METHODS. We performed a retrospective observational study looking at patients admitted to our 7 bedded Level 3 critical care unit (370 patients per annum) for one year after the introduction of citrate RRT. We included patients over 16 years of age who had received RRT in our unit. Data was collected from WardWatcher, a Scottish Intensive Care Society Audit Group (SICSAG) database, electronic patient records (EPR) and PACS (a radiology information system). 53 patients received RRT on the unit during the year. A total of 8 patients were excluded; five of these patients had no RRT prescription chart on the EPR and three of them had received heparin.
RESULTS. There were a total of 53 patients, median age 58 years with 60% males. Of the 45 patients whose data were available, the average time on citrate RRT was 3.1 days vs 4.6 in 2015 giving a p value of 0.157. Average number of set changes was unchanged with 1.8 set changes per patient after introduction of citrate vs 1.8 in 2015, giving a p value of 0.362. We achieved the prescribed blood pump speed 80% of the time with citrate RRT as opposed to only 50% of the time in 2015. In 40% of the patients who received citrate RRT, the filter ran 100% uninterrupted. Filter clotting was still the commonest reason for filter set changes. A subgroup analysis based on line site (i.e. right internal jugular (RIJ), left internal jugular (LIJ), femoral veins (FV), or subclavian veins (SV)) was carried out due to the high proportion of LIJ lines in our unit. This revealed an average of 1.2 set changes for RIJ lines, 1.4 for LIJ, 0.67 for FV and 0 for the single SV line inserted. These included changes due to routine filter set changes at 72 hours.
CONCLUSION. It was predicted that the introduction of citrate RRT would reduce number of filter set changes per patient and filter downtime, ultimately reducing cost. The reasons for not being able to demonstrate reduction in filter set usage may include small numbers, line position (LIJ), and not recommencing filter after short planned interruptions such as CT transfers. It has not been possible to do a composite cost analysis at this stage to demonstrate cost reduction. We hope to feedback results of this study to the multidisciplinary team, improve awareness regarding choice of site for dialysis lines, and re-examine our outcomes in a year's time.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000441

INTRODUCTION. Acute kidney injury (AKI) occurs in up to 50% of patients admitted to the intensive care unit (ICU) [1]. Predicting recovery from AKI could be valuable, for patient and family counseling, prognostication, and post-ICU care planning. Patients with lower predicted probability of AKI recovery could benefit more from a focused health care management. However, early prediction of AKI recovery remains a major challenge.
OBJECTIVES. The purpose of this study was to identify predictors for AKI recovery. For this purpose, we developed and validated an AKI recovery prediction model in adult ICU patients, to predict AKI recovery at ICU discharge.
METHODS. This study was a retrospective preplanned secondary analysis of the EPaNIC multicenter randomized controlled trial database. AKI recovery was defined as no longer having AKI stage 3 [2], not receiving renal replacement therapy (RRT), and not being deceased at ICU discharge. The development cohort (n= 227) consisted of patients with AKI stage 3 and/or RRT during the ICU stay. Clinical data were retrieved from the EPaNIC research database and from the clinical patient data management system database. The model was developed by using a random forest (RF) machine-learning algorithm. Feature selection was performed with a RF-based selection approach. Performance was evaluated by discrimination, calibration, and decision curve, and internally validated (with 95% confidence intervals (CI)) by bootstrapping with 200 replications.
RESULTS. A total of 49 patients (21.59%) recovered from AKI at ICU discharge. Multivariate predictors for AKI recovery included age, baseline serum creatinine (SCr), SCr before onset of AKI stage 3 (mean, 25th percentile, mean of difference above mean, median, and slope), maximum lactate on day1, bilirubin on day1, heart rate before onset of AKI stage 3 (proportion above 75th percentile, and mean of difference above 75th percentile), mean arterial blood pressure before onset of AKI stage 3 (mean of difference below 25th percentile), C-reactive protein (CRP) level on day1, urea level on day1, and urine output volume on day1. The AKI recovery prediction model had an area under the receiver operating characteristic curve (AUROC) of 0.76 (95% C.I. 0.64 – 0.83), calibration slope of 0.98 (95% C.I. 0.43 – 1.73), and calibration in the large of 0.00 (95% C.I. -0.07 – 0.07). At the classification threshold that maximized sensitivity and specificity, sensitivity was 0.76 (95% C.I. 0.63 – 0.89), specificity was 0.74 (95% C.I. 0.61 – 0.86), net benefit with respect to treat-none was 0.09 (95%

C.I. 0.05 – 0.16), and net benefit with respect to treat-all was 0.16 (95% C.I. -0.00 – 0.48).
CONCLUSION. Although the determinants of AKI recovery are difficult to define, a prediction model based on routinely collected clinical data was able to fairly predict AKI recovery at ICU discharge.

INTRODUCTION. Many patients admitted to the intensive care unit (ICU) have some element of kidney injury, whether acute or on a background of chronic renal failure. Acute kidney injury (AKI) requiring renal replacement therapy (RRT) develops in around 5-10% of patients admitted to ICU[1]. It has previously been found that a low serum creatinine is associated with a poor outcome[2]. It has also been shown that AKI is an independent risk factor for mortality[1]. There are many parameters that can be used to identify and monitor AKI, such as urine output, serum potassium, fluid balance and serum creatinine. Raised serum creatinine is also a marker of chronic kidney disease. However, there is little research into the relationship between serum creatinine and critical care outcome. Our primary aim was to investigate whether there is a correlation between serum creatinine and ICU outcome, and hospital outcome.
METHODS. We searched our local ICU database, Ward Watcher, which contains data from 13,927 patients from 1993-April 2019. Emergency and non-emergency admissions were included. Patients with incomplete data regarding outcome were excluded. We assessed whether an association existed between the highest serum creatinine and critical care/hospital outcome.
RESULTS.
CONCLUSION. Our data suggest a relationship between raised serum creatinine, and poor critical care and hospital outcome. Creatinine is a readily available test and is usually measured daily in critical care, so could be considered to be a useful aid in considering a patient's prognosis. While serum creatinine may not be the best marker of renal function (GFR)[3], there does appear to be a relationship between creatinine and ICU outcome. In our study we did not isolate emergency admissions, nor did we account for baseline creatinine or any prior chronic kidney disease. Further work is needed to study the effects of these parameters on unit outcome.

INTRODUCTION. Volatile anesthetic agents have been reported to exert a protective effect on the lungs and heart, whereas intravenous anesthetic agents exert a protective effect on the brain. Acute kidney injury (AKI) is a serious complication associated with morbidity and mortality. The effect of anesthetic agents on renal function remains unclear.
OBJECTIVES. We aimed to investigate the incidence and risk factors of AKI in relation to the use of different anesthetic agents in patients undergoing thoracoscopic and laparoscopic esophageal surgery.
METHODS. We reviewed the electronic medical records and laboratory results of all patients who underwent thoracoscopic and laparoscopic esophageal surgery at Fujita Health University Hospital between November 2015 and February 2018. We excluded patients undergoing hemodialysis. We analyzed sex, age, weight, height, body mass index, anesthesia time, operative time, thoracoscopic and laparoscopic time, volume of fluid infused, urinary output, intake and output balance, blood urea nitrogen, creatinine(Cr), aspartate transaminase, alanine aminotransferase, white blood cell, C-reactive proteinand hemoglobin.We used Mann-Whitney U-test and chi-squared test for statistical analysis. We used EZR statistical software. Postoperative AKI was defined by the Kidney Disease Improving Global Outcomes guidelines. This study was approved by the FHU Ethics Review Committee(HM17-286).
RESULTS. A total of 83 patients [43 inhalation anesthesia (sevoflurane or desflurane), 40 propofol] were included in this review. There were 12 AKI cases in the inhalation anesthesia group (12/43: 28%) but none in the propofol group (0/40: 0%) (p=0.015).Urinary output volume was significantly increased in the propofol group compared with that in the inhalation anesthesia group (p=0.000002) and was significantly decreased in the AKI group compared with that in the non-AKI group (p=0.000006).There were no significant differences between the AKI and non-AKI groups except for height (p=0.036).
CONCLUSION. There was a significant decrease in AKI with propofol. Propofol may have a protective effect on renal function in patients undergoing laparoscopic esophageal surgery. Our investigation was a retrospective single center study. Further studies are required.

INTRODUCTION. Cardiopulmonary bypass (CPB) during cardiac surgery impairs microcirculatory perfusion, which is paralleled by microvascular leakage and associated with acute kidney injury. Thrombin is excessively released during CPB, which leads to endothelial and platelet activation and increased endothelial permeability. Aprotinin (Trasyslol), an anti-fibrinolytic, is also suggested to inhibit thrombin/PAR1-induced endothelial hyperpermeability. Therefore, this study investigated whether aprotinin reduces renal edema formation and whether this is paralleled by preserved renal and cremaster perfusion and reduced renal injury following CPB.
OBJECTIVES. To show that reduction of CPB-induced microvascular leakage by targeting the thrombin/PAR1 system using aprotinin preserves renal perfusion and reduces renal injury.
METHODS. Male rats were anesthetized and subjected to 75 minutes of CPB after treatment with aprotinin (n=15) or PBS (n=15) as control. Microcirculatory perfusion was measured in the cremaster muscle using intravital microscopy and in the renal cortex using contrast echography before CPB, and 10 and 60 minutes after weaning from CPB (post-CPB). Renal perfusion was calculated by multiplying microvascular filling velocity and microvascular blood volume. Wet/dry weight ratios were determined from harvested kidney tissue. Plasma creatinine, kidney injury molecule-1 (KIM-1) and neutrophil gelatinase-associated lipocalin (NGAL) were measured by ELISA as markers for kidney injury.
RESULTS. Onset of CPB decreased hematocrit levels (39±3 to 22±2 %, $P<0.01$) and blood pressure (88±15 to 73±9 mmHg, $P=0.02$). In addition, CPB resulted in a 2-fold reduction in the number of perfused capillaries in the cremaster muscle ($P<0.01$), which did not restore in the first hour post-CPB. One hour post-CPB, renal microvascular filling velocity (1.3±0.4 to 0.9±0.5 /sec, $P<0.01$) and renal perfusion (258±173 to 135±88, $P=0.03$) were reduced, paralleled by increased plasma levels of creatinine (28±3 to 58±13 nmol/ml, $P<0.01$) NGAL (123±37 to 2621±577 ng/ml, $P=0.003$) and KIM-1 (197±39 to 273±81 pg/ml, $P<0.01$).
Aprotinin preserved cremaster perfusion following CPB ($P=0.002$), whereas renal microvascular filling velocity ($P=0.5$) and perfusion ($P>0.9$) were not affected compared to untreated CPB animals. In parallel, no differences were observed in plasma levels of creatinine ($P>0.9$), NGAL ($P=0.7$) or KIM-1 ($P=0.2$). Aprotinin treated animals required less additional fluids (3.9±3.3 vs 7.5±3.0 ml, $P=0.006$) during CPB and reduced kidney wet/dry weight ratios (4.6±0.2 vs 4.4±0.2, $P=0.046$) were found 1 hour post-CPB compared to untreated CPB animals.
CONCLUSION. Treatment with aprotinin preserved cremaster microcirculatory perfusion following CPB, but did not prevent renal perfusion disturbances nor renal injury following CPB despite reducing renal edema formation. Future studies should focus on identifying therapeutic strategies to improve renal perfusion and function following CPB.

INTRODUCTION. Spleen plays an important role in the regulation of immune response during sepsis and acute kidney injury (AKI) [1]. α7 nicotinic acetylcholine receptor (α7nAChR) is a key factor involved in the cholinergic anti-inflammatory pathway. Dexmedetomidine (Dex) can exert protective effects against sepsis through α7nAChR signaling, which is mediated by spleen [2].
OBJECTIVES. To investigate the role of splenectomy in Dex-activated cholinergic anti-inflammatory pathway in alleviating septic AKI.
METHODS. C57BL/6 mice were randomly divided into Control group, LPS group (10mg/kg LPS intraperitoneal injection), Dex+LPS group (Dex 40μg/kg before LPS injection), Splenectomy group, Splenectomy+LPS group and Splenectomy+Dex+LPS group. The mice in splenectomy groups survived for 7days after splenectomy and re-entered the group. Mice were terminated 16 h after LPS challenge.
RESULTS. The septic AKI model was established successfully (Figs1-3). The apoptosis in LPS group increased significantly compared to control group. The Dex reduced the apoptosis of kidney cell, however, the apoptosis increased after splenectomy plus Dex (Fig4). Cr and Cys-C were significantly increased after LPS, which were reduced by Dex treatment. However, Cr and Cys-C increased again after splenectomy combined with Dex (Fig5). The levels of IL-6, NF-κB p65, p-STAT3, Caspase-3 and Bax were significantly increased and the levels of α7nAChR and Bcl-2 were significantly decreased in LPS group. Dex treatment resulted in an attenuation of IL-6, NF-κB p65, p-STAT3, Caspase-3 and Bax, and an increase of α7nAChR and Bcl-2. Splenectomy down-regulated the expression of IL-6, NF-κB p65 and p-STAT3 (Fig6).
CONCLUSION. Dex effectively alleviated septic AKI, while splenectomy could inhibit anti-inflammatory, anti-apoptotic and renal protective effects of Dex. Splenectomy reduced the production of pro-inflammatory cytokines and had a protective effect on kidney. The Kidney-spleen axis mediated by α7nAChR signaling pathway was involved in the development of septic AKI.

INTRODUCTION. Renal ischemia/reperfusion (IR) can induce acute kidney injury (AKI), which often progresses to chronic kidney disease (CKD). Our previous study demonstrated that Dexmedetomidine (Dex), a highly selective α2 adrenergic receptor (α2-AR) agonist, improves renal fibrosis to moderate the AKI-to-CKD transition. However, the precise underlying mechanisms were largely unknown.
OBJECTIVES. This study focuses on the underlying mechanisms related to gap junction (GJ) composed of connexin32 (Cx32)-induced senescent bystander effect responsible for Dex renal protection.
METHODS. Cx32 knockdown mice (Cx32-/-), kidney specific Cx32-overexpressing mice (Cx32-rAAV), and wild-type C57BL/6 mice (Cx32+/+) underwent surgical bilateral renal IR in the absence or presence of treatments with Dex(10μg/kg). Histopathological changes, renal dysfunction, cell senescence and tubular fibrotic markers, reactive oxygen species, inflammatory factors and the expression of NF-κB were studied.
RESULTS. Cx32 deficiency alleviated, while Cx32 overexpression enhanced renal IR-induced AKI, renal senescence and chronic tubulointerstitial fibrosis in later stages (Fig1). Cx32 GJ was found to transfer ROS and further activate NF-κB and the senescence-associated secretory phenotype (SASP) (Fig2). Similar to Cx32 knockdown, pretreatment with Dex also decreased the number of senescent tubular cells and tubulointerstitial fibrosis, and weakened the protein expression of senescence and fibrosis-associated markers including p21, p16, α-SMA and TGF-β1 (Fig3). Furthermore, the expression of SASP markers was also decreased in Dex-treated IR mice; and these protective effects of Dex could be abolished by Cx32 overexpression (Fig4).
CONCLUSION. Cx32 plays a critical role in Renal IR-induced senescence and chronic tubulointerstitial fibrosis and that inhibition of Cx32 function may represent a new and major mechanism whereby Dex alleviated the senescent bystander effect by inhibiting the Cx32 GJ, which further inhibited ROS/NF-κB-mediated senescent bystander effect.

INTRODUCTION. Acute kidney injury (AKI) is a critically ill syndrome with a high incidence and mortality. It was reported that severity of oliguria and anuria were associated with worse outcomes and a rapid decline in urine output might be the earliest indication of renal dysfunction ahead of other indicators. However, the utility of urine output as a specific indicator for renal dysfunction is somewhat controversial. Therefore, we performed this study to evaluate the prognostic value of different level of urine output for critically ill patients with AKI.

METHODS. We conducted a secondary data analysis of the Beijing Acute Kidney Injury Trial (BAKIT) database, which was a multicenter, prospective, observational study involving 9,049 adult patients admitted to 30 ICUs in 28 tertiary hospitals in Beijing [1]. Overall, there were 3,107 patients recruited consecutively into the database. Those who lacked body weight, daily creatinine and hourly urine volume were excluded from the study. All recruited patients were evaluated by the Kidney Disease: Improving Global Outcomes (KDIGO) criteria and four types of urine output [2]. The urine output criteria were as following: UO1, a urine volume of less than 0.5 mL/kg/hour for six hours; UO2, an average urine volume of less than 0.5 mL/kg/hour for six hours; UO3, a urine volume of less than 0.3 mL/kg/hour for six hours; and UO4, an average urine volume of less than 0.3 mL/kg/hour for six hours. Demographic information, underlying disease, diagnostic information, lab and physiological data and patient

outcomes were collected. The prognostic indicators included the renal replacement therapy (RRT), ICU mortality, hospital mortality, 28-day mortality, length of ICU stay, and hospitalization costs. Differences in mortality and other prognostic indicators among the KDIGO criteria and the four different urine volume criteria were compared. Logistic regression analysis was used to assess the association of different criteria with prognostic indicators. P<0.05 was considered to be significant.

RESULTS. Of the 1,080 patients enrolled in the final analysis, 555 (51.4%) patients met the KDIGO criteria, and 191 (17.7%), 290 (26.9%), 110 (10.2%) and 170 (15.7%) met the UO1, UO2, UO3 and UO4 criterion, respectively. The hospital mortality based on the different criteria was 23.1% (KDIGO), 39.8% (UO1), 33.5% (UO2), 47.3% (UO3) and 43.5%(UO4), and UO3 was significantly higher than other groups (P<0.05) (Figure1). The other prognostic indicators including the RRT rate, ICU mortality, 28-day mortality, length of ICU stay, and hospitalization costs were incompletely equal, with the highest in the UO3 (Table 1).

CONCLUSION. Alterations in urine output might be a sensitive prognostic indicator of AKI. A 6-hour average urine volume of less than 0.3 mL/kg/hour might be associated with worse clinical outcomes, such as higher mortality, more RRT, longer ICU stay and higher medical costs.

Categorical variables are shown as number (%). Continuous data are expressed as median (interquartile range).

RRT, renal replacement therapy; CNY, Chinese Yuan

The KDIGO (the Kidney Disease: Improving Global Outcomes) criteria were as follows: an increase in serum creatinine by at least 26.4 μmol/L within 48 hours or an increase in serum creatinine to 1.5 times baseline, which is known or presumed to have occurred within 7 days before, or a urine volume of less than 0.5 mL/kg per hour for 6 hours.

The urine output criteria were as following: UO1, a urine volume of less than 0.5 mL/kg/hour for 6 hours; UO2, an average urine volume of less than 0.5 mL/kg /hour for 6 hours; UO3, a urine volume of less than 0.3 mL/kg/hour for 6 hours; UO4, an average urine volume of less than 0.3 mL/kg /hour for 6 hours.

P value is the results of comparison based on the KDIGO criteria and different urine outputs.

INTRODUCTION. Equations (as CKD-EPI) for renal function estimation are usually used in the critical patient despite not having been validated in this population. Utilization of estimation formulas of renal function may lead to incorrect drugs dosage.

OBJECTIVES. To analyse the concordance between CKD-EPI and the gold standard glomerular filtration rate (GFR) to verify its validity for the correct estimation of renal function in the critically ill patient.

METHODS. Observational study conducted in a polyvalent ICU of a 3rd level hospital. Between March 2017 and August 2018 blood samples and 24h urine samples were collected to determine serum and urine creatinine levels. We graded the sample in stages of CKD for grading severity, and we added a new stage for augmented renal clearance (GFR> 130 mL/min). To evaluate the concordance between CKD-EPI and GFR in the overall sample and in each stage we applied Passing-Bablok and Bland Altman statistic tests.

RESULTS. 949 samples of 255 patients (a mean age of 58 years and 66% of males) were collected. The obtained *n* was excessive for an adequate power for the normal GFR stage so that the size of the sample was automatically and randomly reset and thus the global sample was reduced to 643. In the GFR<30 mL/min stage sample group there is a proportional discordance between both tests. In the other subcategories and the overall sample there is a proportional and constant discordance.

CONCLUSION. There is no concordance between CKD-EPI and GFR. The obtained results question the validity of the CKD-EPI formula for correct renal function estimation in the critically ill patient. Physicians should take into account that CKD-EPI is not accurate for dosing drugs with renal elimination mechanism.

INTRODUCTION. The incidence of acute kidney injury (AKI) in the intensive care units ranges from 32% to 50%. Only 5% of these patients are treated with renal replacement therapy (RRT), but the mortality is high, often reaching up to 50%. In spite of the modality of the RRT, the access point to the circulation is a central venous dialysis catheter (CVDC). The CVDC and the central venous catheter (CVC) are often placed in the same vessel in order to salvage the veins. As a consequence, the tips of both catheters end up in the superior vena cava (SVC). Therefore, there have been speculations that this might cause immediate aspiration of the drug infused via CVC through the CVDC.
OBJECTIVES. Determine the degree of immediate aspiration of the drug infused via central venous catheter (CVC) through the distally positioned central venous dialysis catheter (CVDC).
METHODS. A 9.53mm polyvinyl chloride (PVC) tube was used to mimic the SVC. We used water to simulate blood. A centrifugal pump was used to keep a constant flow rate of 1.2 liters per minute. 1mg/mL (0.1%) methylene blue aqueous solution was selected as a tracer and was infused into the tube using a syringe pump via the CVC as a constant infusion (200ml/hour) and as a bolus infusion (800ml/hour). To simulate RRT we performed a manual aspiration through the CVDC using 20ml syringes at the speeds of 100ml/min and 300ml/min. The CVC point was moved in reference to a fixed CVDC point. The most distal point was at +2 cm, and the most proximal point was at -8 cm distance. Four different sets of samples were generated: continuous infusion - slow aspiration (situation – A), continuous infusion - fast aspiration (situation – B), bolus infusion - slow aspiration (situation – C), bolus infusion – fast aspiration (situation – D). The samples were obtained at every of the 6 different distances between the CVC and CVDC tips. 3 samples were taken per each measurement, mixed to one medium sample, amounting to 24 different sample syringes. Spectrophotometry and Beer-Lambert-Bouguer law were used to evaluate the degree of aspiration.
RESULTS. When the CVC tip was placed at +2cm distance the aspiration of the tracer was <0.027% in all situations. The levels of aspiration were also minimal at the 0cm distance (<0.27%). Moving the CVC catheter up resulted in increased aspiration of the tracer reaching its peak at -4cm: situation A (1.37%), situation B (0.35%), situation C (5.16%), situation D (2.61%). The levels of the aspirated tracer were higher in bolus infusion setting, reaching an average of 2.07% in situation C and 1.77% in situation D compared to 0.46% in situation A and 0.32% in situation B.
CONCLUSION. Our experimental study showed that the degree of immediate drug aspiration is influenced by the position of the adjacent catheters and the speed of infusion. There was no aspiration seen in the +2cm and 0cm positions. These are the safest positions in the setting of adjacent catheters in order to avoid unwanted drug aspiration.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000748

INTRODUCTION. Acute kidney injury (AKI) is a recurrent finding in critically ill patients and is linked to some short- and long-term adverse outcomes. In addition, previous studies(1) showed that Streptococcus pneumoniae (SP) infections could be associated with an increased risk of AKI even if that relationship was not extensively analyzed in critically ill patients.
OBJECTIVES. We compared patients with SP pneumonia and similar patients affected by other types of pneumonia (OP) hypothesizing that SP infection could be linked with increased AKI and mortality rates.
METHODS. We performed a retrospective analysis, reviewing all patients with pneumonia admitted to our Intermediate Care Unit (IMCU) from December 2015 to December 2018. The inclusion criteria were: age ≥ 18 years old; radiological evidence of pneumonia; positive microbiological samples (urinary antigen for SP or Legionella pneumophila; endotracheal aspirate or bronchoalveolar lavage; blood culture; pleural culture). Exclusion criteria were: patients with bronchitis, aspiration pneumonia and lung tumors. We analyzed two groups of patients (SP and OP) matched for age, SAPS2 score, SOFA score, PaO2/FiO2 ratio at IMCU admission, chronic kidney disease (CKD) and circulatory failure (CF). KDIGO criteria were used to classify AKI. We investigated rates of AKI, IMCU mortality and mortality at 90 days.
RESULTS. We reviewed 110 patients and 34 respected the inclusion criteria (17 in SP group and 17 in OP group). The two groups were well matched (age: 78 ± 9 (SP), 74 ± 12 (OP) p= 0.3; CKD 6/17 (SP), 6/17 (OP) p = 1; PaO2/FiO2 149 ± 79 (SP), 134 ± 37 (OP) p = 0.5; SAPS2 42 ± 11 (SP), 40 ± 13 (OP) p = 0.7; SOFA 6 ± 1 (SP), 5 ± 1 (OP) p = 0.3; CF 5/17 (SP), 4/17 (OP) p = 0.7). Furthermore, there was no significant difference in the two groups concerning the use of iodinated contrast media (p= 0.09), aminoglycosides (p= 1), glycopeptides (p= 0.4), colistin (p=1), except for ACEi/sartan use (p= 0.03 in OP). No significant difference was found in AKI rate between the two groups (AKI 9/17 SP; 7/17 OP p = 0.5; KDIGO stage: 1 (5/9 SP; 5/7 OP p= 0.5), 2 (3/9 SP; 1/7 OP p= 0.4), 3/renal replacement therapy (RRT) (1/9 SP; 1/7 OP p = 0.8). As well, IMCU mortality (OR 4.1, 95% CI 0.69-24.24, p= 0.1) and 90-day mortality (OR 1.6, 95% CI 0.41-6.96, p= 0.5) were similar in the two groups.
CONCLUSION. In our cohort of patients, SP pneumonia was not associated with increased risk of AKI and mortality when compared with other types of pneumonia in similar adult patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000770

INTRODUCTION. Among many conditions and interventions diabetes mellitus and major abdominal surgery have been recognized as risk factors in acute kidney injury (AKI) (1). However, some research studies denied association between diabetes mellitus and AKI in patients after surgery (2, 3, 4).
OBJECTIVES. To determine the association and clinical features of AKI in patients with unrecognized and/or poorly regulated diabetes mellitus after major abdominal surgery.
METHODS. This prospective, observational, monocentric study included sixty patients who underwent major abdominal surgery and were admitted to the intensive care unit after the surgery. Patients' follow-up, anamnestic, medical, measured and laboratory data were obtained on the 0, 1st, 2nd, 3rd, 7th, and 14th postoperative days as well as data on patients' condition at hospital discharge. Hemoglobin A1c (HbA1c) was used as a screening tool for previously unrecognized or unregulated diabetes.
RESULTS. AKI was recorded in 33.3% of patients. Patients with previously known diabetes mellitus, poorly regulated diabetes mellitus and unrecognized diabetes mellitus did not have a higher incidence of AKI (P>0.05). In patients with hypertension (P= 0.025) and patients who received furosemide (P=0.034, P=0.036, P=0.033), vasopressor (P=0.036, P=0.036) and blood derivatives (P=0.022) a higher incidence of AKI was observed at one or more days. The appearance of AKI did not affect the length of stay in the intensive care unit (P= 0.567), readmission in the intensive care unit (P=0.548), total hospitalization time (P=0.504) and mortality (P=0.595).
CONCLUSION. The results of this study did not confirmed association between diabetes mellitus and AKI after major abdominal surgery. Use of HbA1c helped in avoiding inadequate interpretation of results due to poorly controlled and unrecognized diabetic patients.

Neurally Adjusted Ventilatory Assist: A cross-sectional staff survey

D. Hadfield
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000013

INTRODUCTION. Clinical effectiveness of Neurally Adjusted Ventilatory Assist (NAVA) has not been demonstrated and feasibility data are required. The aim of this survey was to assess NAVA from the perspective of staff users, and inform a feasibility trial prior to a definitive RCT.
METHODS. Web (SurveyMonkey) and paper-based, anonymous, self-administered cross-sectional survey, approved as part of a concurrent randomised feasibility trial (NCT01826890). Organised into four domains:

- Training and experience
- Advantages and disadvantages
- Barriers and attitudes
- Views on research

RESULTS. Of the 462 distributed surveys, 301 (65.4%) were returned from 236 nurses (78.4%), 56 doctors (18.6%) and 12 physiotherapists (4.0%). Responses were well distributed between levels of staff seniority.
NAVA training had been received by >50% of participants; 227/301 (70.4%) had clinical experience of NAVA and 123 (64.4%) of those had used Edi monitoring. Despite this, NAVA was perceived as infrequently used with staff citing 'low confidence' and 'lack of experience' as key barriers to acceptance.
Most participants agreed or strongly agreed that the NAVA mode was safe (136/177, 76.8%) and clinically effective (99/176, 56.3%), and that Edi monitoring was clinically effective (101/172, 58.7%), citing improved synchrony, comfort and reduced time on ventilation as the main perceived advantages. 'Technical issues' was the most cited clinical disadvantage (129, 68.3%). Mode cross-over was also perceived to occur often, with 'Edi signal problems' the most cited cause (39/168, 23.2%).
In comparison to PSV, respondents perceived NAVA as performing equally well, and to be 'easier' in respect to synchrony, comfort and weaning (all p<0.0001), with no increase in workload. NAVA was, however, perceived as generally harder to use (105/174, 60.3%), particularly in relation to 'set-up and start' and 'reliability' (p<0.01). PSV was preferred to NAVA for ventilator weaning (93/171 [54.4%] versus 29/171 [17.0%]; p=<0.0001), although a large proportion (49/171, 27.1%) were ambivalent.
In relation to research, almost all 161/180 (89.4%) were generally supportive; 110/180 (61.1%) had cared for a patient on the trial; no participants felt that the protocol was unacceptable, with the majority (60/119, 50.4%) finding it very or completely acceptable.
CONCLUSION. These results highlight key factors that may interact with parameters in a future trial. The difficulty and lack of confidence perceived by respondents may be modified via training and NAVA usage guidelines. Of more concern are the technical difficulties as reported here and elsewhere 1. Further assessment of these factors may be necessary prior to a definitive RCT.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000022

INTRODUCTION. Different Lung Injury Prediction Scores (LIPS) had been derived to identify patients at risk for acute respiratory distress syndrome (ARDS).
OBJECTIVES. This study was intended to derive a new ARDS prediction score in high risk critically ill patients.
METHODS. We recruited 200 patients [63(43-70)years old, 120(60 %)males] admitted to ICU with APACE-II≥15 and at least one ARDS risk factor after excluding patients with ARDS on admission, cardiac patients, and readmission. The presence of risk factors together with the admission and 48-hours CRP (CRP-0&CRP-48) were tested in univariate then multivariate regression models for identifying significant predictors whose weights were assigned according to the β-coefficient of the regression model. Our score was compared with a previously derived score by Trillo-Alvarez et al on 2011 (LIPS-T). The primary and secondary outcomes were the development of ARDS and in-hospital mortality respectively.
RESULTS. ARDS developed in 88 patients(44%). Logistic regression revealed that only pneumonia, tachypnea, increased heart rate and increased CRP-48 are significant ARDS predictors. The weight of each predictor was estimated according to its β-coefficient. The new score was 35.5(27-44) and 14(9-24.3) in ARDS and non-ARDS patients respectively(P=0.000). The AUC of the new score was 0.827 compared to 0.74 for the LIPS-T(P=0.014). A score of 20 had a sensitivity and specificity of 82 % and 71 % in predicting ARDS. Our score was significantly lower in survivors compared to non-survivors(P=0.000). Its AUC in predicting in-hospital mortality was 0.761 compared to 0.657 for the LIPS-T(P=0.0045).
CONCLUSION. This study derived new simple LIPS score which could be better than the previously derived scores in terms of predicting ARDS and in-hospital mortality in critically ill ICU patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000024

INTRODUCTION. Blood oxygen desaturation is the most common physiological change in mechanically ventilated patients during nurse cares periods that are routinely performed in the intensive care unit (ICU).
OBJECTIVES. To assess the ability of an automated closed-loop ventilation mode (Intellivent-ASV®) to reduce blood oxygen desaturation incidence and depth during daily nurse cares.
METHODS. We performed a prospective randomized crossover study in a 22 beds French mixed ICU, including mechanically ventilated patients with FiO2 ≤ 60% and without prone position and/or neuromuscular blocking agent. After inclusion, patients had two consecutive nurse cares periods (each separated by six hours) performed in a randomized order: one using Intellivent-ASV® and another using conventional mode. Ventilation modes were set by the attending physician 30 minutes before the procedure. The primary endpoint was the minimal pulse oxygen saturation level (SpO2min) during the procedure.
RESULTS. Among the 265 included patients, 93% were admitted for a medical pathology, and were intubated for pneumonia (50%), coma (32%), sepsis (32%) and acute respiratory distress syndrom (20%). Pressure support was the most common ventilation mode used in the conventional arm (91%). There was no difference between both modes regarding use of sedation, nurse cares duration and ventilator parameters except for spontaneous cycling higher and peak pressure lower in Intellivent-ASV® ($p < 0.001$ respectively). SpO2min ≤ 85% incidence was significantly lower and more patients had a SpO2min in the optimal range (between 90 and 95%) with Intellivent-ASV® ($p = 0.02$ and 0.002 respectively). Nurses had to manually increase FiO2 to 100% less frequently with Intellivent-ASV® ($p = 0.004$). Finally, multivariable logistic regression showed that nurse cares periods performed in Intellivent-ASV® reduced significantly the SpO2min ≤ 85% incidence (OR 0.5; 95%CI [0.3 – 0.9]; $p = 0.01$).
CONCLUSION. In this monocentric study, Intellivent-ASV® mode seems to be an interesting tool for nurses to stay focus on patients cares by reducing blood oxygen desaturation incidence and depth, with less manual interventions in comparison with conventional modes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000036

INTRODUCTION. APRV is a relatively new mode of mechanical ventilation which can be used in treatment of patients with impaired oxygenation, but this mode is not widely used by clinicians. Physiological dead space (VDphys.) is an important parameter to assess respiratory function which is equal to the the volume of airway plus ventilated non- perfused alveoli. We conducted this study to compare APRV and BiPAP modes regarding VDphys. and other respiratory variables (pressures and blood gases). Our hypothesis is that the long inspiratory phase in APRV may increase VDphys. (by impairing perfusion) and may affect other respiratory variables.
OBJECTIVES. To compare APRV and BiPAP modes regarding VDphys., respiratory pressures and blood gases parameters.
METHODS. Mechanically ventilated patients with PO2/FiO2 ratio< 300 were randomized into two groups: Group A (APRV group) :APRV mode was used with high pressure (Phi) 20 cmH2O , low pressure (Plo) 5 cmH2O with I:E ratio (Phi phase: Plo phase ratio) 4:1 for 3 hours. Group B(BiPAP group) : BiPAP mode was used with high pressure (Phi) 20 cmH2O, low pressure (Plo) 5 cmH2O with I: E ratio (Phi phase: Plo phase ratio) 1:1 for 3 hours. Then all patients were left for ventilation according to the preference of the physician in charge. VDphys. was measured using the metabolic module of GE ventilators. Respiratory variables were also recorded. All measurements were done at 30 minutes and at

the end of the intervention period (3 hours).
RESULTS. Sixty patients were available for final analysis (30 in each group). There was no statistically significant difference in age (51.7±15.2 vs 54.3±16.1, p=0.52) and weight (75.80±13.28 vs 76.57±15.93, p=0.840) between the two groups. VDphys/tidal volume (VT) at 30 minutes was (0.47 ±0.09 vs 0.46 ± 0.08, P=0.61) and at 3 hours was (0.44 ± 0.10 vs 0.43 ± 0.11 , p=0.67) in the two groups respectively. there was a reduction in VDphys/VT within each group at 3 hours but it was not statistically significant (p=0.11 for group A and 0.13 for group B). There was improvement of dynamic compliance within each group (36.17 ± 9.1 vs 39.7± 8.33, p=0.002 for group A) and (37.87 ± 7.84 vs 42.37 ± 7.84, p=0.001 for group B). PCO2 was increased in group B (39.17 ± 8.72 vs 42.67 ± 7.73, p=0.013) but it was not clinically significant.

CONCLUSION. APRV mode didn't increase physiological dead space compared to BiPAP mode. Both modes improved dynamic compliance.

Hyperoxia in a General UK Intensive Care Unit (ICU)

R. Charlton[1], M. Carpenter[2]
[1]Newcastle University Medical School, Newcastle upon Tyne, United Kingdom; [2]Intensive care, Sunderland Royal Hospital, Sunderland, United Kingdom
Correspondence: R. Charlton

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000049

INTRODUCTION. Whilst the dangers of hypoxia are well documented, it has recently been proposed that too much oxygen, hyperoxia, may also be harmful to patients. There is a greater risk of mortality associated with hyperoxia, due in part to increased production of reactive oxidative species and vasoconstriction. Due to the widespread use of supplemental oxygen in ICU patients, this group is at a high risk of hyperoxia.
OBJECTIVES.

- To determine the prevalence of hyperoxia in patients receiving supplemental oxygen in ICU.
- To determine whether action is taken to reduce the amount of oxygen delivered to patients based on hyperoxic capillary oxygen saturation (SpO_2) and arterial partial pressure of oxygen (PaO_2).

METHODS. As part of a medical school project, a prospective audit was undertaken in a UK general mixed ICU/HDU of SpO_2 and PaO_2 of 53 consecutive patients receiving oxygen therapy, over 255 patient bed days, between 19/1/2019 and 6/2/2019.
Data was obtained from patient observation charts, and SpO_2 >96% (or >92% in the case of carbon dioxide retention), and PaO_2 >14kPa were considered 'hyperoxic'. Any action taken to reduce the fraction of inspired oxygen (FiO_2) as a result of hyperoxia was documented.
RESULTS. Over 255 bed days on ICU 4338 SpO_2 and 609 PaO_2 of 53 consecutive patients receiving supplemental oxygen were analysed to identify the prevalence of hyperoxia and the likelihood of action being taken to reduce the FiO_2 as a result. 2364 SpO_2 (54%) and 135 PaO_2 (22%) were found to be 'hyperoxic'.
Action was taken to reduce FiO_2 in a total 372 instances of recorded hyperoxia (15%). A PaO_2 above target was more likely to prompt action (FiO_2 reduced in 33% hyperoxic recordings) than an SpO_2 above target (FiO_2 reduced in 16%) as illustrated in Figure 1.
CONCLUSION. A significant proportion of recorded SpO_2/PaO_2 in 53 consecutive ICU patients were above target showing that there is a high prevalence of hyperoxia in ICU patients receiving supplemental oxygen. The FiO_2 delivered to patients was reduced in a small fraction of those found to be hyperoxic. A PaO_2 above target was more likely to prompt action to reduce FiO_2 than an SpO_2 above target.
Staff education with regards to the importance of recognition and management of hyperoxia and conservative oxygenation targets for patients may reduce the risks associated with hyperoxia.

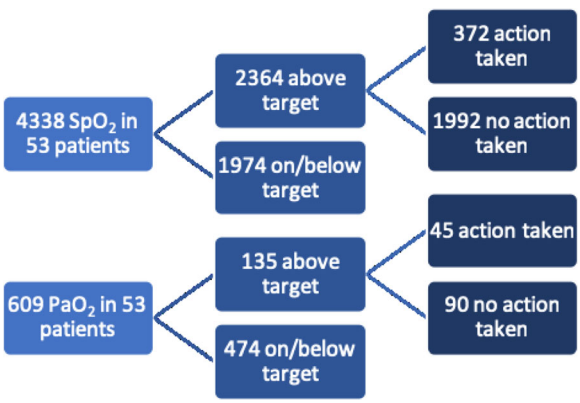

Fig. 1 (abstract 00049). A proportion of hyperoxic SpO_2 and PaO_2 in 53 consecutive ICCU patients resulted in a reduction in FIO_2.

Comparison of various noninvasive respiratory support methods in cardiovascular surgery patients with postextubation respiratory failure

A. Eremenko, P. Polyakova
Intensive care unit, Petrovsky Russian Research Center of Surgery, Moscow, Russia
Correspondence: P. Polyakova

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000058

INTRODUCTION. Postextubation respiratory failure in the early postoperative period occurs in 5-25% [1,2] of cardiac surgery patients and various methods of noninvasive respiratory support are available for it's treatment.
OBJECTIVES. Comparative evaluation of the effect on gas exchange of conventional oxygen therapy (COT), noninvasive positive airway pressure mask ventilation (NIPPV) and high-flow nasal cannula therapy (HFNC) in the patients with postextubation respiratory failure after cardiovascular surgery.
METHODS. 52 cardiac surgery patients (age 60±11years) with respiratory failure manifested in the postoperative period after tracheal extubation were included into the study. Respiratory failure criteria: PaO2/FiO2≤300 mmHg or SpO2≤88% on room air. Patients with pleural effusion, pneumothorax and paresis of diaphragm were excluded from the study. In each patient sequentially performed blood gas analysis when breathing room air, COT (mask with pre-volume bag), HFNC and NIPPV. Duration of application of each method before taking of analyses was 1 hour. Respiratory rate (RR) and SpO2 were monitored throughout the study. Optimal parameters for HFNC were: FiO2 47±9%, flow rate - 36,7±9 l/min, and for NIPPV: PIP - 13,3±4,0 mmH2O, PEEP - 6,65±2,04 mmH2O, FiO2 - 50±8%, TV - 7,2±1,27 ml/kg.
RESULTS. During COT, mean PaO2/FiO2 ratio was 193±73 mmHg. After change to HFNC it increased to 247±87 mmHg (p=0.0025), and on NIPPV - to 234±67 mmHg (p=0.0097). The same tendency was observed with SpO2: at HFNC and NIPPV it was significantly higher than at COT (97.27±2.29% and 96.37±2.1% versus 94.63±3.51%, p= 0.000028 and p=0.0058, respectively). PaCO2 during COT was higher than on air (42.16±8.33 mmHg and 38.64±6.58 mmHg, respectively, p=0.04). After change to the noninvasive ventilatory support PaCO2 decreased by 9.82% (38.02±7.26 mmHg, p=0.015) on HFNC and by 5.86% (39.69±7.59 mmHg, p=0.16) on NIPPV. Significant differences in values were found in RR during COT (21.02±6.59 bpm) compared to HFNC (17.27±6.5 bpm, p=0.0042) and on NIPPV it was not significant (18.89±5.1 bpm, p= 0.072).
CONCLUSION. NIPPV and HFNC in patients with postextubation respiratory failure after cardiac surgery have similar positive effect on gas exchange to compare to the mask with pre-volume bag. HFNC has better effect on RR and CO2 elimination than NIPPV.

INTRODUCTION. Spontaneous breathing trial (SBT) during weaning from mechanical ventilation aims at testing ability of respiratory system to work without breathing assistance. SBT can be delivered through T-piece trial or low pressure support (PS) level. Low PS is thought to compensate for endotracheal tube (ETT) resistance (RET), and, hence no further assistance would be provided by the ventilator. We reasoned that this may not be true with the modern ICU ventilators. The real way to compensate for RET only is the automatic tube compensation (ATC) option. Our hypothesis was that low PS was associated with a significant reduction in work of breathing (WOB) as compared to ATC.
METHODS. We underwent a prospective, short-term, physiological, cross-over study (NCT02939963) where patients with criteria for SBT after at least 24 hours of mechanical ventilation in our ICU received PS7 cmH2O positive end-expiratory pressure (PEEP) 4cmH2O without ATC (low PS group) and ATC PEEP4cmH2O without PS (ATC group) as SBT trial. Patients with chronic respiratory failure under long term home oxygen therapy and/or noninvasive ventilation before ICU admission, tracheotomy, nasogastric tube contra-indicated, thoracic tube in place, no agreement to participate were not included. Low PS and ATC were randomly applied for 30 minutes each and preceded by a 30-min control period with the PS level before the study. ATC was set at 100% compensation of patient's ETT size. Esophageal and airway pressures and flow were measured at ETT proximal end. At the end of each period resistive and elastic components of WOB done by the patient were obtained from the Campbell diagram over a 2-min recording at the end of each period. Power of breathing (W) and W/liter ventilation were determined as WOB times respiratory rate and W divided by minute ventilation, respectively. Primary end-point was total (resistive + elastic) W. We computed that 16 patients should be required for a 4±4 J/min reduction in W with low PS as compared to ATC be statistically significant at 5% and 20% risks, respectively. Analysis was done using linear mixed model testing effect of treatment (low PS vs ATC), period and interaction between them. Values are median (1st-3rd quartiles).
RESULTS. Twenty patients were included over 12 months. Between low PS and ATC, W was 6.4 (4.3-9.3) and 9.8 (5.3-22.0) J/min (P= 0.011) with no significant effect of both period and interaction between treatment and period. Both resistive (3.2 (2.1-4.6) vs. 4.7 (1.5-9.7)J/min P=0.035) and elastic (3.6 (2.3-4.5) vs. 5.2 (3.6-8.8) J/min P= 0.0096) W were significantly lower with low PS than ATC. W/liter minute ventilation was significantly lower in low PS (0.74(0.53-0.93)) than in ATC group (0.97 (0.68-1.54)) J/L (P=0.004). Both resistive and elastic components of W/liter minute-ventilation (0.33 (0.23-0.53) vs. 0.47 (0.22-0.74) (P=0.04) and 0.40 (0.32-0.47) vs. 0.63 (0.45-0.69) J/L) (P=0.00005) were significantly lower with low PS than with ATC, with no significant effect of period and no interaction.
CONCLUSION. When SBT is done by using low PS a respiratory support is provided to the patient above the compensation of RET. Low PS does more than just compensating for RET.

Differences in prognostic factors between direct and indirect ARDS in pediatric patients

DH. Kim, EJ. Ha, WK. Jhang, SJ. Park
Pediatrics, Asan Medical Center, Seoul, Republic of Korea
Correspondence: D. Kim
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000098

INTRODUCTION. Direct (Pulmonary) and indirect (extrapulmonary) acute respiratory distress syndrome (ARDS) differs responses and therapeutic effects of both groups were heterogenous. However, there were few studies to definite results about it, especially critically ill pediatric ARDS (PARDS) patients.
OBJECTIVES. This study aims to compare two ARDS groups in the clinical outcomes and the risk factors for mortality.
METHODS. This was a single center, retrospective study. Among the children admitted to the pediatric intensive care unit (PICU) of a tertiary care children's hospital between October 2010 and October 2018, 144 pediatric patients classified as either pulmonary (n=119) or extrapulmonary (n=25) ARDS were included. Patients who had L-R shunt and heart failure were excluded. We used the unpaired student's t-test and Univariate logistic regression for risk factors of mortality in each sutyptes of ARDS.
RESULTS. There was significant difference in the PICU mortality rate by PARDS level between two groups. The mortality was significant increased by PARDS level in direct ARDS group but not in indirect ARDS group (p=0.002 vs p=0.774). The direct ARDS group showed that PaO2/FiO2 (P:F ratio, p=0.005), Oxygen index (OI, p=0.037), FiO2 (p<0.001), peak expiratory end pressure (p=0.002), driving pressure (p=0.035), peak inspiratory pressure (p<0.001) and mean airway pressure (p<0.001) were significant risk factor in mortality, while the indirect ARDS group had significant risk factor as lactate (p=0.007) and percentage of neutrophil (p=0.002) in mortality

CONCLUSION. Our results, showing that clinical outcomes and risk factors for mortality rate differ by ARDS types suggest that pulmonary and extrapulmonary ARDS could have different clinical courses and thus should be managed distinctly

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000107

INTRODUCTION. Severe pneumonia is major risk factor to develop Acute Respiratory Distress Syndrome (ARDS). Early recognition of patients at risk to develop ARDS is not only crucial but pivotal. The Berlin criteria aids in diagnosis of ARDS however, the absence of a standard diagnostic biomarker may lead to under-recognition and delayed evidence-based interventions. To date, most studies on ARDS biomarkers are retrospectively done. Among these, plasma fibrinogen has shown association with ARDS progression in patients with severe pneumonia.
OBJECTIVES. At present, the clinical utility of plasma fibrinogen for ARDS is unknown. With this study, we sought to find association between plasma fibrinogen levels and progression to ARDS among patients with severe pneumonia.
METHODS. In this prospective cohort study, patients diagnosed with severe pneumonia based on IDSA criteria were enrolled from July 2018 to February 2019. Baseline clinical and laboratory parameters were recorded and disease severity were scored using APACHE II. Two determinations of plasma fibrinogen were done, first within 24 hours of disease recognition and the second after 48 hours. The participants were then followed for 7 days with development of ARDS as the primary outcome. The diagnosis of ARDS was made by the intensivist on-duty and/or the attending pulmonologist.
RESULTS. Forty-seven patients were prospectively monitored within 7 days of enrolment then divided into two sub-groups between twelve (25%) patients who developed ARDS and thirty-five (75%) patients who did not. Fibrinogen levels at baseline had sensitivity and specificity of 41.7% and 57.1% respectively (p=0.932), levels after 48 hours had sensitivity and specificity of 55.6% and 65.6% respectively (p=0.729), and delta fibrinogen levels had sensitivity of 55.6% and specificity of 62.5% (p=0.581) (Table 1). Low platelet counts and higher PEEP levels used were found to be statistically significant parameters for ARDS progression.
CONCLUSION. Based on this study, plasma fibrinogen is an unreliable biomarker for predicting ARDS development in patients with severe pneumonia. To our knowledge, this is the first attempt to investigate on a biomarker for ARDS progression in the Philippines. A higher-powered study with more robust sample size is recommended. However, further analysis regarding local incidence of ARDS should be made. Hopefully, this study will serve as benchmark for further research as relevant information and local data are still lacking. Other biomarkers that can predict ARDS development amongst patients at risk should be further investigated.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000112

INTRODUCTION. A spontaneous breathing trial is commonly performed to assess whether a patient can tolerate without ventilator support. However, the reintubation rate is 10-20% even after successful SBT. Although physiologic parameters during SBT, such as the work of breathing (WOB) or the pressure time product (PTP), may inform the risk of reintubation, measurement of such parameters is not technically simple. Proportional assist ventilation with load-adjustable gain factors (PAV+) can easily estimate the WOB and the peak inspiratory muscle pressure (Pmus).
OBJECTIVES. We investigated whether the WOB and the Pmus estimated by PAV+ during SBT can predict post-extubation respiratory failure and necessity of reintubation.
METHODS. This study was a prospective observational study in a single center in Japan. All patients over 18 years old who were mechanically ventilated and passed SBT using a mode of PAV+ with a support rate 20% were included. We recorded the average of WOB, peak inspiratory pressure (Ppeak), compliance and resistance measured by PAV+ during SBT. And we calculated the peak Pmus from Ppeak. The primary outcome of this study was post-extubation respiratory failure within 72 hours.
RESULTS. A total of 50 mechanically ventilated patients were included. Eighteen patients had post-extubation respiratory failure within 72 hours. The patients with post-extubation respiratory failure showed

significantly higher peak Pmus than those without post-extubation failure (14.0 vs 12.3 cmH2O, p=0.025). There were no siginificant differences in WOB (3.81 vs 3.21 J/min, p=0.115), compliance (63 vs 61 mL/cmH2O, p=0.846), and resistance (5.3 vs 4.8 cmH2O/L/s, p=0.623) measured by PAV+ between the two groups.
CONCLUSION. Peak Pmus estimated by PAV+ during SBT is a possible predictor of post-extubation respiratory failure. Larger sample size is needed to further determine the usefulness of the test.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000142

INTRODUCTION. EVLW accumulates in the lungs even before the changes in blood gases and chest x-ray become apparent. The lungs which have high compliance tend to expand to a greater extent as compared to the lungs with low compliance.Martelius et al found that a significant decrease in the number of B lines is associated with improved static lung compliance in a prospective observational study of 34 infants. However, till date, no study has been done in adults to correlate EVLW with lung compliance. Therefore, we planned to do this study in adult patients.
OBJECTIVES. To assess quantitative correlation of B lines on bedside lung ultrasound with static lung compliance in adult patients on mechanical ventilation. and to assess correlation of B lines with oxygenation index.
METHODS. The study commenced after the clearance of the ethics committee of the institute. Informed consent was taken from the patient or the patient's legal guardian to enroll them in the study. Following approval from institutional ethics committee study was conducted from October 2017 to June 2018. (Ref.No.NK/3868/MD/299).During the study a total of 200 lung ultrasound readings were recorded along with static lung compliance and oxygenation index.
Static compliance was recorded along with lung USG. For static compliance, there should be no patient effort. It was calculated with a tool given in eVent ventilator 10 mins after giving short-acting muscle relaxant like atracurium(0.5mg/kg) and sedatives like midazolam or fentanyl.
Oxygenation Index(OI) = FIO2/PaO2×MAP
FIO2 = Fraction of inspired oxygen, Pao2= Partial pressure of arterial oxygen, MAP= Mean airway pressure
RESULTS. Sixty-one patients, with 200 USG readings in total, were included in our study. Minimum gap between 2 readings was 24hrs.
All patients had a comparable demographic profile. The B line score and static lung compliance appear to be inversely related which means higher the B line score, lower is the static lung compliance. Correlation showed R2 of 0.43 which explains the 43% changes in static lung compliance values could be explained by changes in the B line scores.
A positive linear correlation was found between B line score and oxygenation index. This suggests as number B lines in lung increases the oxygenation index also increases. Correlation showed R2 value of 0.403 explains 40% of change in B line scores correlated positively with the oxygenation index as shown by R2 value of 0.40.
CONCLUSION. The most important finding in our study was a negative correlation of B line score with static lung compliance having a significant R2 value of 0.43. Other findings were a positive correlation of B line score with oxygenation index and a negative correlation of lung compliance with oxygenation index. Through our analysis, we can conclude that increase in number of B lines is associated with concomitant decrease in lung compliance and increase in oxygenation index in adult patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000144

INTRODUCTION. Automatic tube compensation (ATC) is an option available in intensive care unit (ICU) ventilators to compensate for endotracheal tube (ETT) resistance. To achieve this ICU ventilator delivers a certain amount of pressure/flow that compensates for the resistive pressure drop across ETT. It requires notifying size of ETT and percent of compensation. We reasoned that if ATC works properly tidal volume (VT) should be the same without ATC and no ETT as with ATC and ETT. We tested the performance of ICU ventilators on a bench, expecting furthermore differences between them.

METHODS. Seven ICU ventilators (Evita XL and V500 infinity (Draeger), C6 and S1 (Nihon-Khoden), Elisa 800 (Lowenstein), 980 (Medtronic), Carescape 860 (GE)) were set in pressure support 0 cmH2O, PEEP 4 cmH2O, FIO2 21% and equipped with the same double limb ventilator circuit (Intersurgical) without any humidification device. ASL 5000 bench model was set with 3 inspiratory/expiratory resistance (R) and compliance (C) combinations: R13/12-C54, R12/14-C39 and R22/18-C59 mimicking normal, ARDS and COPD conditions, respectively (1). Inspiratory effort generated by ASL 5000 consisted of 30 consecutive breaths obtained from the esophageal pressure in a real patient at the time of a spontaneous breathing trial. For each ICU ventilator and RC combination, two steps were performed: in the first, ATC was not activated and ventilator attached to ASL 5000 without ETT (ATC-ETT-); in the second, ATC was set on at 100% compensation for an ETT 8 mm ID and such an ETT (Shiley Hi contour, Covidien) joined ICU ventilator to ASL 5000 (ATC+ETT+). The null hypothesis is that VTATC+ETT+ minus VTATC-ETT- is 0. Primary end point was the breath by breath paired difference betwen ATC+ETT+ and ATC-ETT-. It was tested to zero for each ventilator in each RC condition.

RESULTS. Median VT was 213 ml. Table 1 displays mean (±SD) difference in VT (ml) between ATC+ETT+ and ATC-ETT-: a negative value means that ATC under delivers and a positive value that ATC over delivers VT for a given patient's inspiratory effort and RC. In four ventilators (C6, S1, Elisa 800 and 980) ATC almost systematically under delivered VT. In several instances under compensation was greater than 10% median VT. By contrast ATC performed better with the other three ventilators (Evita XL, V500 and Carescape 860).

CONCLUSION. ATC tended to under deliver VT. Furthermore, there were marked differences between ICU ventilators the clinician should be aware of when using the ATC option.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000164

INTRODUCTION. Exercise is considered an important intervention to facilitate weaning from mechanical ventilation and limit long-term functional dependence. However, the exercise intensity of individual patients during rehabilitation is not measured. This potentially leads to under training of some and overtraining of others.
Breath-by-breath gas exchange analysis (BBGEA) is the gold standard for measuring oxygen consumption (VO_2) to calculate workload. While an invaluable research tool, it is impractical for use in routine clinical practice. Alternative methods of monitoring exercise intensity during rehabilitation are required.
During BBGEA data collection for previous studies, we noted (i) how closely minute ventilation (VE) tracked VO_2 and (ii) recovery of VE to the pre-exercise state was indicative of VO_2 returning to baseline. While VE could potentially be used as an indicator of recovery between exercise bouts during a rehabilitation session, the complexity of the relationship between VE and VO_2 currently negates its use as a direct estimate of absolute exercise intensity.
OBJECTIVES. We aimed to establish whether exercise VO_2 could be estimated from exercise VE, RR, VT and resting end-tidal CO_2 ($PETCO_2$).
METHODS. VE, RR, $PETCO_2$, VT and VO_2 were recorded using the Medgraphics Ultima device during rehabilitation of 37 patients on 106 occasions.
Principle component analysis (PCA) was used to describe the variation in the data between, VE, RR, VT. The first 2 PCA components accounting for 98% of the variance, were added to a linear mixed effects model along with the explanatory variables; resting $PETCO_2$, age, gender and weight. The fixed effect of the model was patient.
The measured VO_2 values were classed as low 3.5 - 4.5 ml/kg/min, medium >4.5 - 5.5 ml/kg/min and high > 5.5ml/kg/min. The performance characteristics of the model were assessed using a confusion matrix.
RESULTS. In a small sample size we demonstrate good agreement between actual and predicted VO_2 from a model using VE, RR, $PETCO_2$, VT, age, gender and weight. The MROC area under the curve for this model was 88%. The performance classifiers are given in table 1. This model requires future validation in an independent sample to confirm its utility.
CONCLUSION. Predicting VO_2 from easily obtainable observations in ICU may be possible during rehabilitation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000170

INTRODUCTION. During educational process, trainees apply their knowledge to treat patient in intensive care before achieving full clinical competency. Moreover, advances in knowledge regarding mechanical ventilation in particular lung protective ventilation and asynchronies have been shown to be associated with mortality. For these reasons we developed a simulator of controlled and spontaneous artificial ventilation (Sim-VA) and virtual breathing patients. Mathematical model resolved differential equations of chest and lung movements according to inspiratory effort or not, in order to match with a clinical database.
OBJECTIVES. The aim of this study was to compare two teaching modalities on mechanical ventilation: traditional lectures versus virtual simulation.
METHODS. This randomized controlled study involved 54 residents. One group of 22 participants attended the same didactic lecture on mechanical ventilation (3 hours) whereas the other 22 were in the simulator group (3 hours). Performance was measured using a pre and post-test evaluation of knowledge on respiratory settings and pressure flow time curves monitoring in ARDS and COPD patients. A retention test was done at 3 months (The same questioner was used for pre, post and retention test). Comparison was individual in each group (*ANOVA, multiple comparison) and between groups (Mann-Whitney), p< 0,05 was considered significant.
RESULTS. Baseline knowledge was not different between groups; post-test was significantly improved in both groups (figure) but was significantly higher in the simulator group. Retention test was only significantly different from the pre-test in the simulator group.

CONCLUSION. A computer-based simulation with a modelisation of controlled and spontaneous mechanical ventilation has the potential to improve knowledge and skills in ventilator settings in comparison to traditional didactic lectures.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000172

INTRODUCTION. In numerous studies, high-flow oxygen through nasal cannula (HFNC) has proven beneficial for patients with hypoxic respiratory failure (1-3). In these studies, patients with hypercapnia are generally excluded. Therefore, use of HFNC in hypercapnic patients is controversial.
OBJECTIVES. To compare the need for endotracheal intubation and mortality risk in patients with acute respiratory failure with hypoxemia and hypercapnia, admitted to the intensive care unit (ICU) and treated with either HFNC or non-invasive positive pressure ventilation (NIPPV).
METHODS. Retrospective cohort study of adult, hypoxic and hypercapnic patients admitted to the ICU, identified by start of treatment with either HFNC or NIPPV at admission. Patients were included between September 2015 and August 2018 at Zuyderland Medical Center, The Netherlands.
RESULTS. After screening 676 patients with 1109 episodes, 95 patients fulfilled all inclusion criteria. Out of these patients, 35 received HFNC and 60 NIPPV. In both treatment groups, pH and paCO2 values improved 6 and 24 hours after start therapy. Arterial pH improved in the first 24 hours from 7.27 to 7.40 in the HFNC group and from 7.26 to 7.32 in the NIPPV group (p=0.001 between groups at t=24 hours). The pCO2 improved from 9.3 to 7.1 kPa in the HFNC group and from 9.2 to 8.3 kPa for patients treated with NIPPV (p=0.05 between groups at t=24 hours). Need for intubation did not differ significantly between HFNC and NIPPV (35% and 22% respectively; p=0.4). In contrast, mortality was increased using HFNC instead of NIPPV (41% versus 12% in HFNC; p=0.039). Subgroup analysis revealed that in patients with chronic obstructive pulmonary disease (COPD), both the need for intubation and mortality risk were not different between HFNC and NIPPV (p=0.6 and p=1.0, respectively). Time analysis showed no significant difference between groups in time between admission and death (Log Rank p=0.5).
CONCLUSION. This study shows a proof of principle of HFNC in patients with hypercapnic respiratory failure at the ICU in terms of improvement of arterial blood gas (ABG) values. However, when comparing all hypercapnic patients admitted to the ICU in this study, treatment with HFNC seems to be associated with an increased mortality risk. In patients admitted for COPD, there is no increased risk for intubation or mortality when compared to NIPPV. These data suggest that HFNC might be useful for hypercapnic patients with an acute exacerbation of COPD, but may have an adverse outcome in other hypercapnic patient groups.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000177

INTRODUCTION. Respiratory support plays an important role in patient's recovery after cardiovascular surgery. Adaptive support ventilation (ASV) is an automatic closed-loop ventilation mode where minute volume is controlled by a combination of tidal volume (Vt) and respiratory rate settings based on patient's respiratory mechanics. There is an ability to reduce workload for physicians without compromising patient's safety with using intellectual modes of mandatory ventilation.
OBJECTIVES. To compare the effect(s) of ASV and conventional ventilation modes.
METHODS. In this randomized controlled trial 40 adult patients were ventilated with ASV and 38 with conventional ventilation modes after uncomplicated cardiac surgery. Hamilton G5 ventilators were used and 8 physicians were involved into the study. All actions of physician's, ventilator settings and changes were monitored and recorded during mechanical ventilation and weaning. Care of both groups was standardized, except modes of postoperative ventilation.
We compared the physician's workload, through accounting number of manual ventilator settings made before tracheal extubation and time, which they spent near the ventilator in every group.
The secondary endpoints were duration of tracheal intubation in ICU, the frequency of undesirable events and the length of ICU and hospital stay.
RESULTS. There were no significant differences in the duration of respiratory support in ICU: 267,6±76,6 min (ASV) vs 270,5±80 min (control).
In ASV group the number of manual ventilator settings and time spent near the ventilator before tracheal extubation was lower: 2 (1-4) vs 4 (2-6), (p=0,0000) and 99±35 sec vs 166±70 sec (p=0,0001)

respectively. In the control group the time from changing mandatory to spontaneous mode after restoration of patient's respiratory activity took 36,5(12-76) min. In ASV group spontaneous breathing began immediately after recover of patient's respiratory drive, which meant less risk of patient-ventilator asynchrony.
ASV provided more protective ventilation: the driving pressure was significantly lower - ΔP on mechanical ventilation was 7,2± 1,6 cm H2O vs 9,3±2,1 cm H2O (p=0,000001) and on pressure support - 5,5±1 cm H2O vs 7,9±1,5 cm H2O (p=0,0000). There were no significant differences between the groups in Vt values: 7,0 (6-8,5) ml/kg (ASV) vs 7 (6-10) ml/kg (control) during mechanical ventilation and 7,5 (6,6-9,5) ml/kg in ASV vs 8 (7-10) ml/kg in control group during pressure support ventilation as well as in undesirable events and duration of ICU and hospital stay.
CONCLUSION. Application of ASV mode after uncomplicated cardiac surgery provides more protective mechanical ventilation and reduces the physician's workload without compromising the quality of respiratory support and safety of patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000192

INTRODUCTION. Some recent studies have shown that airway pressure release ventilation(APRV) might have some potential benefits in the patients with acute respiratory distress syndrome(ARDS). However, these results are inconsistent.
OBJECTIVES. The aim of our study is to conduct a meta-analysis to analyze the effect of APRV on respiratory variables and outcomes in ARDS patients.
METHODS. All eligible articles from MEDLINE, EMBASE, CENTRAL, and Chinese BioMedical Literature Database (January 2000–January 2019) were incorporated into this study. Studies were assessed independently by two reviewers. We extracted the data(Standard Mean Difference (SMD) for continuous variables and Risk Ratio (RR) for dichotomous variables) from the included studies. Heterogeneity was defined as P < 0.10 or I2 > 50%. Fixed-effect model was used to combine effective sizes if homogeneity was fine (P > 0.10,I2 < 50%),otherwise a random-effect model was used. Results are provided with a 95% confidence interval (CI) and associated p-value. STATA 13.0 software was used for the meta-analysis.
RESULTS. A total of 446 patients from eight studies were included in this meta-analysis. Compared with the LTV group, the patients in APRV group had a shorter length of hospital stay (SMD -0.37[-0.64, -0.10] p=0.006), shorter length of ICU stay (SMD -0.25[-0.45,-0.05] p=0.013) and higher success rate of extubation (RR =1.40[1.02, 1.96] p=0.048).After 72h ventilation, higher mean airway pressures (SMD 1.08[0.37,1.80] p=0.003) ,higher PaO2/FiO2(SMD 0.56[0.08,1.04] p=0.022), greater respiratory system compliance(SMD 0.68[0.11,1.25] p=0.019), lower PEEP(SMD -1.44[-1.75,-1.14] p<0.001) and lower total minute ventilation(SMD -0.74[-1.27,-0.21] p=0.007) were seen in APRV patients.
CONCLUSION. APRV may be a promising ventilation mode for ARDS patients, which can reduce the duration of both hospital and ICU stays, contribute to successful extubation and improve some respiratory indicators in comparison to LTV. However, more prospective and randomized trials are needed to further clarify these issues in the future.

INTRODUCTION. During the period of September 2018 to April 2019, the number of patients admitted to the intensive care unit with influenza A H1N1 in the city of Laredo was alarming. We decided to investigate the characteristics of our population for future health care interventions.
OBJECTIVES. Describe the clinical characteristics of adult patients who were hospitalized with the influenza A 2009 H1N1 virus in the city of Laredo (Texas, USA) from September 2018 to April 2019
METHODS. Using medical charts, we collected data on 38 adult patients who were hospitalized for at least 24 hours for influenza bronchopulmonary infection and who tested positive for influenza A 2009 H1N1 virus with the use of a real-time reverse-transcriptase-polymerase-chain-reaction assay.
RESULTS. Of the 38 adults of patients we studied, 42% were admitted to the intensive care unit for acute respiratory failure. Ninety-five percent of the patients belonged to the Hispanic ethnic group. Twenty-six percent were on intubated on mechanical ventilation and 16% received non-invasive mechanical ventilation. Only 2 patients were identified to be vaccinated against the influenza virus. None of the patients in the ICU had the influenza virus vaccine. There were 6 cases of ARDS of whom two required ECMO. The average body mass index was 23 ± 2.7 Kg/m2 in ARDS population versus 33 ± 9.9 kg/m2 in the non-ARDS patients. There was a moderately statistical significant correlation between BMI and ARDS patients (n=38,r=-0.44, P=0.005). Twenty-one percent of patients were on vasopressors of whom all were on mechanical ventilation. The most common comorbidities were diabetes mellitus (26%), COPD (24%), obstructive sleep apnea (10%), liver cirrhosis (8%) and chronic renal insufficiency (8%). All the patients received oseltamivir on admission. The average age of patients was 58 years old with 20 males and 18 females. The average age of ARDS patients was 51 years old.
CONCLUSION. During the evaluation period, 2009 H1N1 influenza caused a significant number of admissions to the intensive care unit. The most remarkable findings were the moderately significant correlation between a low BMI in the ARDS group vs. the non-ARDS group. Notable, also, was the minimal amount of patients who received the vaccine before admission. The city of Laredo is predominantly of Hispanic ethnicity located at the border with Mexico. This is the first study, in our knowledge, that includes the intensive care unit epidemiological data of influenza A 2009 H1N1 in the city of Laredo, Texas, USA. The impact of higher vaccination rate by patient education and closer surveillance with lower BMI are strategies to be considered for future studies.

INTRODUCTION. More than two thirds of patients who enter in Intensive care unit (ICU) require invasive or non-invasive mechanical ventilation (NIMV), diagnosis of ICU weakness and neuromuscular dysfunction are detected in 25-50% of the patients who require more than five days of mechanical ventilation. However there is lack of data of prevalence of diaphragmatic dysfunction (DD) in patients under non-invasive mechanical ventilation in ICU.
OBJECTIVES. The primary objective of this study was to stablish the prevalence of diaphragmatic dysfunction in non-invasive mechanical ventilation.
The secondary objective is to determine if the patients with diaphragmatic dysfunction had a larger duration of NIMV *vs* patients without diaphragmatic dysfunction.
METHODS. Cohort Study, Observational, Longitudinal, prospective.
73 patients with NIMV were recruited prospectively at the Department of critical care medicine ABC Medical Center. The thickness of the right diaphragm (RDT) was measured in the area of apposition of the diaphragm to the chest in both hemithorax, using an ultrasound transducer of 4 MHz and the right diaphragmatic fraction index (RDFI) and the change in diaphragm thickness(ΔTdi), was calculated.in patients with NIMV. The presence of DD was defined according to the presence of ΔTdi bilaterally less than 20% or less than 15 mm of diaphragm thickness.
RESULTS. The inclusion criteria were met for 73 patients. Overall prevalence of diaphragmatic dysfunction was 20% for a cutoff of 15 mm of thickness of the diaphragm or ΔTdi bilaterally less than 20%. the mean age was 70.4 SD ± 14, with APACHE II mean score of 20 SD±8.2. Charlston comorbidity index mean score of 4.3 SD ±1.6. The variables obtained from USG measurements were as follow. Right diaphragm thickness (RDT) 15.5 mm ± 5 mm, right diaphragmatic fraction index (RDFi) 23.1 ± 10.7% and change in diaphragm thickness(ΔTdi) was 27% ± 10. Media of Length of VMNI was 11.6 days in patients without diaphragmatic dysfunction and 16.6 days in patients in VMNI with diaphragmatic dysfunction. The diagnosis of DD was associated with increment in Length of VMNI with media 5 days OR 5.7 (IC 18.2-7.8).
CONCLUSION. A high prevalence of DD was identified in in patients with VMNI. The presence of DD was associated with an increment in days of VMNI.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001321

INTRODUCTION. In patients with chronic pulmonary disease, high levels of alkaline phosphatase (ALP) are associated with a neutrophilic inflammatory pattern within the pulmonary compartment. (1) Preclinical studies demonstrate markedly elevated ALP levels in animals with acute lung injury along with increased inflammatory markers. (2, 3) The role of ALP in critically-ill patients with acute pulmonary inflammation remains unknown.
OBJECTIVES. This study aimed to investigate if pulmonary ALP activity is associated with pulmonary inflammation in critically-ill patients. We hypothesized that patients with acute respiratory distress syndrome (ARDS) present with higher pulmonary ALP activity levels compared to non–ARDS patients.
METHODS. ALP activity levels were measured in bronchoalveolar fluid (BALF) and plasma samples of 125 critically–ill patients with ≥ 2 SIRS criteria from the prospective cohort trial 'Molecular Diagnosis and Risk Stratification for Sepsis' (MARS). Correlations between ALP activity and inflammatory cytokines were assessed by Spearman's correlation coefficient. Comparisons between groups were performed using Mann-Whitney U test according to data distribution.
RESULTS. There is a strong positive correlation between pulmonary ALP activity and pulmonary inflammatory cytokines. (r = 0.71 for IL–6 (Figure 1A); r = 0.80 for IL–8 (not shown)). In critically-ill patients, no difference in BALF ALP activity was detected between ARDS and non-ARDS patients ($p = 0.413$, Figure 1B), neither between patients with a direct or indirect cause of ARDS ($p = 0.36$, Figure 1C).

CONCLUSION. In this cohort of critically–ill patients, ALP activity strongly correlates with IL–6 and IL–8 levels within the pulmonary compartment. Pulmonary ALP activity is not different in patients with the clinical syndrome ARDS compared to patients without ARDS.

The expression and function of Piezo1 in ventilator associated lung injury in ARDS model

J. Guo
West China Hospital, Chengdu, China
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001328

INTRODUCTION. Acute respiratory distress syndrome (ARDS) is a common critical syndrome in critical care medicine, and lung protective mechanical ventilation has been recommended in ARDS patients. However, the mechanism is still not clear. Piezo1 protein is a recently discovered, which is a stretch-activated channel (SAC) and closely related to the mechanical signal transduction of eukaryotic cells1-3. But, there is still no evidence about its function in the ventilator associated lung injury in ARDS.
OBJECTIVES. To observe the expression of Piezo1 in the ventilator associated lung injury in ARDS in vivo., and study its role in LPS induced type II alveolar epithelial cells (AECII) injury, at last, we explained it`s protective mechanism on AECII injury.
METHODS. We carried animal experiments based on ARDS model treated with ventilator, and cell experiment under cyclic mechanical stretch stress(MSS) in vitro. Different tidal volume was given to ARDS animal induced by oil acid, and lung tissue,blood sample were collected to testify the diagnostic of ARDS, and then observe the expression of Piezo1 in ACEII cells. In vitro, we observed Piezo1 in ACEII injury induced by LPS, then we observed the cell apoptosis changes and studied the influence mechanism of Piezo1 on cells injury which induced by different cyclic MSS. At last, we combined with Piezo1-siRNA to study its role in ACEII injury.
RESULTS. From the artery blood gas and pulmonary tissue detection results, we had built successful ARDS animal model. After treated with ventilator, the lung injury can be improved, and compared with high tidal volume ventilation group (HV), low tidal volume (LV) group improved better. In cells apoptosis of lung tissue and AECII, we found the apoptosis rate was significantly increased in ARDS, and mechanical ventilation significantly reduced the apoptosis, most importantly, LV had lower apoptosis rate compared with HV ventilation. For Piezo 1, we had evidenced that it was enhanced in ARDS animal model and cyclic stretch stress in ACEII cells by western blot and immunofluorescence. The mechanical ventilation could decrease its expression, compared with HV, the gray value was less in LV group. There was same trend of Piezo1`s expression in cyclic stretch stress ACEII, and the less stretch was associated less expression of Piezo1. Further, we detected the lever of Calcium ion concentration and found intracellular Ca2+ was increased by flow cytometry, Immunofluorescence and Laser scanning confocal microscope from lung tissue and ACEII. The intracellular Ca2+ was influenced by the MSS, and it had lower lever in low cyclic MSS group compared with high cyclic MSS. At last, we combined with Piezo1-siRNA to study the piezo1`s role in cell injury, and found Piezo1-siRNA inhibited the Calcium influx, decreased intracellular Ca2+. In cell apoptosis, we found Piezo1-siRNA significantly decreased cell`s apoptosis in ACEII induced by cyclic MSS.
CONCLUSION. Piezo1 was high expression in ARDS animal and cyclic MSS cells, and its different expression was associated with the degree of MSS, the more, the higher. Piezo1-siRNA could decrease intracellular Ca2+ and cell apoptosis induced by cyclic MSS. Piezo1 maybe a new direction in ventilator associated lung injury in ARDS.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001334

INTRODUCTION. Chronic Obstructive Pulmonary Disease (COPD) is the third leading cause of death worldwide and it is responsible of important morbidity and healthcare costs. White blood cell populations are involved in the pathophisiology of COPD. Neutrophil to lymphocyte ratio (NLR), a simple, low cost index, has been recently proposed as prognostic marker of several inflammatory and cancer diseases.
OBJECTIVES. Neutrophil to lymphocyte ratio (NLR) and eosinophil to basophil ratio (EBR) could be considered as potential markers of systemic inflammation. We hypothesize that diagnosis and prognosis of severe patients admitted to Intensive Care Unit (ICU) due to exacerbated COPD, can be predicted with a routine blood test that include these variables.
METHODS. We made a prospective observational cohort study. We analyse consecutive patients who need hospitalization in ICU due to COPD exacerbation that require mechanical ventilation. We exclude patients with other inmunologic disease or antiinflammatory treatment. We analyse NLR and EBR at the moment of ICU admission, and we follow-up them in stable phase in external consultation, during 24 month period. We compare inflammatory markers in both phases and their relation with prognostic factors. Statistical analysis: STATA version 13
RESULTS. We include 55 patients. In the comparative study of inflammatory markers in exacerbated patients vs stable COPD patients, we found significant differences between leucocytes (12,3 x vs 5,6 p<0.001); neutrophils (10,5 vs 5,3; p<0.001); lymphocytes (1,02 vs 1,64; p:0.018); and eosinophils (0.039 VS 0.119; p<0.001). The NLR was significantly higher in exacerbated patients (19.310 vs 4.697; p<0.001). EBR was significantly higher in stable patients (1.305 vs 3.322; p:0.009).
The results of our study showed correlation between NLR, EBR and hospital mortality. EBR was significantly lower in exitus than survivors (1.816 vs 1.290; p:0.017); while NLR was significantly higher in exitus than survivors (28,567 vs 18,043; p<0.001) (cut-off point of 5.23 with AUC: 0.90, S: 86,27% E: 84,62%).

CONCLUSION. NLR and EBR could be considered as new inflammatory markers for diagnosis of severe exacerbation of COPD and for the prognosis. The results of this study show that higher NLR an lower EBR correlated with poor prognosis.

INTRODUCTION. The decision-making to move towards weaning must be based on objective criteria, not only on the criterion of the responsible physician. In the literature, a large number of predictors have been described to facilitate this decision-making with the lowest possible risk, thus minimizing the complications associated with weaning failure. One of the best known is the Rapid Shallow Breathing Index (RSBI), but it has a limited prognostic capacity. Recently a modification has been proposed (D-RSBI) that takes into account the diaphragm, fundamental in the generation of tidal volume.
OBJECTIVES. The aim of the study is to assess the predictive capacity of D-RSBI and compare it with its predecessor in patients subjected to MV> 48 hours
METHODS. Prospective study including 17 patients submitted to MV due to different causes (TBI, CCV, urgent surgery, respiratory failure). Once criteria for advancing weaning are met, a SBT is performed in PSV 5 - 8 cmsH2O over 5 cmsH2O of PEEP, and the following determinations are made: RSBI, FR, Vt, Diaphragmatic excursion, D-RSBI. Epidemiological variables are collected, reason for admission, VM time, weaning failure, mortality.
RESULTS. The average age was 56.12 years +/- 13.95. 70.6% were male. Reason for admission: TBI (29.4%), CCV (29.4%), Urgent surgery (23.5%). The median duration of MV was 11 days. 64.7% presented weaning failure. We observed a significant relationship between D-RSBI and weaning failure (Test Chi2 p 0.016). ANOVA was performed, showing a good correlation between variables (F 8.6 p 0.01). We performed a COR curve presenting AUC 0.86 (p 0.016, 95% CI 0.688-1), finding a cut-off in 1.17 (S 72%, E 83%). RSBI presents AUC 0.79 (p 0.05, 95% CI 0.57-1). However, in the subgroup analysis (Group 1: MV <10 days, Group 2: MV> 10 days), in group 2 we did not observe a significant relationship in the D-RSBI and weaning failure
CONCLUSION. - In our sample, the D-RSBI improves the predictive capacity of the RSBI in patients with short-term respiratory support
- In patients with prolonged mechanical ventilation, the predictive capacity of D-RSBI is limited, similar to the RSBI.

Ventilatory support with non-invasive mechanical ventilation in patients with severe asthmatic crisis

B. Llorente Ruiz, A. Acha, B. Gracia, M. Daguerre, E. Nevado
Intensive care unit, Hospital Príncipe de Asturias, Alcalá de Henares, Spain
Correspondence: A. Acha

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001352

INTRODUCTION. Approximately 10% of the asthma-related hospitalizations do include an ICU stay. Around 2–4% require mechanical ventilation. The use of non-invasive mechanical ventilation (NIMV) for acute respiratory failure has increased and the indications for its use have expanded over the past decade. Although it seems to have many advantages and its use has been extended in asthma exacerbation, its benefits are not well established and no recommendations had been made in the guidelines.
OBJECTIVES. To describe the use of NIMV in adults presenting severe asthma exacerbation with respiratory insufficiency admitted to our ICU.
METHODS. Prospective observational study conducted in a 14-bed intensive care unit of a second level hospital during 18 months. Patients were all adults with a severe asthmatic crisis who failed with first step standard treatment in spite of which they had symptoms of severe respiratory failure with increased in respiratory work with global use of accessory muscles, intercostal retractions and nasal flaring. Demographic data, clinical variables at admission and intensive care unit and hospital length of stay were recorded.
Qualitative variables are described as number and percentages and quantitative variables with normal distribution as mean ± S.D.
RESULTS. The total sample comprises 17 patients, having ruled out the patients that required invasive mechanical ventilation upon admission due to encephalopathy or cardiac arrest. 73.7% were women, with an average age of 48.13 ± 14,04 years and a mean APACHE II score of 11.26 ± 6.2. On admission, the mean pH was 7.22 ± 0.139 with mean pCO2 in arterial blood of 60.5 ± 21.05 mmHg. A therapeutic trial with NIMV was carried out in all of them. In 66.7% the ventilatory mode used was BiPAP, with the use of CPAP being a 13.3%. All patients were monitored both clinically and analytically: average heart rate (115.87 ± 19.31 bpm), average respiratory rate (29.8 ± 6 bpm) and mean FiO2 required (0.5 ± 0.18). Control arterial blood gas was taken two hours after the start of respiratory support. The average pH was 7.35 ± 0.614, with a pCO2 of 40.19 ± 8.29 mmHg. The mean stay in the ICU was 4.93± 4.65 days and in hospital was 15.61 ± 10.33 days. In our group only two patients (11,76%) had NIMV failure.
CONCLUSION. In our experience, the use of respiratory support with NIMV in patients with severe asthma crisis, performed in a safe environment in which there is no delay in recognizing the failure of the same, may limit both ICU and hospital stay and the rate of orotracheal intubation with the complications derived from it.

External expiratory resistances act as expiratory brake and reduce eccentric diaphragmatic contraction during spontaneous breathing ventilation

M. Pellegrini[1], M. Gudmundsson,[2], R. Benzce,[1], M. Segelsjö[3], F. Freden,[1], C. Rylander,[2], G. Hedenstierna,[4], SA. Larsson,[1], G. Perchiazzi,[1]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001353

INTRODUCTION. During spontaneous breathing (SB) a post-inspiratory expiratory contraction of the diaphragm, also defined as eccentric diaphragmatic contraction (EDC), has been described [1, 2]. EDC is minimizing the expiratory flow, preserving the end-expiratory lung volume and reducing atelectasis formation. However, EDC has also been described as cause a of ventilator-induced diaphragm dysfunction (VIDD).
OBJECTIVES. To describe the effects of an additional expiratory resistance (ExpR) during conditions that promote EDC. We hypothesized that ExpR could reduce EDC, while preserving the positive effects of expiratory brake. If it holds true, we expect throughout the expiration a reduction in: 1. expiratory electrical activity of the diaphragm (EAdi exp), 2. expiratory transdiaphragmatic activity (Pdi exp), 3. expiratory flow (Flow exp).
METHODS. Nine anesthetized, tracheostomized, SB pigs underwent lung lavages to achieve mild ARDS (PaO2/FIO2 of 250 mmHg). The animals breathed at three continuous airway pressures (CPAP 12, 5 and 0 cmH2O). For each CPAP, three different conditions were studied, depending on the application of an additional respiratory resistance to the expiratory ventilatory limb: 1) no resistance added (R0), 2) ExpR of 4.8*10-2 cmH2O/mL/sec measured at a flow of 1 L/s (R1), 3) ExpR of 9.6*10-2 cmH2O/mL/sec measured at a flow of 1 L/s (R2). For each breath EAdi exp, Pdi exp and Flow exp were divided in four quartiles. EAdi exp, Pdi exp quartiles were expressed as percent of the end-inspiratory peak. Flow exp quartiles were expressed as absolute values [L/s]. Statistical analysis: Student-T test.
RESULTS. During SB, the application of an external expiratory resistance decreased the EDC: both EAdi exp and Pdi exp were significantly reduced by the application of an ExpR. The higher the expR, the lower the EDC (Figure, first and second rows) at all the applied CPAP levels. The use of an ExpR reduced the expiratory flow, at all the applied CPAP levels (Figure, third row). The increase in CPAP reduced the EDC.
CONCLUSION. Expiratory modulation by application of an external ExpR preserves the positive effects of the expiratory brake while minimizing diaphragmatic eccentric contraction, thus potentially reducing the VIDD and the consequent lung injury in SB subjects.

No "single" EIT parameter can determine optimal ventilator settings

SJH. Heines, U. Strauch, MC. Van De Poll, PM. Roekaerts, D. Bergmans
Icu, Academic Hospital Maastricht, Maastricht, Netherlands

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001357

INTRODUCTION. Electrical impedance tomography (EIT) enables calculation of alveolar collapse (CL) and overdistension (OD) during a PEEP trial[1]. The best balance between OD and CL (ODCL), where the percentage of CL is subtracted from OD is one of the parameters developed to optimize ventilator settings.
OBJECTIVES. The aim of this study is to describe the effect of PEEP on ODCL, OD and CL in hypoxic respiratory failure (HRF), and patients with healthy lungs as a reference group (control).
METHODS. Twenty control and 43 HRF patients (PaO2/FiO2-ratio <250) were analysed from retrospective data and our prospective EIT-trial data. The ODCL, OD and CL was calculated at each PEEP step by EIT during an incremental and decremental PEEP trial. The analysis is performed in 4 consecutive incremental followed by 4 decremental PEEP steps of 2 cmH2O. An ODCL of 0 would indicate an optimal balance between OD and CL. Characteristics between HRF and control patients were compared using independent *t*-test. Changes in ODCL, OD and CL between HRF and control patients were tested using two-way ANOVA.
RESULTS. There was a significant difference between HRF and control patients in APACHE II, PaO2/FiO2-ratio and set PEEP (12 cmH2O (±3) and 8 cmH2O (±0,5) respectively), $p<0.05$. Changes in both OD and CL were directly proportional with changes in PEEP (Fig. 1). The increase in OD is more pronounced by increasing PEEP in HRF then in controls ($p<0.05$). A low ODCL did not exclude OD or CL in HRF nor control patients, mean ODCL 2,5 (±2) with an OD of 7 (±4), CL 7(±3) and ODCL 2,6 (±3) with an OD 8 (±5), CL 7 (±4) respectively.
CONCLUSION. Using solely ODCL to titrate PEEP does not exclude the presence of OD and CL. Ventilation distribution varies widely among patients, especially in HRF. No single optimal PEEP value exist for the entire lung. This reinforces the need for personalised titration of PEEP and tidal volume because the latter also contributes to tidal recruitment and OD. Using EIT regional lung mechanics can reliably be assessed at different PEEP levels and tidal volumes. Therefore, EIT can be very helpful for patient tailored lung protective ventilation.

External expiratory resistances optimize lung inflation in collapse-prone lungs

M. Pellegrini[1], M. Gudmundsson,[2], R. Benzce,[3], M. Segelsjö[4], F. Freden,[3], C. Rylander[2], G. Hedenstierna,[5], SA. Larsson,[3], G. Perchiazzi,[3]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001369

INTRODUCTION. Diaphragmatic expiratory brake has been shown to preserve end-expiratory lung volume and avoid/reduce atelectasis formation [1]. However, the eccentric diaphragmatic contraction (EDC), that naturally brakes expiration, is a possible cause of ventilator-induced diaphragm dysfunction (VIDD) [2] during spontaneous breathing (SB).
OBJECTIVES. To investigate if an external resistance (ExpR) inserted into the expiratory circuit can mimic the natural EDC and improve lung inflation.
METHODS. Nine anesthetized, tracheostomized SB pigs underwent lung lavages to achieve mild ARDS (PaO2/FIO2 of 250 mmHg). The animals were studied with high frequency (20 Hz) dynamic Computed Tomography (CT) at three Continuous Positive Airway Pressures (CPAP 12, 6 and 0 cmH2O) and three ExpR: 1) no resistance added (R0), 2) ExpR of 4.8*10-2 cmH2O/mL/sec measured at a flow of 1 L/s (R1), 3) ExpR of 9.6*10-2 cmH2O/mL/sec measured at a flow of 1 L/s (R2). Image analysis was performed on CT images acquired at end-inspiration and at four quartiles of the expiratory phase (1/4 Exp, 2/4 Exp, 3/4 Exp, 4/4 Exp). Inflation was defined based on voxels radiodensity, according to Gattinoni et al.[3]. Four lung compartments were so defined (atelectatic, poorly-, normally- and hyper- inflated) and reported as percentage of the total lung parenchyma in the same slice. Intrinsic-Positive End Expiratory Pressure (PEEPi) was calculated. Statistical analysis: Student-T test.
RESULTS. The application of an additional ExpR (R1 or R2 vs R0) (Figure) significantly reduced the amount of atelectasis at CPAP 0 and 6 cmH2O; and significantly increased normally inflated areas at CPAP 0 and 6 cmH2O. PEEPi (mean ± SE) varied between a minimum of 0.12±0.06 cmH2O at CPAP 12 and R0 and a maximum of 1.32±0.58 cmH2O at CPAP 0 and R2.
CONCLUSION. The expiratory brake produced by ExpR improved lung inflation in conditions promoting lung collapse (low CPAP) and was not associated with hyperinflation. If confirmed in human patients, external expiratory brakes might gain clinical relevance in ventilated lungs prone to collapse (e.g. laparoscopic procedures, cardiothoracic surgery, pediatric ventilation, prolonged weaning and critical illness).

Predictors of mortality in ICU-admitted patients with an acute exacerbation of COPD (AECOPD)

H. Kallel[1], I. Ben Saida[2], W. Zarrougui[2], MA. Boujelbèn[1], R. Chelbi[1], W. Ammar[1], S. Rouis[1], K. Meddeb[2], M. Boussarsar[2]
[1]Medical intensive care unit, Farhat hached university hospital, Sousse, Tunisia; [2]Medical intensive care unit, farhat hached university hospital, Université de Sousse, Faculté de Médecine de Sousse, LR N° LR12SP09.Heart Failure, Sousse, Tunisia
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001374

INTRODUCTION. COPD is the third leading cause of mortality around the world according to the World Health Organization. It is interesting to identify COPD patients at the time of ICU admission who are likely to have poor short-term outcomes.
OBJECTIVES. To identify the characteristics and predictors of mortality of ICU patients admitted for AECOPD.
METHODS. A prospective cohort study was performed in a 9-bed Tunisian medical ICU between December 2017 and April 2019. All patients admitted for AECOPD during the study period were included. For all included patients, demographic, clinical characteristics, therapeutic interventions and outcomes were recorded. Univariate and multivariate regression analyses were carried out to identify factors independently associated to poor prognosis.
RESULTS. During the study period, 372 patients were hospitalized in the ICU. 99(26%) COPD patients were included. Patients' characteristics were: mean age, 64.0±9.2yrs ; male, 71(91%) ; mMRC≥2, 67(88.2%) ; median SAPSII, 27[22-32] ; invasive mechanical ventilation (IMV) on admission, 10(10.1%). The most common comorbidity was hypertension 31(31.3%), followed by diabetes mellitus 19(19.2%), cardiovascular diseases 19(19.2%) and psychiatric disorders 7(7.1%). The triggering factor of AECOPD was tracheobronchitis 73(73,7%) followed by pneumonia 7(7.1%) and pulmonary edema 3(3%).
During their ICU stay, 46(46.46%) required intubation, 25(25.3%) were put under vasoactive drugs and 12(12.1%) had hospital-acquired infections. The median duration of mechanical ventilation and the length of stay were respectively 11[5.7-15.5]days and 9[6-14.5]days. Mortality rate was 23.3%.
Univariate analysis identified four factors associated with ICU mortality : SAPS II on admission (34[29.5-44] vs 25[20.25-30] ; p=0.001) ; IMV use on admission (21.7% vs 6.6% ; p=0.035) ; vasopressors use (60.9% vs 14.5% ; p<0.001) and NIV failure (78.9% vs 27.8% ; p<0.001). In multivariate analysis, NIV failure was an independent risk factor associated with mortality in critically ill COPD patients (HR, 9.75 ; 95%CI, [2.9-32.9] ; p<0.001).
CONCLUSION. NIV failure was the sole independent risk factor associated with ICU mortality in patients admitted with AECOPD.

Delta of mechanical power in patients with severe ARDS and prone position

AH. Morales-Morales, JC. Gasca-Aldama, SE. Zamora Gómez, LA. Gorordo-Delsol, KJ. Castillo-Medrano, NI. Medveczky-Ordoñez, ML. Pacheco-Rivera, S. Sosa-Santos, LE. Gaytán-Medina, I. Maldonado-Beltrán, A. Rodríguez-Peredo, D. Sanabria-Cordero, JA. Zepeda-Pérez, GD. Hernández-López
Adult intensive care unit, Hospital Juárez de México, Ciudad de México, Mexico
Correspondence: S.E. Zamora Gómez
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001382

INTRODUCTION. 10 % of all patients admitted to the Intensive Care Unit and 23 % of mechanically ventilated patients has ARDS (1). The mortality rate is of 46.1 % for patients with severe ARDS (2). The mainstay of treatment is lung protective ventilation with low tidal volumes and optimal PEEP, prone positioning is a validated strategy for patients with moderate and severe ARDS (3). The driving pressure, more than tidal volume, is the best predictor of VALI, as inferred by increased mortality, DP is one of the components of the mechanical power, which also includes respiratory rate, flow and PEEP. Mechanical Power is the energy delivered per unit of time to the respiratory system by the mechanical ventilator. Finding the

threshold for mechanical power could simplify assessment and prevention of VALI (4).
OBJECTIVES. To analyze the change in Mechanical Power (ΔMP) after prone position and outcome in patients with severe ARDS
METHODS. : An analytical, retrospective and cross-sectional study in patients with severe ARDS and prone position strategy in the Intensive Care Unit of Hospital Juarez de México (January 01, 2018 to March 31, 2019).
RESULTS. 71 patients with ARDS were admitted, 46 (64.7 %) had severe ARDS and received prone position. Global Mortality was 42.2%, Mortality in severe ARDS group was of 65.2%. Average MP before prone position in survivors was 19.5 J/min in contrast with 24.16 J/min in nonsurvivors (OR 9.6, CI 95 %, 0.97 – 95.67, P: 0.052). Average MP after prone position in survivors was 18.5 J/min in contrast with 28.59 J/min in nonsurvivors (OR 9.6, CI 95 %, 0.97 – 95.67, P: 0.052). ΔMP was -0.504 in survivors, but it was +4.103 in nonsurviors (OR: 0.064, (IC 95 %, 0.109 – 3.72, P: 0.61).

	Survivors (n)	Non-Survivors (n)	OR	Confidence interval (95%)	P value
MP before prone (J/min)	19.50 (16)	24.16 (30)	9.66	0.97 - 95.67	0.0524
MP after prone(J/min)	18.50 (16)	28.59 (30)	9.66	0.97 - 95.67	0.0524
Δ MP (J/min)	-0.504 (16)	+4.103 (30)	0.64	0.10 - 3.72	0.619

CONCLUSION. In patients with severe ARDS MP was higher in nonsurvivors before and after prone position in comparison with survivors. ΔMP showed a trend to reduce in survivors and to increase in nonsurvivors after prone position.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001385

INTRODUCTION. Severe acute respiratory failure (ARF) is a main cause of ICU admission, also for elderly patients (1), frequently warranting respiratory support. The proportion of elderly patients receiving mechanical ventilation is reported to be comparable to younger ICU patients (2). Despite representing a rapidly growing ICU population, outcome data are scarce for ARF with or without respiratory support in elderly ICU patients.
OBJECTIVES. The objective is to describe the modality of respiratory support and short-term outcomes in an unselected group of very old intensive care patients (VIP) ≥ 80 years admitted with ARF.
METHODS. This is a predefined sub-study of the VIP-1 study; a prospective observational study enrolling 5132 VIP admitted to 311 ICUs in 21 European countries (3). The patients for the present study are selected from the VIP-1 study population by ARF reported as the main admission diagnosis. Patients presenting with both ARF and acute circulatory failure upon ICU admission are excluded.
RESULTS. A total of 986 patients are included. 864 patients (87.6%) were given respiratory support. Invasive mechanical ventilation (IMV) compared to non-invasive ventilation (NIV) was associated with a significantly longer ICU stay and a trend towards increased mortality, but patients receiving IMV also had a significantly higher degree of organ failure.
CONCLUSION. Acute respiratory failure in very old ICU patients carries a high mortality, ranging from 25% in patients without any form for respiratory support to almost 50% in patients with IMV after a trial of NIV. Patients having received NIV only were less sick and had a shorter ICU stay; however no significant survival benefit of NIV compared to IMV could be shown.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001390

INTRODUCTION. The Integrated Pulmonary Index (IPI) use an algorithm based on the measurement of exhaled carbon dioxide, respiratory rate,

heart rate and oxygen saturation to provide an assessment of the patient's ventilatory status. IPI has been maintained as part of respiratory monitoring but not as part of a mechanical ventilation removal protocol.
OBJECTIVES. Determine whether the lung integration rate predicts success or failure in the removal of mechanical ventilation.
METHODS. In a cohort study, prospective and observational, patients admitted to UTI with support from VMI were analyzed, using the IntelliVue MX800 monitor software to obtain the IPI algorithm. Demographic, hemodynamic and respiratory variables were recorded to perform a multivariable statistical analysis, using regression models to compare patterns in 2 repeated IPI measurements. The extubation protocol kept the patient in support pressure mode (PS) with PS 7 and PEEP 0.
RESULTS. IPI was collected in 90 patients, 79 successfully extubated (88%) and 11 with failure (12%), IPI was taken at the time of weaning from mechanical ventilation and 5 minutes before extubating the patient. The value of IPI at the moment of the extubation had an specificity of 97% and sensitivity of 57%, it was observed that an increase of +2 in the basal number of IPI predicts success to the extubation, but a decrease of -2 may or may not determine failure at extubation, with a p of 0.001.
CONCLUSION. In this study a variation of the basal IPI at the beginning of the mechanical ventilation removal protocol was observed and compared with the IPI at the time of extubation, with a delta of +2 being found, when the patient had an increase in IPI was observed success at extubation, instead when the variation was in decline (-2), extubation could fail or not.

Changes of diaphragm function before and after withdrawal of high flow nasal cannula in patients with acute respiratory failure

T. Takashima[1], N. Nobuto[2], U. Yoshitoyo[1], T. Natsuki[1], T. Yumiko[1], I. Taiga[1], O. Jun[2]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001392

INTRODUCTION. High flow nasal cannula (HFNC) is increasingly used in managements of acute respiratory failure (ARF). HFNC can contribute to improve diaphragm function due to washout of carbon dioxide in anatomical dead space, increasing lung volume, and decreasing work of breathing. However, there are few clinical data to assess the changes of diaphragm function during weaning from HFNC.
OBJECTIVES. To evaluate the changes of diaphragm function before and after withdrawal of HFNC in patients with ARF.
METHODS. We included adult patients with ARF who were stable and ready to have HFNC withdrawn. Diaphragm function were assessed by thickening fraction (TF) and diaphragm excursion (DE) using ultrasonography before and after liberation from HFNC. HFNC was set to deliver 30 L/min flow at FIO2 of 0.21 to 0.30. After liberation from HFNC, patients were treated with low flow oxygen of 1 to 3 L/min through nasal cannula. TF was measured at the zone of apposition, 0.5 to 2 cm below the costophrenic sinus. DE was measured in the subcostal area. TF and DE were measured three times, and the mean values were used for evaluation. We compared the values of TF and DE before and after withdrawn of HFNC.
RESULTS. Twenty subjects (12 male, 8 female; mean age 68 ± 16 years) were enrolled in this study. APACHE II score was 18 (inter-quartile range: IQR, 13, 20), and duration of HFNC was 2 days (IQR, 2, 3 days). There were no significant difference in TF (13.8 vs. 12.5 %, p=.48) and DE (1.4 vs. 1.5 cm, p=0.37) before and after withdrawn of HFNC. However, four patients presented with paradoxical motion of the diaphragm after withdrawal of HFNC.
CONCLUSION. In patients with ARF, HFNC at 30 L/min had no significant effect on diaphragm function before and after withdrawal of HFNC. However, in some cases, paradoxical diaphragmatic movement became noticeable after withdrawal of HFNC. Novel weaning protocol of HFNC to prevent diaphragm dysfunction after liberation from HFNC is warranted.

INTRODUCTION. Positive end-expiratory pressure (PEEP) is an essential treatment for patients with acute respiratory distress syndrome (ARDS) to reopen collapsed or flooded alveoli and closed airways. However, PEEP may also overdistend previously open lung units and/or worsen circulation. The individual response to PEEP depends on lung recruitability but assessing recruitability at the bedside is challenging (1). We propose a simple approach to estimate the recruited volume (ΔVrec) at the bedside, based on the hysteresis-like behavior, which requires only one prolonged expiration maneuver (2). We also propose to standardize the ΔVrec by the real change in pressure for assessing the lung recruitability, taking into account the possible presence of complete airway closure (3). This standardized ΔVrec is defined as the compliance of the recruited lung (Crec) in our study.
OBJECTIVES. To validate an experimental method for measuring ΔVrec and calculating Crec; and to test whether Crec differentiates patients with different responses to PEEP in other dimensions.
METHODS. Patients with moderate or severe ARDS were passively ventilated at two PEEP levels different by 10 cmH2O when possible (e.g., 15 vs. 5 cmH2O). Respiratory mechanics, absolute lung volumes, and low-flow inflation pressure-volume curves were assessed at each PEEP levels. We used the multiple pressure-volume curves as the reference method (4). A reduction in lung volume between two PEEP levels at a given elastic pressure was measured as ΔVrec (4). The airway opening pressure (AOP) was also measured(3). The "real change in pressure" was not always 10 cmH2O but the difference between high PEEP and AOP in patients with complete airway closure (3). ΔVrec was thus standardized in mL per cmH2O, termed as Crec. In other words, Crec was the ratio of recruited volume to the real change in pressure over which recruitment was assessed. To define lung recruitability, we arbitrarily divided patients into "high recruiters" and "low recruiters" by using the median of Crec. We then tested whether the patients have different response to PEEP in terms of gas exchange, mechanics, and circulation.
RESULTS. Forty-five patients were enrolled. In four patients with airway closure, higher PEEP was insufficient to reopen airways and recruitment could not be assessed. In others, the experimental method (single breath) was strongly correlated with the reference method (multiple curves) in measuring ΔVrec and Crec (P< 0.001, R2= 0.798 and 0.817, respectively). Bias in measuring Crec was -2 mL/cmH2O and limits of agreement were -14 to 10 mL/cmH2O. At PEEP of 15 cmH2O, only high recruiters had better oxygenation compared to lower PEEP 5 (P = 0.020), whereas only low recruiters experienced lower mean arterial pressure (P = 0.009).
CONCLUSION. Our simple method can quantify both the recruited volume and the compliance of the recruited lung at the bedside, allowing clinicians to personalize PEEP based on lung recruitability.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001420

INTRODUCTION. Chest ultrasound (CUS) is mandatory to confirm a full lung expansion after pleural drainage for pneumothorax in the critically ill. With regards to high rate of chest drain (CD) malposition its subsequent controls by chest X-ray (CXR) during ICU radiology rounds are warranted. Even a small PNO is still important because it may easily enlarge due to positive inspiratory pressure (IPPV). Our pilot paper (1) utilizing CXR and chest CT showed that greater foreshortening of the CD and a steep angle of inclination of the CD above the horizontal at chest entry taken from CXR should raise suspicion of CD migration. They mandate further investigation by CUS to rule out residual pneumothorax occult on CXR. The role of CD location by CUS in the diagnosis of pneumothorax has not been explored yet.
OBJECTIVES. CD foreshortening taken from CXR may associate with an absence of CD detection between ventral pleural layers on CUS in a supine patient and presence of an occult pneumothorax confirmed on CUS.
METHODS. Patients were prospectively monitored with CUS and CXR after drainage for pneumothorax performed by intensivists using 16-20F CDs and blunt forceps technique in the safe triangle. All drains were connected to a closed suction system providing a pressure of -20 mbar. The foreshortening was estimated as a decrease of chest drain index (CDI=length of CD in chest taken from CXR/depth of insertion on CD scale+5 cm). The angle of inclination of the CD was measured as the angle between the horizontal line and CD at the pleural space entry on CXR. Pneumothorax was diagnosed on CUS according to current standards (2).
RESULTS. 85 pneumothoraces were prospectively monitored in 61 patients on IPPV, age 56.2±19.8, APACHE II 22±4, SOFA 9±2.2. CDs were located on CUS in 55 patients, the full interpleural course of a CD until its tip was detected in 43 patients. There were 6 small occult pneumothoraces in this group (13.9%) particularly due to a steep angle of the CD >50°(n=4), the CDI was 0.96±0.13. In 30 patients the CDs could not be located by CUS, 6 of those were excluded for subcutaneous emphysema. There were 13 pneumothoraces in this group (54%), the CDI was 0.76±0.23 (p<0.001). The risk ratio for pneumothorax in a patient with low CDI on CXR and associating absence of the interpleural CD location on CUS is 3.88, CI 1.70-8.89, p=0.001, NNT 2.49.
CONCLUSION. A low CDI on CXR calls for a CUS verification of a CD position and exclusion of an occult pneumothorax not detected by the CXR.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000078

INTRODUCTION. There is a great concern to carry out surveillance, prevention and control programs of Healthcare-associated infections (HAIs), with emphasis on hand hygiene (HH). It is important to know the perceptions of the healthcare professionals to try to improve the adherence to these programs.
OBJECTIVES. To identify the perceptions and knowledge of the healthcare workers of an Adult Intensive Care Unit (AICU) and a Pediatric Intensive Care Unit (PICU) about HH and correlating them with the adherence of the compliance program to HH.
METHODS. Cross-sectional, prospective, descriptive and comparative study, about the knowledge and perceptions of the health professionals with respect to HH, through the realization of a survey published and validated by the World Health Organization. In addition, these perceptions are compared with the evaluation of the adherence to the HH that had been done prior to this study by direct observation of the workers during their daily work.
RESULTS. 187 surveys were obtained (142 from AICU and 43 from PICU); >80% of total the population. >90% had received formal training on HH in the last 3 years and regularly use of alcohol-based solution (ABS). Regarding knowledge, there are no significant differences between the units. 35% of the AUCI professionals and almost 50% from the PICU consider that hand washing (HW) is more effective than hand friction (HF) with alcohol-based solutions (ABS) for the elimination of microorganisms. >30% believe that it is advisable to perform the HW and HF sequentially. Only 55.8% know the minimum adequate time to eliminate microorganisms by HF. They overestimate the percentage of occasions in which they perform HH correctly with respect to adherence rates to HH, through direct observation, (PICU 89.32% vs 73,8% and AICU 82.93% vs 51,4%)(p = 0.0001).
CONCLUSION. Despite being a sample of professionals with formal training on HH, the results indicate that they have incomplete knowledge and overvalue their perception compared with the adherence rates obtained through observational studies.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000080

INTRODUCTION. The World Health Organization (WHO) promotes that proper hand hygiene (HH) is the main practice, with the lowest economic cost and the easiest to perform to reduce the incidence and spread of antimicrobial resistant microorganisms, which improves patient safety in all health areas. However, WHO rates the HH compliance index by health professionals is insufficient (less than <40%).
OBJECTIVES. To know the adherence rates to the HH, between the Healthcare workers (HCWs) in an adults ICU (AICU) and other pediatric (PICU).
METHODS. An observational study was conducted on the compliance of HH for the five WHO moments. HCWs were observed during their work shift. The observers also measured the technique of HH through hand washing or HH with alcohol-based disinfectant. HH opportunities and attempts were designated as appropriate or inappropriate per WHO criteria.
The percentage of adherence was calculated as the number of opportunities of HH (with soap and water or alcohol-based solutions (ABS)) multiplied by 100 and dividing by the total of identified opportunities.
RESULTS. 391 opportunities were identified in the AICU and 320 in the PICU, a HH adherence rate in the AICU of 51.40% and 73.80% in the PICU was determined. By professional profile it was observed that the nursing staff is significantly the most adherent (64% in the AICU and 82% in the PICU). It was found that in the AICU the adherence is greater after being in contact with the patient), unlike the PICU where they perform it predominantly before in all professional profiles.
CONCLUSION. The adherence to hand hygiene in the AICU is low. The adherence to HH is greater before contacting the patient in the PICU, unlike the AICU where it is predominantly carried out afterwards. So it is necessary to implement effective education programs that improve adherence to hand hygiene compliance.

Stethoscopes- potential sources of cross infections in ICU

N. Navilehal Rajasab, N. Cemm; S. Patel
Intensive care department, King's College Hospital, London, United Kingdom
Correspondence: N. Navilehal Rajasab
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000124

INTRODUCTION. –Emergence of antimicrobial resistance and MDROs has resulted in a global health burden, increasing cost of health care, length of hospital/ ICU stay and mortality. Risk of bacterial transmission through equipment transfer is not given as much importance as hand hygiene.
–Studies have proven contamination of stethoscopes with both non-pathogenic and pathogenic (including MDR) organisms. Jones et al showed that out of 150 stethoscopes used by emergency medical staff, 89% grew staphylococci and 19% S aureus[1]. Marinella et al showed that coagulase-negative staphylococcus was present on 100% of stethoscopes and Staphylococcus aureus on 38% of 40 random stethoscopes examined [2].
–CDC guidelines suggest performing low level disinfection for non-critical patient care surfaces and equipment that touch intact skin e.g. bed rails, blood pressure cuffs and stethoscopes
OBJECTIVES. - To determine whether stethoscopes can be potential sources of cross-infection/cross contamination in our ICU
METHODS. -All 4 adult ICUs (total 73 beds) were surveyed between Nov-Dec 2018 for the number of bedside stethoscopes at random times for a total of 2 weeks. Each bedside stethoscope was also labelled with unique identfier codes, and movement of stethoscopes between bed spaces and patients was tracked on a daily basis.
-A survey questionnaire was also sent to all the ICU medical staff regarding infection control practices with respect to use of bedside stethoscopes in ICU.
RESULTS. -Average number of stethoscopes found in ICU's 1,2,3 & 4 were 71.4%, 66.6%, 77.7% and 110% respectively and number of times stethoscopes were found to be misplaced were 24.4%, 31.7%, 34.92% and 8% respectively
-Unit acquired infection rates from April 2018-March 2019 for ICUs 1,2, 3 & 4 were 17.1/1000, 33/1000, 20.3/1000 & 5.8/1000 respectively
-A total of 210 people responded to the survey questionnaire (23% doctors, 74% nurses). 69% said they share stethoscopes between bedspaces, because of non-availability of 1:1 dedicated bedside stethoscopes (5%), poor

quality of stethoscopes (17%), or (50%). 100% said they clean stethoscopes after every use. Asked whether there was a checklist to ensure stethoscopes are cleaned, 7% answered "yes", 65% said "no" and 28% were not sure.
CONCLUSION. –Our audit revealed that there is evident sharing of stethoscopes between bed spaces mainly because of poor quality and lack of adequate number of dedicated bedside stethoscopes in ICU.
-Units with the highest proprotion of stethoscopes and the lowest frequency of misplaced stethoscopes had the lowest unit-acquired infection rates, suggesting that stethodscopes may play a role in cross infection
–The survey questionnaire showed that there is inadequate education around cleaning stethoscopes and documentation, and importance of having dedicated 1:1 bedside stethoscopes
–CDC recommends monitoring for adherence to recommended environmental cleaning practices as an important determinant for success in controlling transmission of MDROs and other pathogens in the environment[5].
–Based on the above factors, having 1:1 dedicated bed side stethoscopes would be a prudent solution to reduce risk of cross contamination.

Presence of microorganisms in the mobiles phones of professionals in a polivalent ICU

YG. Santana-Padilla[1], JL. Santana Cabrera[1], BN. Santana-Lopez[1], ME. Dorta-Hung[2], MJ. Molina-Cabrillana[2]
[1]Intensive care unit, Maternal and child Hospital, Las Palmas de Gran Canaria, Spain; [2]Preventive medicine, Complejo Hospitalario Universitario Insular-Materno Infantil, Las Palmas de Gran Canaria, Spain, Spain
Correspondence: Y.G. Santana-Padilla
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000148

INTRODUCTION. Many studies have researched about the contamination of differents surface that there are in the different units of hospitals. In the Intensive Care Units (ICU), several studies have found important microorganism in the personal mobile phones of health workers. Some studies have detected germs such as P. aeruginosa, Acinetobacter, S. aureus and Enterococcus. These findings make its important to consider this surface as an element to monitor in the transmission of nosocomial diseases.
OBJECTIVES. Identify the presence of microorganisms in the mobile phones of the profesionals of an Intensive Care Unit (ICU).
METHODS. Experimental controlled trial for 5 months among heath and non-health profesionals who had mobile devices during their workday. The collection was performed by a wet swab in Brain Heart Infusion (BHI). A single researcher was in charge of collecting the samples after receiving specific training. Follow up was done in the microbiological findings of the patients in charge of the professionals of which samples were taken. The Medicine Preventive unit collaborates in the microbiological analysis of the samples collected. This study was approved by the ethical and research committee.
RESULTS. In our study, 111 samples of mobile devices were collected. In these samples, the 49.5 per cent were contaminated by relevant microorganism. Of this samples 64 microorganisms were detected, with the following distribution by groups: Gram (+) 71.8% predominated, followed by Gram (-) 18.7% and fungi 9.3%. It was relevant for the research to find in the contaminated mobiles, the presence of multi-resistant microorganisms of the type of methicillin-resistant Staphylococcus aureus (10.9%), Pseudomonas aeruginosa (12.5%) and Stenotrophomonas maltophilia. (4.7%)
CONCLUSION. Despite not being able to establish causality between the isolations of patients and the findings in mobile phones, if pathogenic microorganisms have been detected, they should alert us that they could serve as a reservoir of transmission to the critical patient. There were only two cases: a nurse and a doctor where a germ of the same type that the patients had, grew in the culture plates. The training in hand hygiene should be carried on. The high adherence in hand hygiene could have an important impact to reduce the contamination of the mobiles.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001467

INTRODUCTION. Ventilator-associated pneumonia(VAP) occurs in 9-27% among patients on mechanical ventilation. The main risk factor is the endotracheal tube and microaspirations. The bacteriology of mouth flora responsible for that, are Gram-negative bacteria and fungal species. Through the past years, different strategies of decontamination of oropharyngeal cavity have been applied with conflicting evidence on effectiveness and safety.
OBJECTIVES. The aim of our study was to compare the effectiveness of antibiotic Selective Oropharyngeal Decontamination(SOD) along with the use of oral antiseptic agent (Chlorhexidine) versus standard care with topical chlorhexidine alone, concerning the prevention of IVAC (Infection-related ventilator-associated complications) and VAP.
METHODS. A randomized controlled study of patients in a general ICU. Inclusion criteria contained all intubated patients of age≥18 years old who were mechanically ventilated for≥48h. Patients admitted in the ICU with respiratory infection were excluded from the study. Two groups during a 6month period were studied. The control group was treated with oral application of Chlorhexidine 2% three times a day. To the other group, antibiotic paste with colistine and fluconazole was applied to the oropharynx twice a day additionally to Chlorhexidine for a period of ten days. We recorded the episodes of Ventilator-associated Complications (VACs)/Infection-related (IVACs) and Ventilator-associated pneumonia (VAP) using the Centers for Disease Control and Prevention (CDC) classification, during the first 10 days of ICU stay.

RESULTS. Overall 72 patients were studied, 37 assigned to standard care with Chlorhexidine and 35 to additional application of antibiotic paste. The patient's characteristics concerning median age (63 vs 57 years), APACHE II score (17.8 vs 17.7), mean ICU days (16.2 vs 16.4days) and death rate (22.8% vs 21.6%) among the two groups respectively were comparable. Using statistical analysis, we compared the VAC/IVAC occurrence between the two groups (95% confidence interval [CI], 0.332, 13.082; p= 0.472; OR 1.87) and VAP (X-squared = 1.3455, p-value=0.246).
CONCLUSION. Applying antibiotic decontamination therapy in addition to standard care with oral Chlorhexidine in our ICU, didn't prove to reduce the development of VAC/IVAC and VAP in intubated patients, in a statistically significant way. Although the comparison between two groups (Figure) showed higher VAP occurrence in the group treated with chlorhexidine alone (21.62% vs 11.43%) this was not statistically significant (p=0.246). Our results are limited by the small size of our sample and more patient recruitment is needed.

Perioerative MDR colonisation and surgical prophylaxis

A. Lerose, K. Donadello, D. Cigolini, V. Schweiger, E. Bonora, E. Polati
Anesthesia and intensive care b unit, University of Verona, AOUI-University Hospital Integrated Trust of Verona, Verona, Italy
Correspondence: K. Donadello
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001544

INTRODUCTION. Multi-drug resistant (MDR) colonization is a major issue worldwide (WHO, 2019), mostly for perioperative and intensive care medicine, frequently resulting in life-threatening infections.
OBJECTIVES. Within our ICU admissions, the aim of this study was to evaluate MDR colonized patients undergoing surgery and their post-operative course compared to non colonized patients.
METHODS. We retrospectively analyzed all consecutive patients undergoing surgery in our hospital for a period of 12 months (July 2017-July 2018) who required ICU admission on POD 0. According to their surveillance swab, we defined patients as negative, negative for MDR bugs, MDR positive (*Enterobacteriaceae* beta-lactamase producer-ESBL, *Enterobacteriaceae* carbapenemase producer-e.g.KPC, non-lactose fermenting-e.g. *Pseudomonas and Acinetobacter spp, MRSA*). We then compared MDR colonized (rectal and/or pharyngeal swab) patients (MDR+) to non colonized patients (MDR-) for post operative complications, ICU and hospital LOS and mortality.
RESULTS. 274 patients were included in the study (186 men), median age 70(61-77) years; they underwent either elective (n=234, 85.4%) or emergency (n=40, 14.6%) surgery; 119 pts (43.4%) were submitted to pancreatic surgery, 67 (24.5%) to hepato-biliary surgery, 51 (18.6%) to intestinal resection and the rest to other abdominal surgery; they were admitted to ICU on POD 0 for scheduled (n =244, 89.1%) or unscheduled intensive PO monitoring. 43 pts were pre operatively MDR+ (15,7%), 13 of whom were either Klebsiella Pneumoniae Carbapenemasis Producer or Enterococcus Faecium VRE colonized and 28 were ESBL colonized. 50 pts resulted colonized early on ICU admission screening. ICU LOS was significantly higher in MDR+ compared to MDR- (6.2±13 vs 2.1±4 days, p <0.05). Hospital mortality occurred in 17 patients, 9 were MDR+, 6 of them died in the ICU. Complication rate and type were significantly different between the two groups. Only 19 MDR+ patients (6.9%) received targeted pre-operative antibiotic therapy compared to standard prophylaxis but, despite a positive trend with regards to infectious complications, LOS and mortality, our results were significant in terms of outcome.
CONCLUSION. Pre-operative surveillance swab positivity correlates with both ICU LOS and post-operative mortality. Might these results be confirmed, targeted perioperative antibiotic prophylaxis should be seriously settled so as to be routinely used to improve patients' outcome. More studies are needed to further investigate the possibile therapeutic options in MDR+ patients undergoing surgery.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001585

INTRODUCTION. Thanks to the development of the most recent culture-independent methods, changes in lung microbiota composition has been

observed in pulmonary diseases. Its role among critically ill patients need to be largely investigated because many questions are still unanswered in particular regarding pathogenesis of infective complications. In our study we tried to understand which are the major changes that occur during mechanical ventilation and which are critical for the development of VAP (Ventilation Associated Pneumonia).

METHODS. Tracheal aspirates were sampled from 23 patients without pulmonary diseases in progress at the moment of the intubation (T0), after 72 hours (T1) and then every 48 hours later until T7 (day 15) or until the moment of the extubation or the dismission/death of the subject. Analysis of microbiota was performed by 16s rRNA amplifications. Results from QIIME related to taxa classification will be described according diversity measures. Bacterial communities diversity will be analysed applying the Principal Coordinate Analysis (PCoA) based on phylogenetic distance (UNIFRAC) among all samples.

RESULTS. The preliminary molecular analysis have shown the presence of 360 different bacterial taxa. In the first part of our study we focused on the description of the microbial community at the moment of the intubation (T0) and after 72 hours (T1). Three out of 23 patients developed VAP during follow up respectively at day 5, 13 and 15 after mechanical intubation. Overall, the comparison of the samples collected at two different times showed that: Bergeyella Veillonella, Leptotrichia, Variibacter, Stenotrophomonas significantly are less present at T1 than T0 while Peptostreptococcus in T0 than T1. Among three patients with VAP genera Eubacterium, Lachnospiraceae, Lachnospira, Lactobacillus, Leptotrichia, Bradyrhizobium and Anaeroplasma were significantly higher in T0 than T1 while commensal strains characteristic of the upper airway such as Porphyromonas, Alloprevotella, Prevotella, Howardella, Solobacterium, Dialister, Veillonella and Fusobacterium increased in T1 than in T0.

CONCLUSION. Preliminary results highlighted the impact of orotracheal intubation procedure on the pulmonary microbiota changes, in agreement with the previous data emerged in literature (Kelly, 2016) (Vladimir Lazarevic, 2014). Given the few cases of VAP, comparisons between VAP and no-VAP patients do not allow to identify microbiota characteristics associated to development of pneumonia. Larger studies are needed to compare healthy controls and cases that develop VAP and in order to clear the significance of our findings and to achieve a better understanding of the phenomenon.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001695

INTRODUCTION. Immunosuppressive therapy following liver transplantation(LT) makes these patients more susceptible to infections which can lead to poor outcomes following LT.1 Recurrent hospital admissions predispose these patients to colonization with drug resistant organisms and gut is the most common site.2. We therefore decided to study the incidence of Carbapenem Resistant Enterobacteriaceae (CRE) colonization in the gut in our LT recipients, risk factors and the outcome of CRE colonization in those LT recipients.

METHODS. This study was conducted between September 2017 and July 2018 at Gleneagles Global Hospital. All adult living donor liver transplant (LDLT) recipients except acute liver failure, re transplantation and combined organ transplants who consented were included. Rectal swab was done in the week preceding the transplant and immediately cultured on Hi chrome KPC Agar. Any growth was subcultured on Blood agar and MacConkey agar, followed by Identification and Antimicrobial Susceptibility Testing in Vitek 2-Compact system. Antibiotics for perioperative period were started as per institution protocol. Preoperative parameters like MELD score, hospital admissions, episodes of infection and antibiotics used, spontaneous bacterial peritonitis (SBP), UGI bleeding, encephalopathy, acute kidney injury (AKI) large volume paracentesis(LVP) and hydrothorax requiring drainage (HTD) were noted. Intra op details like graft versus body weight ratio (GRWR), surgical duration, blood components used and other complications were noted. Postoperative parameters recorded include prolonged ventilator/ vasopressor requirement, AKI requiring continuous renal replacement therapy(CRRT), graft function & other graft related complications, intraabdominal collections & pleural effusions requiring drainage, infections, duration of ICU and hospital stay and mortality. Data collected was analysed using STATA statistical software. Two-sided independent-sample t test to compare means across dichotomous variables & the one-way ANOVA test for comparison of means across multilevel variables were used. A p value <0.05 was considered statistically significant.

RESULTS. Please see uploaded table. 40 recipients were included. 15 (37.5 %)recipients had CRE colonization - CREpos & 25 (62.5%) were CREnegative. No difference in medical comorbidities were noted except high MELD score in CREpos. Ascitis, LVP,SBP,HTD, malnutrition, AKI, UGI bleeding, encephalopathy, preop ICU were more frequent in CREpos. Requirement of PRBC and other blood components, vasopressors, surgical duration and lactate were higher in the CREpos group. Postoperatively graft function was similar but CREpos had more prolonged requirement of vasopressor/ ventilator and CRRT, reintubations, drainage of intraabdominal collection and pleural effusion, more ICU readmissions, wound infection and bacteremia. The duration of ICU and hospital stay was higher in the CREpos. 2 (13.33%)patients died in CREpos while 1(4 %) died in the CREneg group. Statistically significant difference was noted in the requirement for LVP, preop AKI, PRBC requirement, duration of ICU stay and CRRT requirement. More preop carbapenem exposure was noted in CREpos though it was not statistically significant.

CONCLUSION. LT recipients who require more interventions and hospitalizations in the preoperative period seem more susceptible to CRE colonization. These patients are at a higher risk of complications in the intraoperative and postoperative period with higher mortality rates. The most probable cause for CRE colonization is presumed to be gut translocation although the yield of positive cultures is low. Preemptive selective digestive decontamination needs to be vigorously tested in these immunocompromised patients keeping in mind the presumed risk of emergence of more resistant microorganisms.3,4

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001723

INTRODUCTION. Multidrug resistant infection in Intensive Care is increasingly common and is associated with significant patient mortality and morbidity. St Georges hospital is a Level 1 trauma and tertiary referral centre covering the catchment area of South West London and Surrey. The Adult Critical Care directorate provides 61, level 2 and 3 beds spread across three units; General, Cardiothoracic and Neuro Intensive Care. The aim of this retrospective observational study is to assess the frequency and degree of antimicrobial resistance among common Gram Negative (GN) and Gram Positive (GP) bacteria isolated from patients in a large London Intensive Care Facility.
METHODS. Clinically indicated specimens collected from the three intensive care units over a four year period (2013-2016) were included consisting of community and hospital acquired infection, and colonisation specimens. Resistant categories were defined by Minimum Inhibitory Concentration (MIC) using EUCAST breakpoint recommendations. Data was collected and analysed using WHONET software
RESULTS. 2911 patient isolates over a 4-year period from January 2013 to December 2016 were included. Of these isolates 59% (1726) were gram negative organisms and 40% (1185) gram positive. Among Enterobactericae, all tested isolates were sensitive to meropenem. 3rd Generation cephalosporin resistance was most prevalent among *Enterobacter clocae* with 22.8% and 24.4% of isolates resistant to ceftazidime and cefotaxime respectively. 10.6% of *Escherichia coli (E. coli)* isolates were resistant to ceftazidime and 13.3% to cefotaxime. Ceftazidime and cefotaxime resistance was present in 8.6% and 9.3% of *Klebsiella pneumonia (K. pneumonia)* isolates. Ciprofloxacin resistance was highest among *E. coli* (15.5%) followed by *K. pneumonia* (8.9%). Meropenem resistance was present in 3.7% of *Pseudomonas aeruginosa* (*P. aeruginosa*) isolates, ciprofloxacin resistance in 7.8% and piperacillin/tazobactam resistance in 6.1%. Vancomycin resistance was present among 14.3% of *Enterococcus faecium* isolates.
CONCLUSION. Intensive care is commonly considered to be a reservoir for infection due to its vulnerable immunosuppressed population, frequency of invasive procedures, and use of medications such as muscle relaxants and sedation. A significant percentage of *E. coli* and *K. pneumonia* at our ICU were resistant to 3rd line cephalosporin. This is comparable to national data demonstrating resistance to 3rd generation cephalosporin's to be 10.8-12.4% for E. coli and 10.0-11.5% for K. pneumonia over similar period (2012-2016). Carbapenem resistance among *P. aeruginosa* is a growing concern nationally. London has the highest level of resistance with over 10-14% resistance recorded between 2012-2016. Interestingly the percentage resistant isolates was significantly lower among our critically ill patients (3.7%).This study provides an interesting insight into the ecology of a large London ICU and how it compares to national UK nosocomial data. It reinforces the need for appropriate and diligent infection control practices and antimicrobial stewardship going forward

INTRODUCTION. Early administration of appropriate empirical antibiotic therapy has been shown to reduce the morbidity and mortality in severe infections. Nowadays, in the context of increased antibiotic resistance, clinicians who treat critically ill patients at risk of multidrug resistant bacteria (MDRB) infections initiate broad-spectrum antibiotic therapy with one or more antibiotics, entailing an additional risk of increased resistance. Many studies have shown that surveillance cultures allow us to assess the dimension of the multi-drug resistance problem in an ICU.
OBJECTIVES. Our aim was to analyse the impact of surveillance cultures in predicting multi-drug resistant bacterial infections.
METHODS. We conducted a prospective observational study in an 8-bed medical ICU between January 2016 and November 2018. All patients included in the ENVIN-HELICS database (ICU-acquired infection surveillance program promoted by the Spanish Society of Intensive and Critical Care Medicine and Coronary Units, SEMICYUC) were analysed. ENVIN-HELICS database collects data from all infections within the ICU. We routinely performed a nasal and rectal swab test to all patients upon admission and on a weekly basis for the detection of MDRB. We describe demographics, severity at admission (APACHE-II), ICU length of stay (LOS), MDRB colonisation on admission and ICU-acquired MDRB infections. We analysed previous MDRB colonisation in patients with ICU-acquired MDRB infections.
RESULTS. 735 patients (57% males) were included during the study period. Mean age was 68.5 years (SD 16.37), mean APACHE-II at admission was 21.5 (SD 8.08) and mean ICU LOS was 7.5 days (SD 13.45). Intra-ICU mortality among our cohort of patients was 16.3%. On admission, 16.6% of the patients were colonised by a MDRB. Most frequent microorganisms were: *ESBL-producing Escherichia coli* (32.3%), *carbapenemase-producing Klebsiella spp.* (19.8%), *methicillin-resistant Staphylococcus aureus* (MRSA - 17.6%) and *ESBL-producing Klebsiella spp.* (13.2%). During ICU stay (after 48 hours of admission) a MDRB was isolated in 7% of the patients. *Carbapenemase-producing Klebsiella spp.* (49.1%), *ESBL-producing Klebsiella spp.* (12.3%), *Pseudomonas spp.* (7%) and MRSA (7%) were the most frequent microorganisms. Twenty-one patients (2.9%) had 23 ICU-acquired MDRB infections. Ventilator-associated tracheobronchitis (VAT - 47,8%), ventilator-associated pneumonia (VAP - 13%), urinary tract infection (13%) e skin and soft tissue infection (13%) were the most frequent infections. Most frequent microorganisms were: *carbapenemase-producing Klebsiella spp.* (47,8%), *ESBL-producing Escherichia coli* (13%) and *Acinetobacter baumanni* (13%). Among patients with an ICU-acquired MDRB infection, 69.5% were previously colonised by a MDRB and in 21.7% a MDRB was isolated in a rectal swab and in clinical samples simultaneously. Only 8.7% of the patients were not colonised at the time of infection.
CONCLUSION. In the majority of ICU-acquired MDRB infections, infection is preceded by colonization. VAT is the most frequent ICU-acquired MDRB and *carbapenemase-producing Klebsiella spp.* is the most frequently isolated microorganism.

INTRODUCTION. Peripheral intravenous catheter (PIVCs) is the easiest, quickest and least resource demanding way to administer intravenous fluids, medication and blood transfusion. PIVCs are considered harmless devices, however they account for a mean of 38% of catheter associated bloodstream infections (CABSI) of *Staph.aureus* (1), which is a serious complication often in need of long antibiotic treatment, ICU stay and with high mortality. PIVC related CABSI are preventable complications if PIVC quality is addressed properly. However, there exist no quick validated tool to assess and improve PIVC quality and thereby CABSI reduction (2). Thus, we aimed to develop and test validity for an efficient screening tool regarding overall PIVC quality for systematic measurements of quality improvement to reduce PIVC related CABSI.
METHODS. The *PIVC-miniQ* consists of 16 items (yes/no) regarding observation of problems related to the insertion site, condition of dressing and equipment, documentation, and indication for use. Each problem gives one point and all items can be summed up in a total score (0-16). Two hospitals tested the *PIVC-miniQ* for feasibility and inter-rater agreement. Each PIVC was assessed twice, 2-5 minutes apart by two independent raters. We calculated the intraclass correlation coefficient (ICC) for each hospital and overall. For each of the 16 items, we calculated negative agreement, positive agreement, absolute agreement and Scott's pi.
RESULTS. Sixty-three raters evaluated 205 PIVCs in 177 patients. ICC between raters was 0.678 for hospital A, 0.577 for hospital B, and 0.604 for the pooled data. Mean time used for each PIVC assessment was 3.02 (SD 1.76) minutes, where most of the time was used to answer the documentation item. The most frequent insertion site symptom was "pain and tenderness" (14.4%), followed by "redness" (12.6%), whereas the most prevalent overall problem was lack of documentation of the PIVC (26.8%). Up to 50% of PIVCs were placed near joints or were inserted under suboptimal conditions, i.e. emergency department or ambulance.
CONCLUSION. We found the *PIVC-miniQ* sum score to be a reliable and efficient outcome measure for quality control, taking only 3 minutes on average to complete. The measure of consistency can be described as moderate to high with an ICC of 0.604 for the sum score. The observed PIVC quality were far from optimal and the *PIVC-miniQ* can thus reliably measure development in PIVC quality in point prevalence audits and evaluate interventions to reduce CABSI.

Should CDC's recommendations for promptly removing unnecessary central venous catheters be enhanced?

S. Iordanou,[1], N. Middleton[2], A. Kastoris[1], O. Lambrianidou,[1], C. Timiliotou-Matsendidou,[1], L. Palazis,[3], E. Papathanasoglou[1], V. Raftopoulos,[2]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000763

INTRODUCTION. Catheter related bloodstream infections (CR-BSIs) not only increase hospital length of stay, affecting the cost of hospitalisation but may, as an independent factor, affect mortality. According to the CDC there is consensus regarding the strong recommendation for the prompt removal of intravascular access that is no longer essential, and the preference of peripheral venous catheters that seem to be rarely associated with bloodstream infection. The implementation of ultrasound guided peripheral venous cannulisation (UGPVC) seems to be helpful according to the relevant literature and clinical practice especially in cases of difficult or failed peripheral cannulisation especially in ICU patients.
OBJECTIVES. The main aim of this study is the incorporation of UGPVC and the subsequent examination of the effect of the use of ultrasound guidance for peripheral vein cannulisation on CR-BSIs.
METHODS. A retrospective cohort study was performed in the ICU of the Limassol General Hospital, Cyprus from January 2015 until December 2016. During the study data was collected regarding CR-BSIs using ICU protocol (ECDC-NHSN, HAI-ICU Protocol, v1.01 standard edition). Additionally, during 2016 data was collected regarding the use of UGPVC on patients where methods for vein cannulisation such as palpation from experienced practitioners were expected to be difficult or else failed. Patients were included in the study that were admitted in ICU for more than 48 hours. Data was collected regarding demographics, CVC utilization, acute physiology and chronic health evaluation (APACHE II), simplified acute physiology score, days of patient's device exposure, length of stay and outcome on discharge from ICU. During 2016 a UGPVC survey was conducted with additional data being collected regarding attempts of cannulation, number of succeeded or/and failed cannulations, peripheral cannulation site, cannula diameter size, and body mass index.
RESULTS. During 2015, surveillance data was collected for 198 (125 males) patients hospitalized in the ICU for a total of 2,269 ICU days. A total of 43 instances of DA-HAIs were detected in 25 of the 198 patients. CR-BSIs was the most commonly encountered type of infection accounting for 21(48.8%) incidents with a rate of 15.93 (9.9-24.3) per 1000 CVC days. During the 2016 period of the study, surveillance data was collected for 184 (113 males) patients hospitalized in the ICU for a total of 2,029 ICU days. A total of 24 instances of DA-HAIs were detected in 16 of the 184 patients. CR-BSIs was the least commonly encountered type of infection accounting for 4 (16.7%) incidents and a rate of 4.16 (1.1-10.6) per 1000 CVC days. CVC utilization ratios was reduced by 10.7% ($p<0.05$) (58% to 47%) and CR-BSI incidence rate was reduced by 11.7 per thousand device–days (15.9 to 4.16/1000 CVC days).
CONCLUSION. The reduction of CR-BSIs found in the current study (74% reduction) seems to be more than the reduction described in relevant literature (about 66%). The combination of five evidence-based procedures recommended by the CDC together with the utilisation of UGPVC, may effectively decrease the CR-BSIs, affecting costs, length of stay and even patient outcome.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000768

INTRODUCTION. Increased hospital exposure and transmission of Multi-Drug Resistant Organisms (MDROs), increase costs, length of hospital stay, morbidity and mortality and facilitate the need for increased surveillance and facility level prevention strategies. The CDC recommends in cases of positive MDROs cultures, single room isolation and specific dedicated staff allocation additional to standard contact precaution measures, and other prevention strategies. In the absence of single room facilities, the CDC advises the cohorting of patients with similar culture results. The compliance nevertheless with the recommendations of single room isolation and cohorting of patients may be impossible due to the ICU configuration.
OBJECTIVES. The development and implementation in the ICU of a unique MDRO transmission prevention and infection approach was evaluated. The approach was named the "Z Concept Approach".
METHODS. The study was conducted in the ICU of the Limassol General Hospital in Cyprus. Since isolation rooms and cohorting MDRO-positive patients was not feasible, the open plan ICU space was divided in theory in two grading zones (red and green zone) with application of behavioural restrictions, together with contact precautions based on the above-mentioned zones. The effectiveness of the approach was studied in a prospective cohort study. Data regarding active MDRO screening was collected using a protocol based on the ICU (ECDC HAI-ICU Protocol, v1. 01 standard edition) for a period of four months. All patients admitted in the ICU, were screened for MRSA & MDROs by obtaining nasal and rectal culture swabs during admission, followed by weekly screening and on discharge. In the event of MDRO positive patients, pathogen/s species and resistance pattern were correlated with the rest of the infection positive ICU patients (colonization pressure), in order to locate or decline the patient/infection source.
RESULTS. During the 4-month study period, 78 patients were admitted to the ICU for a total of 942 patient days. In total 432 swabs for the detection of MRSA and MDROs were collected during the study period. Patients were monitored for a total of 942 ICU days leading to MDROs incident density of colonisation on admission of 17 per 1000 days [95% CI, 12. 1 – 31. 4]. Furthermore, the overall colonisation pressure during the study period, was 19/78 (24. 4%). A total of 17 (21. 8%) patients were admitted with a pre-existing infection and 2 (2. 5%) patients acquired an infection during their stay. The two microorganisms involved in the two acquired ICU infections were Acinetobacter baumanni and Pseudomonas aeruginosa, with one acquisition respectively. The acquisition rates for each of the MDROs in our ICU were 1.28 instances of A. baumanni and P. aeruginosa per 1000 patient days, while no acquisitions were documented for Klebsiella pneumoniae, Enterococcus faecalis and Staphylococcus aureus.
CONCLUSION. The low MDRO acquisition rates documented in the current study, indicated that the development and implementation of unique infection control strategies may effectively prevent pathogen transmission in the ICU. This strategy was successful even in an open plan ICU with high colonization pressure, inadequate space separation, and understaffing by nursing professionals.

INTRODUCTION. The most important risk factor for the development of nosocomial Urinary Tract Infection (UTI) is the presence of a urinary catheter (UC). The duration of catheterization is also important for CAUTI development in patients with long-term Intensive Care Unit (ICU) requirements.
OBJECTIVES. Between the years of 2014-2018, the aim of this study was to evaluate the catheter associated urinary tract infection (CA-UTI) rate, invasive device use rate and causative microorganisms isolated in these infections.
METHODS. This study was conducted in an Anesthesiology and Reanimation Intensive Care Unit. Five year's surveillance data was evaluated in this study. CA-UTI rate per 1000 UC-days and device utilization ratios are retrospectively evaluated. Microbiological culture results of invasive device associated urinary tract infection were also evaluated. Standard laboratory methods were used to identify and test the susceptibility of the microorganisms, and standardized US Centers for Disease Control and Prevention (*CDC*) definitions was used for CA-UTI diagnosis (CA-UTI rate = CA-UTI number / Urinary catheter day x 1000).
RESULTS. 2944 patients were included in the study**.** Urinary catheter usage ratio was 97.2 % in the ICU for 41.972 catheter days. The mean rate of CA-UTI was 7.56. The total CA-UTI number was 271and the mean was 54.2/year. The CA-UTI rate was 10.8 in 2014. This rate was decreased to 5.3 in 2018, although the urinary catheter use ratio were similar. Most commonly detected causative agents were Escherichia coli (20.9 %), Klebsiella spp. (20.4 %), and Enterococcus spp. (14.8 %) for catheter associated urinary tract infections during the five-year study period. When we analyze by years, the most commonly isolated microorganisms were Candida spp. (20.2 %), Escherichia coli (21.6 %), Klebsiella spp. (18.7 %), Escherichia coli (26.4 %) and Klebsiella spp. (31.1 %), in 2014, 2015, 2016, 2017 and 2018, respectively.
CONCLUSION. Patients admitted to ICU are the most appropriate candidates for CA-UTI due to their more frequent necessity of urinary catheterization and longer duration of catheter use. CA-UTI rate in studies involving European countries was 62.2 %. Short-term catheterization rate was 90.8 %. Risk factors leading to CAUTI in ICU and microorganisms should be considered in order to prevent CAUTIs.

INTRODUCTION. Sternal wound infections (SWI) following open-heart surgery are a serious complication that have a significant impact on patient morbidity, mortality and length of hospitalization. Despite the implementation of a SWI policy in 2017 in our in center , after one year the incidence of infection is still significant and it needs a proactive action from our team.
OBJECTIVES. Identify risks factors for SWI and lack of adherence to our policy. Plan strategies to decrease SWI.
METHODS. Review of our SWI prevention policy based on Lazar at al.2016 recommendations.Retrospective review of 684 cardiac surgical procedures performed in 2018. A dedicated Infection Control Nurse (IC) reviewed charts and conducted audits during the pre-op admission, assessing for SWI risks factors and surgeons' performance. Descriptive statistics and plan for quality improvement are presented
RESULTS. 684 procedures were performed. Age 64±12.4 , 65% were male. Surgeries: 259 valve replacements, 38%; 116 valvuloplasty, 17%; 116 CABG, 17%; 13 transplants, 2 %; 26 type A aortic dissection 4%; 150 others, 22%.EuroScore 3.39± 4.98,length of stay in ICU 3,56± 6,3,lactate level 4,06 ±4,45,SOFA score4,9±2,48,CEC 111.1±53,38.
SWI were n=24 (3,4%) compared to 3,6% in 2017with a benchmark in literature of 0.5%.
SWI age : 64 ± 12.4, 33% were male. Surgeries: 15 Valve replacements 63%; 6 CABG 25%; 1 transplant,4%; 1 type a Aortic dissection 4%,1 other4%
15 Patients(63%) had pre-op outpatient consultation, 9(37%) were transferred from other hospitals and had no infection prevention screening. No evidence of Pre- op patient education on nutritional status or smoking cessation.
N=9 ;60% had a nasal swab performed pre-op, 4 (44%) were positive to Staph. Aureus, and for them there was no evidence of Mupirocin therapy and Chlorhexidine 4% shower prescription. Showers with chlorhexidine 4% were prescribed for 21 patients (88%), but a lack of accurate documentation makes it impossible to assess this.
Oncall antibiotics were administered to 100% of patients, however, there was no standardized documentation on timing for the second dose. Intraoperative glycemic control was rarely performed. On 86% of the 15 patients, insulin drip was started post-op.
We identified grey areas in which we need to improve.Mupirocin will be prescribed to all patients undergoing cardiac surgeries, whether they are positive or negative;our IT team will make some changes on the electronic medical and nursing notes in order to obtain accurate nursing and medical records, an educational brochure and video on smoking cessation, nutrition, diabetes control, and oral care will be provided to patients pre-op.
CONCLUSION. Despite the presence of an up to date policy, the rate of SWI is still high at our center.The audit was able to highlight grey zone in clinical practice that were used to revise the current policy in SWI prevention.The role of an IC nurse dedicated to SWI will be crucial in identifying SWI champions to further train staff and create a multidisciplinary network for SWI prevention.The involvement of leadership will be decisive in order to put into place what we have on policy.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001067

INTRODUCTION. Paromomycin is a aminoglycoside antibiotic. Emergence of bacterial resistance led to many of us to consider the combination of antimicrobial agents. We tested the effect of paromomycin on isolates of multidrug resistant pathogens (MDR) including: *Pseudomonas aeruginosa, Klebsiella pneumoniae, Escherichia coli,* and methicillin-resistant *Staphylococcus aureus*. Paromomycin combined with ceftriaxone, ciprofloxacin, ampicillin/sulbactam, azithromycin, clindamycin or doxycycline showed mostly synergistic effect on these clinically important MDR pathogens. We routinely apply Selective Digestive Decontamination (SDD) with topic colistin. However, some patients had rectal colistin and / or carbepenemase (CPN) resistant microorganisms colonization. The aim of this study was to administrate enteral paromomycin to decontaminate these MDR microorganisms and to prevent the development of ICU nosocomial infections.
METHODS. All consecutive patients admitted to the ICU from October 2011 to June 2017, expected to require tracheal intubation for longer than 48 hours were given SDD with a 4-day course of intravenous cefotaxime, plus enteral colistin, tobramycin and nystatin in an oropharyngeal paste and in a digestive solution. Patients with rectal swabs colonized by colistin and / or carbepenemase resistant microorganisms were treated with enteral paromomycin 1 gr every 6 hours a day, in order to become it negative and prevent nosocomial infections. Categorical variables were summarized as frequencies and percentages and the continuous ones as medians and interquartile ranges (IQR) or means and standard deviations. Statistical significance was set at $p \leq 0.05$.
RESULTS. We applied paromomycin treatment to 102 colonized patients with rectal colistin resistant microorganisms. All of them but six had colonization by Extended Spectrum Beta-lactamases (ESBLs) producing *Klebsiella pneumoniae*. Two patients was colonized by ESBL producing

Enterobacter spp , other one by ESBL producing *Escherichia coli*., 1 by *Acinetobacter baumannii* and 2 by *Serratia marcescens*. Demographic data and type of admission are shown in Table 1. Seventy-nine out of 102 (80.5%) negativized the rectal exudate after paromomycin. Of those negativized, 26 patients received an appropriate antibiotic during the application of paromomycin. Five out of the seven patients with CPN were decolonized. 47 patients died in the ICU and 24 of them, died without being de-colonized being two of them with CPN resistant microorganisms. Only 3 patients developed infections after decolonization.

CONCLUSION. Our data show that enteral paromomycin is effective in treating rectal colistin and / or carbapenemase resistant microorganism colonization to prevent the development of ICU nosocomial infections.

INTRODUCTION. Selective digestive decontamination (SDD) have been associated with reduced mortality and lower ICU-acquired rates However, the effect SDD in areas where multidrug-resistant Gram-negative bacteria are endemic is less clear. We want to prospectively.evaluate the impact of SDD application on nosocomial muli-resistant (MR) infections (NI) and colonization rates, after 7 years in a mixed ICU.
METHODS. This study was conducted in a 30-bed-medical-surgical ICU. All consecutive patients admitted to the ICU from October 1, 2011 to September 30, 2018 expected to require tracheal intubation > 48 hours were given SDD (SDD study group) with a 4-day course of intravenous cefotaxime, plus enteral colistin, tobramycin, nystatin in an oropharyngeal paste and in a digestive solution. Oropharyngeal and rectal swabs were obtained on admission and once weekly. We used ENVIN NI criteria. We compared all patients admitted to ICU with ICU NI from October 1, 2010 to September 30, 2011 (non-SDD group) to the SDD study group. A univariate and a multivariate logistic regression analysis was performed. For each one of the infections the incidences per 1000 days of exposure in each cohort and the corresponding relative risks were obtained using the Poisson regression. Statistical significance was $p \leq 0.05$.We analyzed colistin- and tobramycin-resistant colonization and also antibiotic consumption as Defined antibiotics Daily Doses (DDD).

VAP: ventilator associated pneumonia; MV: mechanical ventilation; CRB: Catheter related bacteremia; CVC: Central venous catéter.

RESULTS. Results are shown in Tables 1, 2 and 3. There were no statistical significant differences between both groups in type of admission or demographic data. Patients with SDD had significantly less Extended Spectrum Betalactamase (ESBL), Gram Negative Bacteria Multirresistant (GNB-MR) and *Acinetobacter spp* infections. We had also a significant reduction in ventilator associated pneumonias (VAP), urinary infections and other secondary bacteremias and antibiotic resistant bacteria infection rates, in SDD group versus non SDD. There was no infection by *Clostridium difficile*. The exogenous infections were 499 (74%). Colistin resistant colonization was 16,5% and tobramycin resistant colonization was 25,7% of samples. There was a decrease on the DDD/100 ICU stays after SDD.
CONCLUSION. After 7 years applying SDD a significant reduction of infections by ESBL, GNB-MR and *Acinetobacter,* was observed. A significant decrease of VAP, secondary bacteremias, urinary and ARB infections rates was also shown. An antibiotic consumption reduction was found after SDD. Low rates of colistin and tobramycin-resistant colonization bacteria were observed

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000017

INTRODUCTION. Risk stratification is essential to decide the best location and resource use for each patient.
OBJECTIVES. To describe the risk factors and their association with mortality of the patients with pulmonary embolism (PE) who are admitted to the Intensive Care Unit (ICU).
METHODS. We conducted a retrospective observational study in the Intensive Care Unit of a single university hospital. All the patients who were admitted to the ICU with PE as a primary diagnosis were

included, over an 8-year period. Demographics, comorbidities and worst values of vital signs and laboratory tests within the first 24 hours of admission were registered. Risk stratification was performed with the simplified Pulmonary Embolism Severity Index (sPESI) and according to the recommendations of the European Society of Cardiology (ESC). Chi-square, Fisher's exact test and Student's T test were applied as appropriate. Bivariate analysis was performed to show the relationship between variables and mortality.
RESULTS. A total of 82 patients were included, 43% male, aged 64 (44-77), APACHE-II 12 (8-17), 42% fibrinolytic therapy, 15% hospital mortality. Mortality risk according to sPESI: high 82%, low 18%. Mortality risk according to ESC: high 34%, intermediate 56%, low 10%. Common comorbidities were: arterial hypertension 34%, dyslipidaemia 22%, hospital admission/surgery/trauma (HA/S/T) within the previous 3 months 22%, smoking 18%, previous episode of deep venous thrombosis (DVT) 12%, use of oral contraceptives 12%, diabetes mellitus 11%, neoplasm 10%, autoimmune disorder 8%, thrombophilia 6%, previous episode of PE 6%. Reasons for admission were: recovered cardiopulmonary arrest (CPA) 5%, cardiogenic shock (CS) 11%, acute heart failure 7%, acute respiratory failure (AFR) requiring mechanical ventilation (MV) 17%, ARF with no need for MV 29%, high-risk stratification with clinical stability 30%. Risk factors for mortality were: male sex (OR 3.3, p=0.07), presence of ≥1 cardiovascular risk factor (OR 1.7, p=0.39), HA/S/T (OR 3.1, p=0.07), previous DVT/PE (OR 1.1, p=0.93), presence of ≥2 items in the sPESI (OR 16.5, p<0.01), severe form of presentation (CPA, CS, ARF with MV) (OR 37.1, p<0.01). Vital signs and laboratory test results, survivors vs deceased: MAP 107 vs 81 mmHg, p<0.01; HR 103 vs 122 bpm, p=0.02; SpO2 91 vs 85%, p=0.05; RR 25 vs 30 bpm, p=0.05; haemoglobin 13.2 vs 11.8 g/dl, p=0.03; platelets 232 vs 168×10³/μl, p=0.03; creatinine 0.95 vs 1.59 mg/dl, p<0.01.
CONCLUSION. The presence of ≥2 items in the simplified PESI score predicts mortality better than the simply positive result (≥1 item) within patients with PE who are admitted to the ICU. These patients might benefit from a closer and more aggressive management in the ICU.
Severe forms of presentation (CPA, CS or ARF requiring MV) dramatically increased the risk of mortality, and should be admitted to the ICU. However, high-risk stratification with clinical stability was not associated with mortality, so admission in a regular ward might be safe.
Patients who died because of a PE showed more hypotension, tachycardia and kidney failure within the first 24 hours of presentation, so admission to the ICU should be considered when these parameters are abnormal.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000054

INTRODUCTION. Cardiogenic shock (CS) is a state of critical end-organ hypoperfusion due to primary cardiac dysfunction. Most epidemiological data for CS focus on patients with acute myocardial infarction managed in intensive care units (ICUs) of cardiology departments. Little is known about the most severe forms of CS, with multi-organ failure, managed in general ICUs.
OBJECTIVES. Identify main predictors of mortality in CS and evaluate their impact in the outcome. Evaluate usefulness of SOFA, APACHE II and SAPS II scores in predicting the outcome in CS patients (P) and identify the most useful one, if applicable
METHODS. Retrospective analysis of patients (P) admitted in our ICU, with confirmed diagnosis of CS, within a period of 5 years (January 2012- December 2016). We analyzed common epidemiological variables, evolution during ICU stay, established therapeutics and outcome.
RESULTS. 90 P were included. The mean age of the population was 69,59 ± 12,23 years, with a predominance of males (56,7%). Majority of P coming from the Emergency Room (45,6%) and 26,7% presenting cardiopulmonary arrest at admission. Admission SOFA of 10,39 ± 3,19. The main cause of CS was non-ischemic (66,7%). In 27,8% of P the presence of mixed shock was verified. 68,9% needed mechanical invasive ventilation. Maximum PEEP of 8,22 ± 2,76 and median weaning of 3 days during ICU stay, respectively. PaO2/FiO2 ratio and lactactes at admission of 178,5 and 2,85, respectively. All the patients needed aminergic support. 34,4% needed renal replacement therapy. At discharge, the patients presented median ICU stay of 5 days with SOFA, APACHE II and SAPS II of 7.6±5,06, 24,5 and 56,61 ± 19,71, respectively. Hospital mortality of 45,6%.
We found a statistically significant association between outcome and:1) etiology (p=0,024), 2) admission SOFA (p=0,006), 3) APACHE II (p< 0,001), 4) SAPS II (< 0,001) and 5) lactates variation in the first 24h (p=0,027). We also point out that after applying a logistic regression, to compare the impact of the used scores, only APACHE II (OR: 1,13; IC95%: 1,028-1,253) had relevant prediction power.
CONCLUSION. CS requires rapid diagnosis and appropriate therapy to have a positive influence on the outcome. In our study, we found that APACHE II was the best score to use in this kind of patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000093

INTRODUCTION. Cardiac surgery performed with cardiopulmonary bypass (CPB) is frequently complicated by hemodynamic [1] instability due either to an inflammatory response [2] or to cardiac dysfunction during or immediately after the weaning from CPB [3]. There are limited studies on the incidence and the risk factors of prolonged vasopressor dependence following cardiac surgery [4].
OBJECTIVES. The objective of the study was to identify risk factors related to prolonged dependence on vasopressors after weaning from bypass.
METHODS. Approval has been obtained by our Research Ethics Committee. In this single-center retrospective cohort study, we analyzed data from consecutive adult patients who underwent cardiac surgery with CPB enrolled in two prospective studies between November 2016 and July 2017 in a specialized cardiac surgery center. The study excluded all cardiac surgery without CPB, heart transplantation and ventricular assist devices. Postoperative prolonged vasopressor dependence was defined as the need for at least one vasopressor agent from the end of CPB for a duration greater than 24 hours. Vasopressor agents included norepinephrine, vasopressin, epinephrine, dopamine and phenylephrine. A follow-up was conducted for all patients until the end of intensive care unit (ICU) day 1. A multivariable logistic regression model using a forward stepwise selection approach was developed to identify independent predictors of vasopressor dependency.
RESULTS. A total of 247 out of 263 patients underwent cardiac surgery with CPB between November 2015 and July 2017 using our exclusion criteria. The mean age of the study patients was 65 ± 12 years old and 126 (51%) were female (Table 1). The incidence of prolonged vasopressor dependence was 40% and was associated with more prolonged mechanical ventilation (5h (IQR4-9) vs. 4h (IQR3-5); p<0.001), prolonged ICU stay (3 days (IQR1-2) vs. 1 day (IQR1-2); p< 0.001) as well as hospital stay (7 days (IQR6-10) vs. 5 days (IQR4-7);

p<0.001). In multivariable analysis, pre-existing reduced left ventricular ejection fraction (LVEF<30%) (OR: 9.52, 95%CI:1.14-79.24; p=0.03), preoperative pulmonary hypertension (PH) (moderate PH (sPAP≥30 but <55mmHg) OR:2.5, 95%CI:1.14-5.52, severe PH (sPAP>55mmHg) OR:8.12, 95%CI:2.53-26.02; p=0.001) and first 24h cumulative fluid balance (OR:1.78, 95%CI:1.41-2.24; p<0.0001) were independently associated with the development of prolonged vasopressors dependence: with a good ability to predict vasoplegia after cardiac surgery based on ROC analysis (AUC=0.80, 95%CI: 0.73-0.86; p<0.0001).
CONCLUSION. Vasopressor dependency remains a frequent complication after CPB surgery. Its associations with PH and large fluid balance is unreported and potentially reversible. Prospective studies and clinical trials should explore the role of these two factors in future studies.

The use of levosimendan on weaning from venous-arterial extracorporeal mechanical oxygenation support: results of a tertiary centre

F. Caetano[1], V. Templeman[1], C. Remmington[1], M. Passariello[1], R. Trimlett[2], S. Price[1]
[1]Adult intensive care unit, Royal Brompton & Harefield Nhs Foundation Trust, London, United Kingdom; [2]Cardiac surgery, Royal Brompton & Harefield Nhs Foundation Trust, London, United Kingdom

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000108

INTRODUCTION. Levosimendan (Lv) is a calcium sensitizing inotrope indicated for short-term treatment of acutely decompensated severe chronic heart failure (1). Venous-arterial extracorporeal membrane oxygenation (VA-ECMO) provides temporary mechanical circulatory support in patients with refractory cardiogenic shock (2). Few data is available on the impact of Lv on VA-ECMO weaning.
OBJECTIVES. Evaluate the safety and efficacy of Lv on VA-ECMO weaning in patients admitted to intensive care.
METHODS. Retrospective study of 68 patients (57% male; mean age 48.9 years) who received Lv to assist weaning from VA-ECMO.
Successful outcome was described as VA-ECMO decannulation within 48 hours after Lv infusion and patients had also to be alive for, at least, 48 hours after the procedure.
Safety data (hypotension, arrhythmias and hypokalaemia) was recorded.
RESULTS. More than half of the patients (54.4%) were established on VA-ECMO after cardiac surgery.
The first Lv infusion was started ± 7 days after admission to intensive care. 2 patients received loading dose. The infusion ran for ± 23 hours and the maximum infusion rate (0.2mcg/kg/min) was achieved in 66.2%.
After the first Lv infusion, 4 patients (5.9%) were successfully bridged to a long term ventricular assist device (VAD) and 26 (40.6%) were successfully weaned off VA-ECMO. On the remaining group of 38 P, 10 received at least one further dose of Lv, 7 or more days after the first dose, enabling successful VA-ECMO decannulation in other 4 patients and bridging to VAD in 1 patient.
Side-effects analysis documented: 53% of clinical significant hypotension and 25% of new atrial fibrillation. One patient had ventricular fibrillation and 3 patients hypokalaemia.
The average ITU length of stay was 25 days and 44.1% of patients survived intensive care admission.
CONCLUSION. In this heterogeneous group of patients that required VA-ECMO for cardiogenic shock, the administration of Lv prior to trial of decannulation was associated with successful weaning in 51% of the patients. Nevertheless, the incidence of known side-effects, namely hypotension and arrhythmias, cannot be neglected, highlighting the high level of monitoring that this specific population demands.
The identification of surrogate markers of potential successful decannulation is warranted, enabling a more tailored therapy.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000147

INTRODUCTION. Cardiac index (CI) is one of the hemodynamic variables to be assessed and monitored in shock patients. FloTrac/Vigileo is a less-invasive uncalibrated arterial pressure waveform analysis. However, its validation is limited in hemodynamically unstable septic shock patients.
OBJECTIVES. The aim of our study was to compare CI measured by 4th generation of FloTrac/Vigileo device with transpulmonary thermodilution obtained by PiCCO in septic shock patients.
METHODS. A prospective observational study was performed in the Medical Intensive Care Unit. We simultaneously measured the CI using a Vigileo device (CIv) and compared it with the CI derived from transpulmonary thermodilution (CItp) as well as the pulse contour-derived CI using PiCCO (CIp). The measurement agreements were evaluated using the Bland-Altman analysis, percentage error and concordance analysis.
RESULTS. Thirty-one septic shock patients were included. Their mean APACHE II score was 26.5±8.1. All of the patients received norepinephrine with a mean dose of 0.33±0.18 ug/kg/min. In the comparison of CIv with CItp, there were 156 data pairs. The CIv and CItp values ranged from 1.5 to 6.8 and 1.5 to 6.9 L/min/m2, respectively. CIv correlated with CItd as indicated by r = 0.62 (p< 0.001). The Bland-Altman analysis corrected for repeated measurements showed a bias of 0.14, and the limits of agreement were -1.62 to 1.91 L/min/m2 with a percentage error of 48.4%. When comparing CIv with CIp (n=352 paired measurements), CIv ranged from 1 to 6.2 and CIp ranged from 1.4 to 6.9 L/min/m2. Here, the Bland-Altman analysis revealed a bias of -0.163, and the limits of agreement were -1.46 to 1.79 L/min/m2 with a percentage error of 45.7%. The overall correlation coefficient between CIv and CIp was 0.63 (p<0.001). Moreover, a four-quadrant plot analysis was performed to evaluate the trending ability of ΔCI change between the two devices. The concordance rate between CIv *vs.* CItd was 95.6%, and that for CIv *vs.* CIp was 85.4%. There were 56 and 16 pairs of CI measurement performed before and after the increase of norepinephrine dose and fluid bolus, respectively. In terms of the absolute changes in CIv and CIp induced by the increased dose of norepinephrine, the bias value was -0.47, and the limits of agreement were -1.73 to 0.8 L/min/m2. In addition, the coefficient of correlation and concordance rate between the percent changes in CIv and in CIp were 0.8 (p< 0.001) and 95.8%, respectively. However, the bias was 0.05 and the limits of agreement between the absolute changes in CIv and CIp induced by volume expansion were -0.28 to 0.38 L/min/m2. Finally, concerning the percent changes in CIv and in CIp induced by fluid expansion, the coefficient of correlation and concordance rate was 0.49 (p=0.05) and 83%, respectively.
CONCLUSION. Our study demonstrated a moderate agreement between the CI derived from a 4th generation FloTrac/Vigileo device with that using the transpulmonary thermodilution method. However, the

uncalibrated CI measured using updated FloTrac software exhibited a more reliable trending ability to track changes in CI compare to transpulmonary thermodilution CI obtained by PiCCO.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000151

INTRODUCTION. Pharmacological scores, such as inotrope score (IS) and vasoactive-inotropic score (VIS) were created to improve the adrenergic dose evaluation in infants cardiac surgery. Later these scores have started to use in adult. However, the significance of IS and VIS as an indicator of hemodynamic profile and predictor of the clinical outcomes in adult cardiac surgery remains unclear.
OBJECTIVES. To estimate IS and VIS as an approach for monitoring of the hemodynamic profile and clinical outcomes in adult cardiac surgery.
METHODS. 144 patients over 18 year had undergone cardiac surgery with CPB were enrolled in prospective observational study. The average age was 63.6 ± 10.4 years. Hemodynamic was estimated by a Swan-Ganz catheter, at the same time points we calculated IS and VIS using standard formulas. For further analysis, we used data that was obtained 6 h after ICU admission. Differences were assessed by the Mann-Whitney and Fisher's exact tests. Data are presented as: median (25th percentile, 75th percentile).
RESULTS. At 6 h after ICU admission, VIS ≥10 was observed in 53/144 patients (36.8%), when only 7/144 (4,9%) patients had IS ≥10.
VIS ≥10 did not show high prognostic significance for adverse outcomes. Thus, in the ROC-analysis, the area under the curve (AUC) of the duration of respiratory support (RS) was only 0.58, and AUC of ICU length of stay (LOS) was 0.59. There was no significant difference between VIS ≥10 and VIS <10 in the duration of RS (12 (6; 18) vs 9 (5; 16) h, p = 0,07), LOS (24 (20; 58) vs 22 (19; 24) h, p = 0,06) and mortality (3.8% vs 0, p = 0,13).
IS ≥10 was significantly associated with adverse postoperative outcomes. ROC analysis showed good prognostic models for both the duration of RS (AUC = 0.86) and the LOS (AUC = 0.91). We found significant differences between IS ≥10 and IS <10 in the duration of RS (83 (15; 120) vs 9 (5; 16) h, p = 0,002), LOS (85 (60; 143) vs 22 (19; 26) h, p = 0,001) and mortality (28.6% vs 0, p = 0,02).
VIS ≥10 was not associated with low cardiac output syndrome (LCOS). There were no significant differences between VIS ≥10 and VIS < 10 in stroke volume index (SVI), SvO2 and lactate. 43.4% patients with VIS ≥10 were treated only with vasopressors without any inotropes.
In contrast, patients with IS ≥10 tended to a lower SVI than ones with IS > 10 (31(17; 47) vs 35(30; 41) ml/m2, p = 0,36). Moreover, patients with IS ≥10 had significantly higher lactate level (7,6(6; 10) vs 2,2(1,7; 3) mmol/l, p = 0,001).
CONCLUSION. We suggest that VIS ≥10 is less sensitive than IS ≥10 for adverse postoperative outcomes. The results of our study indicate that VIS ≥10 characterizes patients with postoperative vasoplegia, while IS ≥10 is associated with LCOS and organ perfusion disorder.

An infraclavicular, real-time, ultrasound-guided, approach to the axillary artery for arterial line placement in critically ill patients: a preliminary report of an AxFemArt randomized controlled trial

R. Gawda[1], T. Czarnik[1], R. Kaplon[2], M. Piwoda[1], M. Marszalski[1], K. Filipiak[1], M. Molsa[1], M. Pietka[1]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000158

INTRODUCTION. Axillary artery catheterization from the axillary fossa is an alternative approach for arterial line placement in intensive care. However, this access is cumbersome and has many drawbacks. Another technique - an ultrasound-guided approach via an infraclavicular route has been described, but to date, it is unknown whether this method is clinically useful in critically ill patients [1].
OBJECTIVES. To examine the efficacy of the infraclavicular, real-time, ultrasound-guided, in-plane percutaneous catheterization of the axillary artery in mechanically-ventilated critically ill patients.
METHODS. A prospective randomized controlled study was conducted in a 11-bed mixed ICU. We included mechanically-ventilated adult patients who had an arterial catheter inserted to monitor arterial pressure or to perform hemodynamic monitoring. An arterial catheter for arterial pressure monitoring was inserted only when radial artery catheterization was impossible. Patients were randomly assigned into two groups. In the A-group, an infraclavicular ultrasound-guided, real-time, in-plane catheterization of the axillary artery was performed using an arterial catheter 3.8Fr (Arrow/Teleflex, USA) or PiCCO catheter 4Fr (Pulsion, Germany). In the F-group, an ultrasound-guided, real-time, out-of-plane catheterization of the common femoral artery was performed using an arterial catheter 3.8Fr (Arrow/Teleflex, USA) or PiCCO catheter 5Fr (Pulsion, Germany). In both groups Seldinger's technique was used. The artery puncture success rate, catheterization success rate, and early mechanical complications were assessed.
RESULTS. From January 2018 to February 2019, a total of 51 patients were randomized: 25 to the A-group and 26 to the F-group. There was no difference in demographic variables. Out of 51 patients, 88.2% were in shock and treated with norepinephrine. Hemodynamic characteristics were similar in both groups (Table 1). The puncture success rate of the artery was 100% in both groups. The catheterization success rate of the axillary and femoral artery was 96% and 92.3%, respectively (difference – 3.7%, 95%CI: [-9.1%, 16.5%]). Directly after the procedure, a small periarterial hematoma in six patients in each group (11.7%) was identified using an ultrasound examination. The rate of inadvertent puncture of the opposite wall of the artery was 15.4% in the F-group and 4% in the A-group (difference – 11.4%, 95%CI: [-4.5%, 27.2%]). No puncture of the vein in the A-group occurred. There was one inadvertent puncture of the vein in the F-group.
CONCLUSION. Preliminary results indicate that the catheterization success rate of the ultrasound-guided axillary artery catheterization via an infraclavicular route is comparable to the femoral approach – we have not found a sufficient evidence against that claim. In terms of early mechanical complications, the axillary approach is not inferior to the femoral approach.

Effect of early negative fluid balance on the early postoperative recovery in children after surgical repair of complex congenital heart disease with enlarged right ventricle

X. GONG
Cardiac ICU, Shanghai Children's Medical Center, Shanghai, China
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000166

INTRODUCTION. To estimate the effect of early fluid removal on the early postoperative recovery in children after surgical repair of complex congenital heart disease with enlarged right ventricle via a randomized trial.

METHODS. One hundred and twenty patients with right-sided complex congenital heart defect who underwent cardiac surgery by cardiopulmonary bypass during 2017.1-2017.6 were enrolled and were divided to two groups when the hemodynamics was stable within 3 hours after the surgery. Patients in Group-E were treated with early fluid removal, but Group-C remained conventional therapy. The Data of the hemodynamics and outcomes were collected from the post-operative day to the 2ndday post-operation.
RESULTS. Fluid removal therapy was started in Group-E at 4.39± 0.85hr postoperatively vs. 10.17±2.77hr(P<0.05)in Group-C. Patients in Group-E showed lower extravascular lung water index (ELWI) , lower fluid overload and lower NT-proBNP compared with patients in Group-C on the first day of post-operation(P<0.01). Also, the advantages remained in Group-E on the second day but the ELWI showed no remarkable difference. The rate of reintubation(P<0.05), the duration of mechanical ventilation and the length of ICU stay (P< 0.01)were significantly reduced in Group-E.
CONCLUSION. In patients with right ventricle enlarged complex congenital heart defect who underwent cardiac surgery by cardiopulmonary bypass, utilizing early negative fluid balance when the hemodynamics were stable and the right ventricle is obviously enlarged could achieve negative fluid balance, get extubated and discharge from ICU earlier, also present lower extravascular lung water index, lower incidence of weaning-induced pulmonary edema and reintubation.

A multi-center survey of current status for postoperative application of vasoactive agents in children undergoing congenital heart surgery with cardiopulmonary bypass

L. ZHU
Cardiac ICU, Shanghai Children's Medical Center, Shanghai, China
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000168

INTRODUCTION. The aims of this survey is to know the current status and specialty of postoperative hemodynamic monitoring and perioperative application vasoactive agents in 17 pediatric heart centers in China, and to establish some basics for further investigations.
METHODS. A survey was raised with perioperative hemodynamic monitoring, prophylactic using of vasoactive agents during surgery with cardiopulmonary bypass and postoperative application of vasoactive agents according some articles and surveys published recently.
RESULTS. Basic hemodynamic monitoring can be 100% implemented, but only 77% and 41% of the centers measured cardiac output and microcirculation. Dopamine was preferred by most centers for preventing low cardiac output syndrome (LCOS) following heart surgeries. Patients suffering from LCOS with high systemic vascular resistance (SVR) , LCOS with low SVR and LCOS with high pulmonary vascular resistance were more likely be treated with Milrinone, Dopamine or Adrenaline and Milrinone+Catecholamines+Pulmonary vasodilators, which was similar to the results in western countries.
CONCLUSION. Basic hemodynamic monitoring can be implemented well in Chinese pediatric heart centers, but the application of advanced hemodynamic monitoring still has a great disparity comparing to some centers abroad. The using of vasoactive drugs was similar to foreign centers but differs obviously, lacking symposiums or guidelines. More randomized control tests and clinical guidelines were prospected to instruct intensivists to utilize vasoactive agents in the future.

INTRODUCTION. The Sepsis-3 Task Force proposed the quick Sequential (Sepsis-related) Organ Failure Assessment (qSOFA) to replace SIRS as a new screening tool for the identification of patients with sepsis [1]. Diagnostic and prognostic value for patients outside the ICU is controversial. Further, there are no data regarding the usability in patients with heart failure.
OBJECTIVES. To assess the prognostic accuracy of qSOFA score in patients with heart failure admitted to a Heart Failure Unit (HFU).
METHODS. Data from patients admitted to HFU were retrospectively analyzed. qSOFA, and sSOFA score as well as SIRS criteria were assessment at admission. In addition, demographic, clinical, laboratory and echocardiographic value were recorded. A follow-up was performed 30 days after discharge. Primary outcome was death or readmission to hospital due do worsening of heart failure symptoms
RESULTS. Of 240 patients (73% male, median age 64 years), 25 patients (10%) had a qSOFA score ≥2 points and 126 patients

(53%) fulfilled none of qSOFA criteria (0 points). Within these patients 28 patients (12%) fulfilled the criteria of cardiogenic shock.
Patients with a qSOFA score ≥1 point more frequently had a severe systolic heart failure (EF ≤30%) and had a higher risk to develop multi organ failure during hospital stay (28% vs. 9%, P=0.005).
Within 30 days, the primary endpoint occurred in 46 patients (19%). Seventeen patients (7%) died and 34 patients (14%) were readmitted to hospital due to heart failure. Patients with positive initial qSOFA score reached this endpoint significantly more frequent (48% vs. 19%, p=0.002). Follow-up showed that with positive qSOFA score reported a more often a worsening of heart failure symptoms (p=0.021) representing a higher median NYHA class (p=0.008).
CONCLUSION. In our study, qSOFA was useful to identify patients with heart failure with a high risk to have a worse outcome.Therefore, identification of these patients is of vital importance but the diagnosis of sepsis is often not easy made in patients with heart failure because of overlapping symptoms (hypotonia, dyspnoe, tachycardia). qSOFA score is useful to operationalize disease severity in adult in-patients with heart failure.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000205

INTRODUCTION. Substantial blood loss can induce Irreversible Hemorrhagic Shock (IHS), which can lead to adverse patient outcomes and mortality [2]. We hypothesize that a patient's response to rapid but short blood loss, such as blood draw, can be indicative of cardiovascular reserve and thus predictive of the risk of developing IHS when subject to prolonged bleeding.
OBJECTIVES. To develop an approach to predict the likelihood of IHS due to blood loss during surgery by analyzing the physiological patterns of response to pre-operative blood draws.
METHODS. 36 healthy pigs were anesthetized and had a 20 mL of blood rapidly drawn while stable, then bled at 20 mL/min until mean arterial pressure (MAP) fell to 30 mmHg. 10 pigs had IHS (defined as MAP < 20 mmHg) despite cessation of bleeding. Plethysmograph (PLE) was recorded at 250 Hz. One-minute segments of data centered at blood draw start were statistically featurized and normalized using pre-draw stable baseline data. Patterns were extracted from data using Graphs of Temporal Constraints [1], and a decision forest (GTC-DF) model was trained to identify patterns most informative of IHS. To mitigate overfitting and for easy interpretation, only a few patterns with the highest information gain were used to assess the subjects (GTC-Top).
RESULTS. In a leave-one-subject-out cross-validation, GTC-Top and GTC-DF respectively identify 70% (95% CI: [55.6%, 84.4%]) and 60% (95% CI: [44.8%, 75.2%]) of the subjects who are prone to develop IHS, while giving only 1 false alert in 10,000 predictions on average. They both outperform logistic regression (LR) and random forest (RF) models [Fig 1, Tab 1].
CONCLUSION. We can identify, pre-operatively, the majority of patients who are likely to develop IHS due to blood loss during surgery, by using a tractable number of highly interpretable patterns found in plethysmograph waveform changes during pre-operative blood draws.

INTRODUCTION. Primary percutaneous coronary intervention (pPCI) is the ideal method of reperfusion for acute STEMI. Although, in some areas it is very difficult to implement pPCI between two hours, and it is well-known that 'Time is myocardium'.

OBJECTIVES. To evaluate the preservation of left ventricular ejection fraction (LVEF) in patients undergoing a pharmacoinvasive therapy protocol in a setting without primary percutaneous coronary intervention , Campo de Gibraltar (CG) area.

METHODS. Multicentre observational prospective study of consecutive patients with STEMI treated with fibrinolysis in the CG area and transferred to our intensive care unit for coronarography and PCI between January 1, 2012 and March 31, 2018, included in the ARIAM ANDALUCIA registry. We considered as early fibrinolysis those given in the first 3 hours from symptom onset. LVEF was measured by post-fibrinolysis echocardiography and/or by ventriculography during coronarography. Preserved LVEF was defined as >55%, moderately-reduced LVEF 35-50% and severely reduced LVEF <30%.R-comander statistic pack was used for analyses. All continuous variables are described as their mean values ± standard deviation and chi square tests for discrete variables. CI 95%. P< 0.05.

RESULTS. 437 patients were included, mean age (sd) 59.79 (11.89), 242 were inferior STEMI and 194 anterior STEMI. Culprit arthery : none 44, ACD 192, ADA 163 and ACX 38. Distribution (n) of Killip grades I, II, III and IV were 383, 10, 13 and 31 respectively. Mean GRACE (sd) was 149.59(33.49).

80.3% of fibrinolysis treatments were given early and 79.4% in hospital, with a median symptoms-to-needle time of 95 minutes. TIMI 3 was achieved in 79.17% of the cases. 264 coronarographies were performed in the first 24 hours (76 rescue-PCI) and 188 in 48-72 horus. PCI were effective in 382 (87.8%) cases. 210 ventriculographies and 230 echocardiographies were performed. 265 had a preserved LVEF (64.6%). Preserved LVEF was significantly associated to early fibrinolysis (p<0.05). We did not find significant differences between PCI performed in 24 hours or more than 48h.

CONCLUSION. Fibrinolysis in the first 3 horus favours LVEF preservation in patients undergoing pharmacoinvasive therapy. Early fibrinolysis is an effective alternative to primary PCI for for CG patients unable to achieve a symptoms-to-ballon time lesser than 180 minutes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000248

INTRODUCTION. Low cardiac output syndrome (LCOS) after cardiac surgery,- defined as the need for postoperative intraaortic balloon pump or inotropic support for longer than 30 minutes to maintain the systolic blood pressure greater than 90 mm Hg and the cardiac index greater than 2.2 L/min/m2 -is associated with significant morbidity and mortality

OBJECTIVES. Aim of this study is to identify risk factors for LCOS after isolated CABG surgery with the use of cardiopulmonary bypass in patients with low ejection fraction(<40%).

METHODS. Patients who underwent isolated elective CABG from June 2012 to March 2019, in our Cardiothoracic Department were retrospectively investigated. The following factors were compared between patients with postoperative LCOS and the rest of the cohort: Age>75years old, gender, smoking habit, Diabetes Mellitus(DM), history of percutaneous coronary intervention(PCI), history of myocardial infarction(MI), preoperative pulmonary hypertension(PHT) defined as systolic pulmonary pressure >30mmHg (ECHO study)and CPB time >120 min. Chi square test was used for statistical analysis.

RESULTS. A total of 2024 pts underwent isolated CABG. From 395 pts who had preop EF<40%, LCOS complicated 108 pts (27,3%) Results of our study are shown in table 1

CONCLUSION. In our study preoperative pulmonary hypertension and prolonged CPB time found to have statistical significant correlation with postoperative LCOS in patients with low EF.

Table 1 (abstract 000248). See text for description

	LCOS n=108	Control group n=287	p
Age >75	15(13,9%)	44(15,3%)	0,75
Females	16(14,8%)	28(9,8%)	0,2
Smoking	46(42,6%)	106(36,9%)	0,35
DM	47(43,5%)	109(38%)	0,35
PCI	22(20,4%)	47(16,4%)	0,37
MI	80(74,1%)	197(68%)	0,64
PHT	51(47,2%)	56(19,5%)	<0,01
CPB >120	41(38%)	67(23,3%)	0,05

Analyzing Myocardial Infarction with Non-obstructive Coronary Arteries in the ICU of a regional hospital. ARIAM database

R. Torcuato, I. Fernández, A. Alvarez, M. Salgado, P. Cobo, A. Ubeda
Intensive care unit, Hospital Point Europe, Algeciras, Spain
Correspondence: A. Ubeda
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000254

INTRODUCTION. Acute myocardial infarction (AMI) with coronary arteries without significant obstructions (MINOCA) is a frequent syndrome that accounts for 5% to 25% of all AMI. It is a challenge in clinical practice since there are gaps in their knowledge and therapeutic attitude. It assumes an adjusted 1-year mortality risk significantly higher than patients with non STEMI (*Non-ST-elevation myocardial infarction)* and associated obstructive coronary disease.

OBJECTIVES. To analyze the differences observed among patients with AMI with and without angiographically significant coronary lesions (MINOCA) in patients admitted to the Intensive Care Unit (ICU) of Hospital Punta Europe, using the ARIAM database.

METHODS. Retrospective descriptive analysis, on a prospective cohort, accomplished in an ICU of 12 beds for 6 years (2013-2018). Demographic variables have been registered, comorbidities, risk factors, previous illnesses, previous medication, diagnosis initial, initial Killip, location of AMI, stratification scales (TIMI, GRACE) and risk intrahospital hemorrhage (CRUSADE), arrhythmias, ICU medication, complications and attention times and procedures. Statistical analysis: variables categorical (frequencies and percentages), numerical (mean and standard deviation or median and interquartile range). Comparisons: chi2 (percentages), Student's T test (means). Statistical significance with p <0.05.

RESULTS. 767 patients were included. 564 men (73.53%), 203 women (26.47%). STEMI (ST-segment elevation myocardial infarction) n=362 (47.2%), non-STEMI (*Non-ST-elevation myocardial infarction)* n=405 (52.8%). Non-MINOCA ACS comparison n=722 (94.1%) vs. MINOCA n=45 (5.86%): female (24.3% vs. 62.2%, p =<.001), DM (37.4% vs. 22.2%; p=.038), obesity (14.5% vs. 26.7%, p=.021), previous history of AMI (15.8% vs. 2.2%, p=.045), sinus bradycardia (2.12% vs. 6.8%, p=.047), shock during ICU stay (9.2% vs. 0%; p=.033), recurrent angina (4.9% vs. 13.3%, p=.015).

Worst Killip (p=.026): I (45.2% vs. 68.4%), II (27.7% vs. 21.1%), III (18.7% vs. 10.5%), IV (8.5% vs. 0%). ICU length of stay (LOS) (days): 3.8 ± 4.9 vs. 3.3 ± 2.8, p=.543. Hospital LOS (days): 9.5 ± 8.3 vs. 13.9 ± 16.9, p=.308. Mortality 7.1% vs. 0%, p=.065. Multiple logistic regression: female (OR 7.47, 95% CI [3.80-14.68], p=<.001), age (OR 0.97, 95% CI [0.94-0.99], p=.016) and DM (OR 0.44, 95% CI [0.21-0.94], p=.035). AUROC: 0.765 (95% CI 0.685-0.845).

CONCLUSION. In our Unit, the prevalence of MINOCA was 5.86%, similar to the one described in literature. Female sex, a younger age and the absence of diabetes mellitus were independently associated with diagnosis of MINOCA. No differences were observed in mortality among MINOCA and ACS with significant coronary lesions.

STEMI vs. NSTEMI in a regional hospital. ARIAM database

I. Fernández, R. TorcuatoA. Alvarez, M. Salgado, P. Cobo, A. Ubeda
Intensive care unit, Hospital Point Europe, Algeciras, Spain
Correspondence: A. Ubeda
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000256

INTRODUCTION. Eventhough the incidence of STEMI has been declining over the past 20 years, to produce an accurate assessment of risk and mortality individual patients have a combination of clinical features that influence prognosis, and these factors must be appropriately weighted. Time is really important, as nearly half of potentially salvageable myocardium is lost within 1 hour of the coronary artery being occluded, and two-thirds is lost within 3 hours.

OBJECTIVES. To analyze the differences between patients diagnosed with ST-segment elevation myocardial infarction (STEMI) and those diagnosed with non ST-segment elevation myocardial infarction (NSTEMI) admitted to the intensive care unit (ICU) of Punta de Europa hospital using ARIAM database.

METHODS. Descriptive retrospective analysis on a prospective cohort performed in a 12-bed ICU for 6 years (2013-2018). Two groups were compared, STEMI vs. NSTEMI. Demographic variables, comorbidities, risk factors, initial Killip, extension, TIMI, GRACE, CRUSADE have been registered. Statistical analysis: categorical (frequencies and percentages) and numerical variables (mean and standard deviation). Comparisons: X2 test (percentages), Student's t (means). Statistical significance with p<0.05.

RESULTS. 767 patients were included: STEMI 362 (47.19%) vs. NSTEMI 405 (52.80%): male (76.8% vs. 70.6%, p=.053), age (62.14 [±13.16] vs. 67.17 [±12.55], p<.001), arterial hypertension (AH) (39.2% vs. 52.1%, p=.002), smoker (46.1% vs. 32.6%, p=.001), diabetes mellitus (DM) (27.9% vs. 44.2%, p<.001), previous myocardial infarction (MI) (8.3% vs. 21%, p<.001), previous coronary lesions (8.6% vs. 18.8%, p<.001), heart failure (HF) (1.1% vs. 9.6%, p<.001), stroke (3% vs. 8.1%, p=.006), chronic renal failure (CRF) (1.4% vs. 11.4%, p<.001), coronariography (83.2% vs. 49.2%, p<.001), TIMI (3.44 [±2.71] vs. 2.72 [±1.41], p<.001), GRACE (155.86 [± 38.63] vs. 147.86 [±46.03], p=.021), CRUSADE (28.78 [±15.45] vs. 35.97 [± 18.66], p<.001). Responsible artery (p<.001): anterior descending artery (LAD) (35.7% vs. 45.6%), right coronary artery (RCA) (40.9% vs. 18.3). Diagnosis (p<.001): unstable angina (2.5% vs. 44.2%), MI (94.2% vs. 52.3%). Mortality 6.4% vs 6.8% (p=.756). Time (expressed in minutes): first contact-EKG (14.6 [±24.8] vs. 20.9 [±22.7], p=.019), first contact-ICU (149.9 [±284.3] vs. 493.5 [±674.0], p<.001), first contact-percutaneous coronary intervention (PCI) (2316 [±3928.7] vs. 7245.2 [±8647.7], p<.001). Time (expressed in days): first symptoms-ICU discharge (3.5 [±4.2] vs. 4.8 [5.7], p<.001), ICU admission-ICU discharge (3.3 [±3.9] vs. 4.2 [±5.5], p=.006), PCI-ICU discharge (1.7 [±4.7] vs. 0.27 [±6.0], p=.002).

CONCLUSION. Patients diagnosed with STEMI were older and had higher prevalence of AH, DM, previous MI, HF, stroke, CRF and smoking. RCA was the most commonly affected in STEMI while LAD was in those diagnosed with NSTEMI. Time indicators were worse for STEMI than NSTEMI except ICU length of stay after PCI.

Plasma zinc concentration is associated with postoperative vasopressor requirement and hospital length of stay in cardiac surgery patients

A. Jansen, M. Kox, P. Pickkers
Intensive care, Radboud University Medical Center, Nijmegen, Netherlands
Correspondence: A. Jansen
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000284

INTRODUCTION. Zinc is an essential trace element involved in a plethora of functions, including wound healing, neurological signaling and immune function. Zinc deficiency is associated with the development of atherosclerosis and is prevalent among cardiac surgery patients.

OBJECTIVES. To assess the relationship between zinc status and the inflammatory response, endothelial activation and clinical outcomes in cardiac surgery patients.

METHODS. One hundred and seventy-nine patients undergoing on-pump cardiac surgery were included. Blood samples were obtained at predefined time points before, during, and after surgery to assess zinc levels (preoperatively) and markers of inflammation (TNF-α, IL-6, IL-8, IL-10, IL-1RA, MCP-1, MIP-1α, MIP-1β) and endothelial activation (VCAM, ICAM) serially. The correlation between zinc concentrations and the area under the curve (AUC) of circulating cytokines, chemokines, and markers of endothelial cell activation was determined. The relationship between zinc status and clinical outcomes was assessed by dividing patients into a low-zinc (below median) and a high-zinc (above median) group.

RESULTS. The median zinc level of the enrolled patients was (median [IQR]) 7.0 [5.7-9.2] μmol/L and 84% of the study population displayed below-normal levels (<10 μmol/L). Cardiac surgery induced a substantial increase in postoperative plasma levels of all measured inflammatory mediators, except TNF-α. Zinc status was not related to plasma cytokine levels, but weak negative correlations were observed for the chemokines MIP-1α and MIP-1β (r=-0.16, p=0.04 and r=-0.15, p=0.04, respectively). Furthermore, a weak, but statistically significant, inverse correlation was found between zinc status and VCAM (r=-0.21; p<0.01), and a trend for ICAM (r=-0.14; p=0.06). The proportion of patients requiring vasopressors on the day of surgery and on the following day did not differ between the low and high-zinc groups (84.1% vs. 76.7%, p=0.22 and 53.4% vs. 53.5%, p=0.99, respectively), but was significantly higher in the low-zinc group on the second postoperative day (20.5% vs. 7.1%, p=0.01). Zinc status was not related to ICU length of stay (21.5 [19-24] vs. 22.0 [19-24] hours in the low and high zinc groups, respectively, p=0.65), but hospital length of stay was significantly prolonged in the low-zinc group (220 [192-297] vs. 195 [171-264] hours, p=0.02).

CONCLUSION. A majority of cardiac surgery patients has low zinc levels and this is weakly associated with increased levels of chemokines and endothelial activation markers. Furthermore, low zinc status is related with increased postoperative vasopressor requirement and prolonged hospital stay. Further research is warranted to elucidate the mechanisms behind these findings and to assess a possible role for preoperative zinc supplementation in deficient patients.

Acute coronary syndrome: predictive factors for the need of invasive mechanical ventilation

I. Fernández, R. Torcuato, A. Alvarez, M. Salgado, P. Cobo; A. Ubeda
Intensive care unit, Hospital Point Europe, Algeciras, Spain
Correspondence: A. Ubeda
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000302

INTRODUCTION. Patients with acute coronary syndromes (ACS) may develop serious complications and require prolonged intensive care. The need for invasive mechanical ventilation (IMV) is a common reason for prolonged intensive care in patients who are admitted with an ACS.

OBJECTIVES. To identify factors associated with the need of IMV in patients diagnosed with ACS admitted to the intensive care unit (ICU) of Hospital Punta de Europa using ARIAM database.

METHODS. Retrospective descriptive analysis using a prospective cohort performed in a 12-beds ICU for 6 years (2013-2018). Two groups were compared: patients who suffered ACS and did not required IMV vs.

those diagnosed with ACS and required IMV. Demographic variables, associated comorbidities, risk factors, Killip classification at the beginning, damage extension, TIMI, GRACE, CRUSADE, complications occurred during ICU admission, lesions founds in coronary angiography, diagnosis at ICU discharge and mortality were collected. Statistical analysis was performed: categorical variables (expressed in percentages and frequencies), continuous variables (expressed using mean and standard deviation). Comparison: Chi-squaretest (percentages) and T-student test(mean). Multiple logistic regression. Statistical significance was set at p-value < 0.05.

RESULTS. 756 patients were included. 35 patients (4.63%) were under IMV, and 721 patients (95.37%) were not. Those who were under IMV: male (54.38% vs. 74.3%, p=.009), age (69.7 [±11.7] vs. 64.4 [±13.1], p=.019), body mass index (29.01 [±5.64] vs. 27.02 [±3.87], p=.031), diabetes mellitus (DM) (60.0% vs. 35.1%, p=.003), previous ACS (37.1% vs. 13.9%, p<.001), creatinine values (1.91 [±1.13] vs. 1.23 [±0.95], p=.006), heart rate (91.9 [±22.65] vs. 78.94 [±19.67], p=.002), systolic blood pressure (102.14 [±20.66] vs. 124.21 [±26.01], p<.001). Complications occurred during ICU admission: shock (71.4% vs. 5%, p<.001), infectious complications (20% vs. 0.4%, p<.001), renal complications (14.3% vs. 1.5%, p<.001), encephalopathy (5.7% vs. 0.6%, p=.001). Myocardial infarction location (p=.027): anterior(53.6% vs. 43.2%), inferior (28.6% vs. 45.2%). Coronary angiography findings (p=.009): left anterior descending artery (60.9% vs. 39.2%), right coronary artery (26.1% vs. 31%), left main coronary artery (13% vs. 3%), circumflex artery (0% vs. 15.2%). ICU length of stay (LOS) (days): 10.46 ± 12.13 vs. 3.41 ± 3.80; p=.002. Mortality: (48.6% vs. 4.2%, p<.001). Multiple logistic regression: female (OR 2.82, CI 95% [1.12-7.13], p=.028), infectious complication (OR 176,37, CI 95% [30.74-1011.90], p<.001), shock (OR 62.40, CI 95% [23.36-166.70], p<.001), previous MI (OR 2.30, CI 95% [0.86-6.14]. AUROC: 0.92 (CI 95% [0.85-.98]).

CONCLUSION. Female sex, shock and infectious complications were predictive factors for the need of IMV in patients diagnosis with ACS. The need of IMV was associated with higher rates or mortality in ICU stay.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000026

INTRODUCTION. Persistent Inflammatory, Immunosuppressed, Catabolic Syndrome (PICS) is a phenotype of critically ill patients that correlates as a potential origin of chronic critical illness (CCI). We defined PICS as a combination of clinical and laboratory criteria to predict the occurrence of CCI.

OBJECTIVES. To evaluate the prognostic capacity of our predefined criteria of PICS on the 8th day of admission (PICS-8) for the development of CCI. We analyzed the association between the presence of PICS-8, one event of PICS, or the accumulation of PICS events with intensive care unit (ICU) length of stay (LOS), hospital-LOS, mortality, and functional capacity up to 12 months after hospital discharge.

METHODS. We designed a multicenter prospective study enclosing all patients on 8th day of ICU admission over 3 consecutive months. Patients were monitored for PICS-8, every 7 days for PICS status and evaluated 3 times within one year after discharge for functional capacity. When data follows a normal distribution, categorical variables are expressed as frequencies and percentages; and continuous variables as mean and standard deviation (SD), or median and interquartile range as needed. If hospital mortality occurred then ICU-LOS and Hospital-LOS were censored to the right. The distributions of both times were estimated in each group, defined by the status of PICS, by the method of Kaplan-Meier (KM) and compared using the log-rank test. We performed multivariate logistic regression analysis to identify the factors that maintain independent association with PICS (at least once throughout the follow-up period). The variables showing significant association with PICS in univariate analysis were entered into the multivariate analysis. The model was summarized as p-values and OR with confidence intervals at 95% (CI95%). For multivariate Poisson regression model, the days between admission to ICU or Hospital mortality were censored again; these time intervals were summarized using KM. The number of PICS events along the follow-up period was considered as the marker of PICS severity. Statistical significance was set at p<0.05.

RESULTS. In the study period, 3398 patients were admitted to 15 hospitals right across Spain. We identified 478 patients that met the inclusion criteria. ICU LOS (p=.001), hospital LOS (p=.018), and ICU mortality (p=.022) showed predictive capacity for PICS-8. The medians of ICU-LOS and Hospital-LOS were increased in PICS-8-patients (25 and 47 days respectively) compared with Non-PICS patients (18 and 36 days respectively). Mortality in the ICU was greater for patients with PICS-8 (OR 1.74 CI95% 1.08;2.81). The factors associated with the number of PICS were: male gender, mechanical ventilation (MV)>16 days, Total parenteral nutrition/complementary nutrition (TPN/C), and Simplified Acute Physiology Score (SAPS3). There was a greater incidence of at least one episode of PICS in those patients who died (43.2% vs 29.7%; p=.004). However, the multivariate logistic regression showed that PICS was not an independent factor of mortality.

CONCLUSION. PICS-8 showed higher ICU LOS, hospital LOS, and hospital mortality. PICS severity was greater in males, patients with high SAPS3, MV time>16 days, and recipients of TPN/C.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000052

INTRODUCTION. The proper bed management of an ICU is crucial for its performance, as well as for the prognosis of patients.

Simulation has a long history in medical education (1), valued for its ability to reproduce some conditions in clinical practice and to allow students to act in a safe environment. More recently, it has been used as a technique to support improvement in health care systems and processes (2,3). Virtual simulation allows analysing decision-making processes in a secure environment and assessing their impact (4).

OBJECTIVES. A computer application development that simulates the operation of an ICU and which allows analysing how bed management decisions are made for optimization.

METHODS. All information was obtained by Big Data analysis of data collected, and previously anonymized, by MetaVision® system (iMD Sof, Tel Aviv, Israel) implemented in the ICU of the Hospital Complex of Navarre, Spain (a tertiary care center). Simulator was based on a dynamic, discrete and stochastic model that represents the evolution of an ICU over time. The discrete event simulation model was programmed in JAVA language with a visual interface that reproduces the general condition of the ICU, surgical programming for the following days and provides the clinical information of each patient, through screens that mimic those consulted by physicians in their usual practice and enough for decision making about discharge (Figure 1). The simulator will advance in time generating both urgent and scheduled patient arrivals according to real or simulated patterns and events that evolve the health status of each patient admitted (Figure 2), having enough flexibility to be able to define different ICUs and specific scenarios. The decision-making process about the discharge of patients is reproduced, so that, in certain moments (clinical sessions, urgent or programmed arrivals, exitus…) it will interact with the user waiting for indications about possible discharges or admissions, allowing them to modify the occupation of the ICU. The program will record all the events that occurred during the simulation, including all decisions made by users related to bed management. Finally, validation and verification of the simulator was carried out.

RESULTS. We have developed an interactive simulation program that, according to ICU staff, reflects the operation of an ICU in a real way and allows the analysis of the bed management decision making. The simulator facilitates the definition of different types of ICU. It allows analyzing the consequences of decisions in a virtual environment and proposing better management strategies. It provides performance measures of the management of the ICU, in relation to the admission (acceptance or rejection), the shortening of the stays and the delay in admission. It analyses the level of dissimilarity in decisions among users in a quantitative way, identifies its causes and quantifies its influence on bed management, detecting situations or patients in which there is a greater discrepancy.

CONCLUSION. A valid simulator has been built, which gathers the characteristics to reproduce the real operation of an ICU. The quantitative analysis of decisions concerning bed management is possible in virtual environments that faithfully reproduce the characteristics and evolution of an ICU. The proposed methodology allows for the first time to collect relevant and objective information for the analysis of medical decisions, being able to present scenarios that cause variability. In this way, the best management strategies are identified, quantifying their influence on bed management.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000074

INTRODUCTION. In the 1999 landmark report, "To Err is Human: Building a Safe Health System", the Institute of Medicine estimated that avoidable errors in health care contributed to 44 to 98,000 deaths and more than 1 million injuries annually in the United States. Prospective clinical surveillance using triggers as a tool to identify the risk of adverse events, along with prompt implementation of interventions may be the answer to improving patient safety, which remains to be a major public health problem 20 years after the publication of the reference "To err is human".

OBJECTIVES. To evaluate the impact of prospective trigger tools and near-real-time interventions on the mortality of critically ill patents, and to determine the impact of these triggers on time taken to stabilize and specific clinical outcomes.

METHODS. All adult patients admitted to one of the three intensive care units of a tertiary hospital between November, 2017 to October, 2018 were observed by a multidisciplinary surveillance team composed of physicians, nurses, physiotherapists and pharmacists. If any one of the five triggers was activated, a team member approached the care team responsible for the patient within 24 hours, and the data was presented in the daily multidisciplinary round. This moment was used to establish change in the therapeutic plan in order to achieve the expected goal of each trigger. The triggers used were: **KDIGO**: early identification of AKI to prevent RRT. **Hypoglycemia**: glycemia < 60 mg/dL to prevent recurrence. **Drug interation (D or X)**: early identification to prevent ADR; **Antimicrobial stewardship**:new/modified antimicrobial. Adjustments with MALDI-TOF, MIC or antibiogram to optimize antibiotic therapy. **Delta SOFA**. 3rd >admission SOFA. Expected result 5th day SOFA < 3rd day SOFA.

RESULTS. The analysis was conducted with 948 patients, out of which 391 had not identified triggers (group 1) and 557 (group 2) had identified triggers and were subjected to interventions. In relation to the patient population baseline characteristics there was no significant difference between the two groups except for a worse SAPS 3 score observed in group 2. Patients in group 2 had a longer duration of ICU stay; median duration was 5 (IQR, 4 – 10) days for group 1 and 7 (IQR, 4 – 14) days for group 2 ($p < 0.001$). Stabilization within estimated time was comparable between the two groups and preventable and non-preventable complications were higher in group 2. There was no difference in the mortality rate between the two groups ($p= 0.436$). Interventions prevented adverse events in the triggers KDIGO ($p<0.001$); Hypoglycemia ($p=0.005$); Risk/incompatibility ($p<0.001$) and antibiotic

stewardship (p<0.001) but not in the trigger Delta SOFA. (p=0.433). In the logistic regression analysis of each trigger against time taken to stabilize which was the dependent variable the only trigger intervention that impacted on time taken to stabilize was hypoglycemia.
CONCLUSION. This methodology of prospective surveillance using trigger tools and near-real-time interventions was effective in the prevention of adverse events in critically ill patients. Although patients that had identified triggers were more severely ill, their mortality rate was comparable to the patients who did not have identified triggers.

An exploration of the relationships between staff perceptions of safety in adult intensive care (ICU) and patient and staff characteristics

C. Leon-Villapalos[1], M. Wells[2], SJ. Brett[1]
[1]Critical care, Imperial College Healthcare NHS Trust, London, United Kingdom; [2]Directorate of nursing, Imperial College Healthcare NHS Trust, London, United Kingdom

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000087

INTRODUCTION. Providing a staffing model that meets patients' needs is essential to the delivery of high-quality care. There is incomplete evidence for staffing models in ICU. These are primarily influenced by staff:patient ratios and draw on indices of illness severity (Table 1), which may not be sensitive to patient need. Uniprofessional staffing guidance may not reflect the multi-professional nature of ICU. Staff perceptions of safety, of which staffing is a factor, are important organisationally. Perceived safety deficits may contribute to stress and "burnout" in ICU staff, a current field of concern (Seaman 2018).
OBJECTIVES. Aim To explore relationships between staff perceptions of shift safety, (how safe patient care felt) and patient and staff characteristics, using a bedside professional reported safety score (BPR). **Objective 1** To explore the relationship between BPR scores and the percentage of patients classified as Level 1, 2 or 3. **Objective 2** To explore the relationship between BPR scores and the percentage of nursing staff with a specialised critical care course (CCC).
METHODS. UK Health Research Authority approval was obtained (ID249248). Data were collected for 29
consecutive days at Imperial College Healthcare Trust (comprising 70 general critical care beds on 3 sites). The BPR asked all ICU staff to rate each shift as "safe, unsafe, or very unsafe". These scores were explored with relation to; the percentage of Level 1, 2 and 3 patients per shift and the percentage of nurses per shift who had completed a CCC. Relationships between reported perceptions of safety and these factors were analysed for correlation and regression using PRISM.
RESULTS. A total of 2836 BPR scores were recorded. Results were received from 98% of 174 shifts. We found;a significant, positive relationship between perceptions of safety and the percentage of Level 3 patients (p=0.0001, r= 0.32); no significant relationship between perceptions of safety and the percentage of Level 2 patients (p= 0.9729, r= 0.003) and a significant inverse relationship between perceptions of safety and the percentage of Level 1 patients on a shift (p=<0.0001, r= -0.42). We also found a significant relationship between perceptions of safety and the percentage of staff with a specialist CCC (p=0.0001, r= 0.42).
CONCLUSION. Staffing models in ICU categorise patients by acuity and allocate staff accordingly. In this study, staff reported feeling less "safe": when there were a larger proportion of less acutely unwell patients in ICU and conversely reported feeling things were safer with higher volumes of more acute patients. This may indicate that staffing models and training are not fully responsive to the needs of intensive care patients, these relationships should be investigated further. The study supports the guidance that 50% of nursing establishment should have a CCC. The mechanism by which this improves perceived safety could be explored.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000103

INTRODUCTION. Timely recognition and escalation of physiological indicators of worsening conditions in acute hospital wards remains challenging. Vital signs monitoring using Early Warning Scoring (EWS) is time consuming and the prescribed observation frequency may be suboptimal or undeliverable. Wearable ambulatory monitoring systems (AMS) may provide an alternative in the form of continuous monitoring, whilst maintaining patient mobility and comfort. AMS can also reduce nursing burden of intermittent vital signs monitoring, improve early detection of abnormal physiological values, facilitate timely escalation and offer an intermediate monitoring option for patients being stepped down from intensive care unit (ICU).
OBJECTIVES. This project directly follows previous research and involves a series of linked studies. There are 3 main objectives: test currently available and validated AMS; capture and integrate data into current hospital systems; and evaluate implementation of AMS in clinical practice.
METHODS. Phase 1: In-house testing of AMS wearability, to identify the most wearable available devices to move into the next phases. Phase 2: Semi-structured interviews with staff and patients, exploring current monitoring practices within an emergency surgical unit. Phase H-Hypoxia study: Accuracy test of selected AMS in the detection of hypoxia and movement artefacts during clinical use in healthy volunteers. Phase 3: Locational implementation of the AMS to provide continuous data recording in a clinical setting. A human factors approach will direct modifications to both hardware and software and further wearability and user satisfaction assessments will be conducted on clinical staff. Phase 4: Development of a functional user

interface (UI) integrating AMS data within current hospital systems. We will introduce the devices to patients, collect wearability data and finalise the locational testing. Phase 5: Implementation of the AMS and UI in clinical practice to test the acceptability and usability of the system with clinical staff. We will also analyse patient specific outcomes such as mortality, length of stay (LOS) and deterioration episodes captured by the AMS.
RESULTS. Phase 1 provided wearability data from 15 volunteers and shortlisted half of the AMS to next phases (1 chest patch and 3 wrist-worn) collecting HR, RR and SpO2 data. The selected devices are now being subject to locational (phase 3, n=20) and accuracy testing (hypoxia study, n=30). Fifteen clinical staff have been interviewed and identified challenges with current monitoring practices, such as the impact on nursing workload and patient mobility. Current perceptions of an AMS were also explored. These themes will be considered during user interface development in phase 4 (n=50), alongside continuous user input (Figure 1).
CONCLUSION. Technology to monitor patients' vital signs is advancing and clinical vital signs documentation systems need to be synchronous with these changes. Our proposed work aims to develop an electronic system to continuously capture and report vital signs. This will integrate real-time AMS data into current hospital systems via a user interface. The final system has the potential to offer benefits to patient outcomes, nursing workload and facilitate quicker referral and smoother step-down from ICU. We will discuss current outcomes and future plans for this project, the first of its kind outside of a critical care department.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000120

INTRODUCTION. Pressure injuries are costly, potentially preventable but frequently occurring adverse events (Padula et al., 2018). Intensive care patients have major risk factors for pressure injury with a reported pressure injury prevalence of 12-33% (Chaboyer et al., 2018). Multi-faceted interventions, also known as programs or care bundles, are recommended to prevent pressure injuries.
OBJECTIVES. This systematic review aimed to: identify pressure injury prevention programs and their components; the way these programs were implemented; and their effectiveness.
METHODS. We followed the recommendations from the Preferred Reporting Items for Systematic Reviews and Meta-Analysis. We searched databases including PubMed, EMBASE, MEDLINE, CINAHL, and Cochrane Library databases for papers published in English and Chinese from the year of 2000 to May 2018. Data extraction and quality assessment was conducted by one and checked by a second author. Content analysis was conducted to summarise the findings.
RESULTS. Twenty-one peer reviewed papers (12 quality improvement projects, and 9 research papers from 8 studies) were included in this review. Pressure injury prevention care bundles with 2-11 components were commonly implemented. Common components of programs included clarification of staff roles/introducing new roles, repositioning, staff and patient education, support surfaces use, pressure injury risk assessment, skin assessment, nutrition needs assessment, documentation, multidisciplinary team involvement, and mobilisation. Implementation strategies commonly used were education, audit and feedback, and standardising documentation. Five of the research studies reported significant decrease in pressure injury prevalence, significant increase in family satisfaction and participation, and increase in compliance to pressure injury prevention protocols and strategies. Two quality improvement study reported cost savings of $1 million and £2.6 million respectively after the implementation of the programs.
CONCLUSION. Most of the included papers reported findings from either qualitive improvement projects or before and after research studies. However, positive outcomes and strong theoretical rationales for the components in the programs suggest they are beneficial. In addition, the success of the programs did not seem to be associated with the number of components included in or complexity of the programs. This calls for future high-quality research such as randomised controlled trials to test the effectiveness of multi-component programs.

Antithrombin deficiency has lower prognostic value in comparison with increased INR in ICU patients with SIRS

E. Neporada, A. Travkov, S. Astrakov
Anaesthesiology and intensive care department, Novosibirsk State University, Novosibirsk, Russia
Correspondence: E. Neporada
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000156

INTRODUCTION. Low platelet count and increased INR are frequent laboratory findings in patients with systemic inflammatory response syndrome (SIRS) and have prognostic value. Antithrombin (AT) deficiency is reported to be observed early in SIRS, but this test is not used routinely.
OBJECTIVES. The aim of the study is to determine if AT deficiency is a useful prognostic tool in ICU patients.
METHODS. 135 consecutive ICU patients with 3 or 4 criteria of SIRS were included. During 4 days after SIRS manifestation patients were assessed for thrombocytopenia <120 cells/mcL or severe platelet decline ≥50% during 24 hours in combination with INR>1,2. Also

general condition, clinical and laboratory test results and 30-days mortality were evaluated.
RESULTS. Significant laboratory haemostasis disorders (thrombocytopenia in combination with increased INR) were observed in 26.6% of patients with SIRS. In patients with severe AT deficiency<50% odds ratio for laboratory haemostasis disorders was 3.5 (95% CI 1.2; 10.4).
ratio for laboratory haemostasis disorders was 3.5 (95% CI 1.2; 10.4). However AT deficiency did not demonstrate significant prognostic value (p=0.18), while INR was a significant predictor of outcome (p= 0.024)
CONCLUSION. AT deficiency is a frequent finding in patients with SIRS the same as low platelet count and increased INR. Yet such common laboratory test as INR in comparison with AT deficiency has higher prognostic value in ICU patients with SIRS.

Table 1 (abstract 000156). Variables, predicting laboratory haemostasis disorders (thrombocytopenia in combination with increased INR)

Independent variables	Regression coefficient	p	Odds Ratio	95% CI for OR
Gender (females/ males)	1.58	0.007	4.85	1.54; 15.30
AT deficiency <50%	1.26	0.022	3.52	1.20; 10.40

Use of a digital checklist and database to improve patient safety in critical care

J. Turner, A. Kuravi
Theatres, anaesthesia and critical care services, Walsall Healthcare NHS Trust, Walsall, United Kingdom
Correspondence: J. Turner
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000157

INTRODUCTION. Safety huddles and checklists are recognised methods to improve patient safety, and computer-based tools such as automatic early warning score systems and electronic patient records can be used to further augment patient care. In a 13-bed critical care unit within a 550-bed UK district general hospital, a delay in identification and treatment of critically ill patients, and identification of potential patient safety issues was noted. A structured electronic communication tool was developed with the aim of providing accurate, real-time data on patient safety issues, allowing rapid multidisciplinary response.
METHODS. A digital checklist was designed using Microsoft Access, and a morning multi-disciplinary safety huddle was instituted. Data on the number and location of patients at risk of deterioration as well as other safety critical issues were systematically highlighted, recorded electronically, and automatically audited by the software.
RESULTS. In two months, 202 patients were identified as requiring urgent review, of whom 68 were outside the critical care unit. Nurse staffing matched patient acuity only 61% of the time, with equipment issues present on 40% of days. Airway equipment had been checked 91% of the time, and high flow nasal oxygen or non-invasive ventilation machines were available to outreach on 73% of days. There were infection control issues on 52% of occasions. When surveyed, staff reported more rapid resolution of patient safety issues, and feeling more engaged with the process of task prioritisation following the introduction of the safety huddle.
CONCLUSION. Use of an automatically audited digital checklist to facilitate a daily safety huddle has allowed recognition of potentially significant patient safety issues, and ensured that these are highlighted to everyone including the most senior members of staff, allowing corrective action to be undertaken promptly. The data has led to the ward round being redesigned to facilitate rapid senior review of the most unwell patients. The digital format obviates the need for laborious data collection, in addition to allowing remote monitoring by senior management. Following the success of this, we have increased the huddle to twice daily.

Towards better governance in Focused Intensive Care Echocardiography (FICE)

MSF. Chong, J. Aron
General Intensive Care Unit, St. George's Hospital, London, United Kingdom
Correspondence: M.S.F. Chong
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000184

INTRODUCTION. With the introduction of Focused Intensive Care Echocardiography (FICE) training programmes in the UK, it is essential that each FICE training unit should have a local echo governance structure.
OBJECTIVES. Our quality improvement project involved auditing the process for local image storage and review and quality assurance of echo reporting and referral pathways before and after introduction of a formal echo reporting form.
METHODS. A prospective observational study was performed to examine all transthoracic echos performed in our tertiary referral general intensive care unit over a two week period in November 2018 for: (i) local image storage, (ii) network archiving, (iii) echo reporting documentation and (iv) referral for formal echo. After a teaching session and introduction of an echo reporting form on the electronic health record system (Cerner), the data was reaudited two months later in January 2019.
RESULTS. 20 scans were performed by FICE trainees on ICU in November 2018 and 22 scans in January 2019 over the two week periods. Image storage on the local ultrasound hard drive occurred 100% in both periods and network archiving increased from 45% to 50%. Echo reporting documentation improved from 30% to 68% after introduction of the echo reporting form. Formal echo referral increased from 20% to 45% with performance of formal echo on ICU occurring 75% and 80% respectively prior to ward discharge.
CONCLUSION. Introduction of a formal echo reporting form has led to improved quality assurance of reporting and referral pathways.

Is after-hours intensivist staffing required in a surgical intensive care unit?

MK. Kim, IK. Kim
Department of surgery, Yonsei University College of Medicine, Seoul, Republic of Korea
Correspondence: M.K. Kim
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000190

INTRODUCTION. The need for 24-hour intensivist coverage of the intensive care unit (ICU) presents several controversial issues. Surgical patients are rapidly deteriorated compared with medical patients. In this study, we evaluated the necessity of after-hours intensivist staffing in a surgical intensive care unit (SICU).
METHODS. This study was performed in a tertiary referral teaching hospital in Korea from March 2018 until February 2019. A total of 586 cases admitted to SICU. The work-hours was defined as 07:00-19:00, from Monday to Friday. Among them, 571 SICU admissions which had complete medical records were enrolled in this retrospective study. We determined the in-hospital mortality as the primary outcome according to the time of SICU admission.
RESULTS. 333 SICU admissions and 238 SICU admissions were developed in work-hours and after-hours respectively. The mean age of the work-hours group was higher than those of the after-hours group (work-hours vs. after-hours = 68.55±12.52 vs. 64.06±13.84, $p<0.001$). APACHE II score of 30 or more of the after-hours group was two times more than those of work-hours group (work-hours vs. after-hours = 6.0% vs. 12.6%, $p=0.004$). Unplanned admission during work-hours was about one and half times more during after-hours (work-hours vs. after-hours = 33.3% vs. 47.1%, $p<0.001$). When compared to the work-hours group, the proportion of patients with ventilator treatment was two times more in the after-hours group (work-hours vs. after-hours = 17.4% vs. 34.0%, $p<0.001$). Among 571 SICU admissions, 27 patients died in hospital. In multivariate analyses for clarifying whether the time of SICU admission affected in-hospital mortality, the time of SICU admission was not the independent factor for in-hospital mortality (OR = 2.385; 95% CI 0.928-6.133, $p=0.071$).
CONCLUSION. In this study, the time of SICU admission did not foment greater in-hospital mortality. However, these results revealed our specific situation, high-intensity ICU model. Therefore, in order to generalize these results, related studies should be preceded.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000219

INTRODUCTION. Post-ICU sequellae including physical and mental problems interfere with successful rehabilitation [1]. However, data on the incidence of long-term non-recovery after critical illness seem to be lacking.
OBJECTIVES. To assess the incidence of and to identify risk factors for non-recovery in long-stay ICU patients.
METHODS. In this retrospective, single-centre study, we identified long-stay ICU patients who visited a specialized post-ICU clinic at 3 months after ICU-discharge. During this visit a Dutch 36-item Short Form (SF-36) questionnaire was completed. At 12 months, patients were requested to repeat the SF-36 questionnaire and return by mail.
RESULTS. Between 2012 and 2018 591 patients visited the specialized post-ICU clinic. 241 Patients with a mean age of 64±13 and an APACHE III score of 79±32 completed a SF-36 questionnaire at both time points. At 3 months 52 patients (21.5%) recovered to reference values of the physical functioning (PF) SF-36 domain. However, after 12 months only 36 remained within this normal range (14.9%). At 3 months 190 patients (78.5%) were below the reference values of the PF SF-36 domain. At 12 months 152 (62.8%) still remained below this reference values. In total 168 (69.4%) did not reach reference values for the PF SF-36 domain at 12 months. Between 3 and 12 months 126 patients (52.1%) improved over time, whereas in 116 patients (47.1%) the PF SF-36 score decreased or remained equal over time. In a binary multivariate analysis diabetes (OR 0.028, 95% CI 0.001-0.788, p=0.036), days on mechanical ventilation (OR 0.901, 95% CI 0.821-0.988, p=0.026), need for renal replacement therapy (OR 9.249, 95% CI 1.286-66.551, p=0.027) and the Morton Mobility Index score (OR 1.063, 95% CI 1.017-1.111, p=0.007) all remained independent predictors for recovery between 3 and 12 months.
CONCLUSION. In the majority of long-stay ICU patients the PF SF-36 score did not fully recover at 12 months after ICU-discharge. Moreover, only half of the patients improved between 3 and 12 months. Determination of risk factors may help to identify patients in danger of non-recovery, and to design individualized rehab strategies.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000224

INTRODUCTION. Socioeconomic deprivation is associated with less access to health care services, including intensive care. Choice and quality of treatment during intensive care may also be influenced by socioeconomic factors leading to inferior care and poor outcomes among deprived patients.
OBJECTIVES. Our purpose was to examine if low education and low income was associated with worse survival after critical illness.
METHODS. We examined records of adult patients in the Swedish Intensive Care Registry with an ICU stay > 48 hrs during 2008-2016. The Charlson comorbidity index (CCI) before critical illness was

computed by linking to the Swedish hospital discharge register and SAPS3 was used to describe critical illness severity. Linking with Statistics Sweden provided disposable household income for the year preceding ICU admission, level of education (low, medium, high) and survival. Patients were grouped in quintiles by their income, from low to high. Outcomes were odds ratios for survival on discharge from ICU or hospital and at 90 days after admission. The influence of education and income, separately and combined, was modelled using multi-level logistic regression after adjusting for age, gender, CCI and SAPS3 scores. The study was approved by the regional ethical review board.

RESULTS. We analysed 55,091 patients admitted to 74 ICUs (mean age 64 yrs, SAPS3 risk 0.25, CCI score 2.2; median ICU and hospital stay was 4.1 and 12 days, respectively). Low income and low education was not associated with decreased survival to discharge from ICU or hospital but they were associated with decreased 90-day survival (Table).

CONCLUSION. Low education and low disposable income was not consistently associated with adjusted lower ICU or hospital survival indicating that ICU and hospital care was not inferior for deprived patients. However, adjusted 90-day survival was significantly lower suggesting that post-discharge care was inferior.

Table 1 (abstract 000224). Odds ratios (ORs) for the separate models and the combined model. All models were adjusted for age, gender, CCI and SAPS3 scores ** and *** denotes that ORs were significantly different from 1 (P<.01 and <.001, respectively). NA=not applicable

Self-perceived discomfort in critically ill patients: comparison between stays in 2 separate units of a single department, ICU vs. intermediate care unit

J. AUDIBERT, P. Bachelier, A. Bensalah, I. Rabaud, A. Conia, O. Gontier, M. Hamrouni, C. Jourdain, G. Badre, L. Lehaie, M. Pépineau, B. Mauchien, P. Kalfon
Intensive care unit, Hospital Louis Pasteur, Le Coudray, France
Correspondence: J. AUDIBERT
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000251

INTRODUCTION. A tailored multicomponent program for discomfort reduction in critically ill patients decreases self-perceived discomfort in unselected adult critically ill patients (1), with a probable positive impact on the post-traumatic stress disorder assessed at 1 year (2). Patient-centered outcomes and long-term psychological side effects of the critical illness have gained a growing interest and must now be taken into consideration.

OBJECTIVES. Should the dissemination of such a program be actively promoted also for patients requiring intermediate care? Which organization of care should be recommended? The aim of our pilot study was to assess and compare discomforts reported by patients after a stay in an intensive care unit (ICU) and after a stay in a dedicated, separate, intermediate care unit, both units belonging to a single department and managed by the same healthcare team.

METHODS. Our intensive care department was composed of a 12-bed ICU and a 6-bed dedicated, separate, intermediate care unit. On the day of discharge, the bedside nurse (or the assistant nurse) administered the 18-item version of the French questionnaire on ICU-related self-perceived discomforts (IPREA) to adult patients who survived a stay of 3 calendar days or more (3). IPREA contains the following discomfort items: noise, excess of light, discomfort related to sleeping in a different bed from home, sleep deprivation, thirst, hunger, feeling of cold, feeling of heat, pain, being tied down by perfusion lines, tubes or other connected devices, no respect for privacy, anxiety, isolation, limited visiting hours, absence of phone, lack of information, shortness of breath, and feeling depressed. Each item was scored from 0 to 10 (minima to maximal) leading to an overall discomfort score (from 0 to 100) used as the primary outcome.

RESULTS. Between May 1, 2018 and April 20, 2019, 191 and 174 patients were interviewed using IPREA, respectively after an ICU stay and after a stay in the intermediate care unit. Stays in the ICU and in the intermediate care unit were similar for gender (female gender resp. 42% and 36%), age (resp. 62±17 and 62±17 years), and median length of stay, resp. 6 (IQR 4-11) and 6 (IQR 4-8) days. Patients hospitalized in the ICU reported a higher overall discomfort score than patients hospitalized in the intermediate care unit: 23±15 vs. 18±12, *P=0,0008.* The greatest differences in favor of the intermediate care unit were found for feeling of cold (0.9±2.0 vs. 2.3±3.2), shortness of breath (2.1±2.7 vs. 3.3±3.5), lack of phone (0.5±1.7 vs. 1.6±3.0), and thirst (2.4±3.0 vs. 3.4±3.6). In contrast, patients complained more about heat in the intermediate care unit in comparison with the ICU.

CONCLUSION. Patients hospitalized in a dedicated, separate, intermediate care unit reported a lower overall discomfort score than patients hospitalized in the ICU. Although patient severity was different depending on the unit, these preliminary results raise the question of the optimal organization of care for patients receiving intermediate care: hospitalization inside the ICU for all the patients or hospitalization in a dedicated, separate, intermediate care unit, before, after, or without the ICU stay, according the course of the critical illness? Further studies are needed to compare perceived discomforts according these two different organisations of care for patients requiring intermediate care.

INTRODUCTION. Many instruments have been developed to evaluate hospital mortality, but less attention has been paid to the long-term functional status and quality of life of traumatic brain injury patients
OBJECTIVES. To analyze the quality of life (QOL) and its different components one year after ICU admission to traumatic brain injury (TBI).
METHODS. Prospective cohort study. TBI in Carlos Haya Hospital (Málaga, Spain) between 2004-2008. Evaluation of QOL with questionnaire PAECC (Project of Epidemiological Analysis of Critical Patients), We analyzed physiological activities (oral communication, urinary and defecation control, food intake), daily life (mobility, work activity, etc.) and emotional state. (0 normal to 29 major deterioration).
RESULTS. N=531. Age 40.35±19.75 years, APACHE-II 17.94±6.97, GCS admission 7.53±3.83 points. TAC admission: Type I (10.4%), type II (28.1%), type III (24.5%), type IV (8.3%), mass evacuated (22.6%), not evacuated (6.2%). Hospital mortality: 28.6%. Mortality 1 year: 32.2% (lost:6.6%). Quality of life at one year (n=324) 9.44±8.73 points (significant deterioration).
Almost 80% patients have normalized the basic physiological activities, except oral communication that only maintain 54.8%, another 16.6% communicate with difficulty although with coherent dialogue. Low percentage of work reintegration and to make great efforts. They present normality in a high percentage in tolerance to minimum efforts, movements of precision and social relations. Low percentage presents normality in the items on emotional state or subjective aspects of the patient.
CONCLUSION. Patients who enter the ICU due to TBI at one year present significant deterioration in quality of life. Although a high percentage present normality in basic physiological activities, social relationships and physical activities that require little effort. On the contrary, a low percentage present normality in the subjective aspects, make great efforts and work activity.

Table 1 (abstract 000261). See text for description

Normal 1º year (%)			
Basic physiological activities		Normal daily life activities	
Oral communication	54,8	Movements	83,1
Urinary control	79,1	Minor effort	71,2
Defecation control	81,9	Major effort	35,3
Food intakes	81	Walking	63,8

INTRODUCTION. Cardiogenic shock (CS) describes a physiological state of end-organ hypoperfusion characterized by reduced cardiac output. Almost all the data in literature pertains only to CS related to myocardial infarction (AMI-CS), reporting a mortality up to 45%(1).
OBJECTIVES. We sought to analyse clinical and epidemiological data on patients admitted to general ICU enrolled in nationwide GiViTi registry (Gruppo italiano per la Valutazione degli interventi in Terapia intensiva) with a diagnosis of primary CS
METHODS. Observational prospective study. Out of 485509 admitted in 301 general ICUs from 2011 to 2017, 19250 patients met the enrolment criteria: > 18 years old, diagnosis of CS due to primary cardiocirculatory failure. Only patients with all data from the admission to the outcome in the last discharge hospital have been included in the analysis. CS secondary to other reasons of circulatory shock have been excluded (2). Patients demographic, admission, complications, treatment and mortality data have been analysed
RESULTS. Patients mean age admission was 70.9 (±12.7), 61.9 % were male and 92.3% presented cardiovascular comorbidities in the past medical history. 16709 (86.8 %) patients were transferred in ICU from of the same hospital; 12.7% were referred from another hospital and 0.5% from hospices. 52% were transferred from the emergency department while 10.5% were centralized from an another ICU. The main cardiovascular disorder leading to ICU admission were: Cardiac arrest (36.9%); Acute decompensated heart failure (40.1%); myocardial infarction (17.9%); pulmonary embolism (3.9%). Right ventricular heart failure was diagnosed in 6.9% of the population. 96.2% required catecholamine; 90.8% of patients underwent invasive ventilation during the admission, 11.7% renal replacement therapy; 13.8% intra-aortic balloon pump, 2 % received ECMO and 0.5% implanted a ventricular assisting device.ICU mortality was 50.4%, In-hospital mortality was 57.3% and the mortality at discharge from the last hospital further increased to 59.5% (Table 1). The mean ICU admission duration of survived patients was 9.3 days (±11.9) and for those who did not survive was 11 day (± 19.1)
CONCLUSION. Primary CS has a unacceptably ICU and intra-hospital mortality.This preliminary descriptive nationwide analysis underlines the urgency of a better delineation of the pathophysiology and treatment of CS. The organization of large registry aiming at the CS clinical phenotypization in the view of therapy titration has effectively reduced the burden of adverse outcome in acute heart failure and myocardial infarction, and it should be considered also for the CS syndrome

Lung Protective Ventilation in the Emergency Department

A. Rasheed
St John of God Hospital Group, Perth, Western Australia, Perth, France
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000735

INTRODUCTION. Mechanical ventilators in the Emergency Department (ED) are becoming more common and more advanced. The benefits of lung protective ventilation versus conventional ventilation have been well established in the ICU setting1. The LOV-ED trial2 is the first trial of its kind that displays the benefits on lung protective

ventilation in the ED setting, showing a decrease in patients developing Acute Respiratory Distress Syndrome (ARDS) when ventilated using lung protective strategies.
We carried out this audit in our ED to discover how many patients were receiving lung protective ventilation. Secondary outcomes included adequate oxygenation and time taken to perform the first arterial blood gas (ABG) while receiving mechanical ventilation.
METHODS. We retrospectively recruited all patients who received mechanical ventilation in the first nine months of 2018. Patients with restricted medical files were excluded. Using the ventilator observation sheet in each patient's medical record, the initial ventilator settings were identified. Initial ABG times and measurements were recorded from the ClinicalLabs application and cross referenced with the CIS database.
Patient weight was based on recorded actual weight or estimated weight, there was no recordings of height and therefore no access to predicted body weight.
RESULTS. 49 patients were recruited. 8 patients had to be excluded due to restricted records. Of the 41 patients audited, 17 patients (41%) had lung protective tidal volumes (4- 6mls/kg) initiated in the ED. Mean tidal volume was 6.5ml/kg.
15 patients (37%) of patients had no ABG performed during the duration of their stay in ED while ventilated. Average length of stay (LOS) for these patients with no ABG performed in ED was 3.6 hours – the same as the overall LOS of the whole cohort.
Of the remaining 26 patients, only 12 had an ABG performed in the first 30 minutes of being intubated. Average time to ABG was 72 minutes.
Of the patients who did have an ABG performed post ventilation in the ED, 17 (65%) were hyperoxaemic (paO2 >120mmHg). Mean length of stay in the ED post intubation was 3.6 hours.
CONCLUSION. The lack of predicted body weight had a very negative effect on this audit. Lung protective ventilation settings are all based of lean body weight, rather than actual or estimated weight. This resulted in mostly over-estimating the tidal volumes required for lung protective settings. On initial glance the mean tidal volume (6.5ml/kg) may seem quite close to the recommended lung protective volume (4-6ml/kg), however if the overestimated weights were to be taken into account, the mean tidal volume would be much higher.
A surprising secondary outcome was the time to first ABG. 15 patients not having an ABG performed at all until in a different department is a poor statistic. Furthermore, of the patients who did have a gas done while in the department, most were much too
delayed. A large proportion of patients received high FiO2 resulting in hyperoxaemia,
thus making the initial ABG timing even more crucial to allow adequate titration.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000696

INTRODUCTION. Stress-induced hyperglycaemia in the critically ill trauma patient is associated with increased mortality and morbidity [1]. The benefits and risks of strictly controlling glucose have yet to be determined in this population.
OBJECTIVES. To investigate the effects of strict glycaemic control, in polytrauma patients, on adverse outcomes through systematic review and meta-analysis.
METHODS. This review was prospectively registered on the Prospero database (CRD42018102948). A systematic literature search was carried out in three electronic databases: Medline, EmBase, and Web of Science from 1980-2018. Both randomised controlled trials (RCTs) and non-randomised controlled trials (nRCT) were included. Studies were included if they compared two groups under either a strict or loose glycaemic regime. Risk of bias was carried out by a single reviewer. The primary outcome was risk of mortality and the secondary outcomes were risk of hypoglycaemia (<3.33mol/L), days in hospital, days on ventilation, and occurrence of septicaemia. Data was analysed using the random-effects model in RevMan 5.3. Dichotomous outcomes are given as risk ratios (RR) and continuous outcomes as mean difference (MD), both with 95% confidence intervals.
RESULTS. 2 RCTs (n=957) and 7 nRCTs (n=6104) were identified. Risk of bias was high among the studies. The RCTs revealed: no change in mortality RR 1.07 [0.43, 2.71], increased risk of hypoglycaemia RR 15.66 [3.02, 81.09], and reduced risk of septicaemia RR 0.69 [0.59, 0.80]. The nRCTs revealed: no change in mortality RR 0.83 [0.63, 1.09], increased risk of hypoglycaemia RR 2.14 [1.65, 2.77], no reduction in days on ventilation MD -3.19 [-6.64, 0.27], no reduction in risk of septicaemia RR 0.95 [CI 0.66, 1.35], however a reduction in hospital days MD -6.70 [-13.06, -0.34].
CONCLUSION. Strict glycaemic control in the polytrauma patient may not reduce mortality and days on ventilation. There is a significant increase in the risk of hypoglycaemia, however the risk of septicaemia is inconclusive. There is weak evidence suggesting a reduction is hospital days. High risk of bias, especially within the nRCTS, limits strong conclusions. High quality RCTs are needed to further investigate strict glycaemic control in the polytrauma patient.

INTRODUCTION. Trauma is one of the ten leading causes of dead in the world. Responsible for about 1.4 million deaths a year. Death secondary to trauma is classified as early (post-injury) due to blood loss followed by hypovolemic shock; and late (post-resuscitation), if dead occurs more than 7 days post-injury, due to development of systemic inflammatory syndrome, tissue damage and multi-organ failure. In order to improve clinical outcomes permissive hypotension and minimizing fluid administration is considered as an effective strategy to reduce coagulopathy. Therefore, Hypertonic saline solutions have emerged as a promising for "low volume" fluid resuscitation in trauma patients. Moreover, some animal models have shown that using HSS in trauma may have immunomodulatory effects and may prevent injury of the glycocalyx. However,

these effects have not been studied in polytrauma human patients. Therefore, this study will attempt to resolve this gap in the literature.
OBJECTIVES. To determine the impact of 3% hypertonic saline solutions in clinical outcomes in polytrauma patients.
METHODS. This an analysis of a retrospective cohort of patients hospitalized due to polytrauma in a reference hospital in Bogotá, Colombia, between 2010 and 2016. Only patients over the age of 18, admitted to the intensive care unit (ICU) due to polytrauma were included. Trauma severity, APACHE, fluid strategy, use of vasopressors, development of MOF at 72 hours after ICU admission and 7-days mortality rate were recorded. Categorical variables were studied by Fisher's test and the continuous variables by Wilconxon and Anova test. Logistic regression (independent association) was used in order to study the association between variables and clinical outcomes.
RESULTS. A total of 217 patients were included in the study. Among them, 123/217 (57%) patients were resuscitated with HSS during the first 72 hours of ICU admission. Out of patients treated with HSS, 59/123 (48%) were treated with 3% HSS. A total of 101/217 (47%) patients developed MOF and 42 (19%) died within the 7-days after ICU admission. Demographic characteristics were similar between patients treated with 3% HSS and those who did not. After adjusting for APACHE, trauma severity and type of HSS used in the multivariate analysis; 3% HSS was associated with decreased of MOF (OR: 0.37, 95% CI: 0.17-0.78). However, ICU length of stay, vasopressor requirement and mortality at 7-days among groups remain unchanged in the multivariate analysis.
CONCLUSION. Hypotensive reanimation with 3% HSS may decrease multiorgan failure in ICU patients admitted due to polytrauma. Further randomized controlled trials are needed to confirm this beneficial effect and to determine underling mechanisms.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000834

INTRODUCTION. Enzymatic escharolysis is a non-surgical treatment method for removing necrotic tissue in severe burn injuries, leaving intact neighboring healthy tissue. In addition it reduces blood loss and the need for autologous skin grafting.
OBJECTIVES. To describe our experience in the use of NEXOBRID® in critical burn patients admitted in the Burn Centre at Vall d'Hebron University Hospital; between January 2015 and December 2018, and to assess differences between survivors and non-survivors.
METHODS. Retrospective monocentric cohort study of patients of at least 18 years with major burn injury; defined as total body surface area (TBSA) burned over 15% who had NEXOBRID® treatment method for remove total or partial necrotic tissue. Demographic data, comorbidities, mechanism of burn, vasopressor support requirement, length of mechanical ventilation (MV-LOS), length of stay (LOS) and mortality were collected from hospital medical records.
RESULTS. One hundred and thirty-three patients were admitted with major burns during the study period, 18 received enzymatic escharolysis (13.5%). When comparing patients treated with either enzymatic or surgical debridement no differences in gender, age, TBSA, Baux score and comorbidities were observed. Seventeen (94.4%) patients in the enzymatic group required mechanical ventilation versus 57 (49.56%) in the surgical group p= < 0.001, without difference in the MV-LOS median days (15, IQR25-75:7-38 versus 14, IQR25-75:5-33). No differences were observed in blood transfusion units (7, IQR25-75:4-19 versus 5.9, IQR25-75: 0-8). A higher proportion of patients in the surgical group required renal replacement therapy 13 (11.3%) versus 3 (16.3%) in the enzymatic group p= 0.06. Four patients (22%) died in the enzymatic debridement group versus 30 in the surgical group (26%) p= 0.003.
CONCLUSION. Patients treated with NEXOBRID® required more commonly mechanical ventilation, however no difference in the length of mechanical ventilation was noticed. Less mortality was observed in the enzymatic escharolysis when compared to surgical debridement.

Angioembolization versus Laparotomy in Patients with Isolated Blunt Splenic Injury; cluster-exact propensity score matching

T. Suzuki[1], A. Shiraishi[2], Y. Otomo[3]
[1]Interventional radiology center, Teikyo University Chiba Medical Center, Ichihara, Chiba, Japan; [2]Emergency and trauma center, Kameda Medical Center, Kamogawa, Chiba, Japan; [3]Trauma and acute critical care medical center, Tokyo Medical and Dental University, Bunkyo-ku, Tokyo, Japan
Correspondence: T. Suzuki

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000872

INTRODUCTION. Angiography with embolization (angioembolization) is an emerging hemostatic procedure for bleeding from splenic injuries. However, its mortality benefit compared with laparotomy remains unclear in patients with blunt splenic injury.
METHODS. This retrospective matched cohort study used data from the Japan Trauma Databank (2004 to 2017), a nationwide trauma registry of injuries with the injury severity score ≥9 at 272 institutions in Japan. Trauma patients who underwent angioembolization or laparotomy for isolated blunt splenic injury were studied. Patients were excluded if they needed cardiopulmonary resuscitation before hospital or in the emergency department, or had unsurvivable injury of any region of the body as defined by the Abbreviated Injury Scale. Missing values were handled by multiple imputation. Logistic regression analysis was done to estimate propensity scores for

angioembolization from known outcome predictors, including the age, gender, vital signs, resuscitative procedures in the emergency department, severity of injury, and type of splenic injury. Cluster-exact propensity score matching was performed to select pairs of patients from the same center, who undergoing angioembolization or laparotomy. The primary outcome was hospital mortality, while secondary outcomes were the 28 hospital-free days and complications (abdominal complications, organ failure, infection, and central nervous system complications).
RESULTS. Of 294,274 trauma patients registered in the JTDB, 1,796 patients had blunt splenic injury treated by angioembolization (N= 1,333) and/or laparotomy (N=564). 101 patients of whom underwent both angioembolization and laparotomy. Propensity score matching selected 240 patients each undergoing angioembolization or laparotomy. Hospital mortality was similar in both groups(8.0% versus 8.9%, odds ratio 0.90, 95%CI [0.46-1.73], P=0.74), but 30 patients receiving primary angioembolization (12.5%) required subsequent laparotomy. There were no significant differences of secondary outcomes (the 28 hospital-free days (7 versus 7 difference 0 [-1, 1]), abdominal complications (5.4% versus 5.9%, odds ratio 0.91, 95%CI [0.41, 2.04]), organ failure (7.2 versus 7.3 odds ratio 0.99, 95%CI [0.48, 2.03]), infection (5.4 versus 10.1 odds ratio 0.51, 95%CI [0.25, 1.07]), and central nervous system complications(4.1 versus 2.3, odds ratio 1.82, 95%CI [0.60, 5.51])).
CONCLUSION. This propensity score-matched observational study found that angioembolization did not significantly reduce hospital mortality compared with laparotomy.

INTRODUCTION. Descriptive study in trauma patients about the correlation betwwen inflammatory parameters and mortality, severity of illness, multiorganic dysfunction (MODS) and nosocomial infection.
OBJECTIVES. OBJECTIVES: To analyse the levels of procalcitonine, C-reactive protein and leukocytes in the first 24 hours as well as their correlation with severity scores and association with mortality, MODS and nosocomial infection.
METHODS. MATERIAL AND METHODS: Cohort study of trauma patients admitted at intensive care unit from January 2018 to March 2019. Independent variables: age, sex, type of trauma, levels of procalcitonine, C-reactive protein and leukocytes in the first 24 hours. Dependent variables: nosocomial infection, MODS and mortality. Descriptive statitic with mean and standard deviation or median and interquartile range for quantitative variables; absolute and relative frequencies for cualitative variables. Bivariant statitic; Student's t-distribution for independent samples with normal distribution and Chi-squared test for cualitative variables.
RESULTS. RESULTS: 157 patients were included during the period under review. Mostly were males (114, 72.6%) and blunt trauma (149, 94.9%) with a mean age of 47.45 ± 19.3. The mean stay at ICU was 5,04 days. ISS score, NISS and APACHE II scores were respectively 23.3 ± 12.4; 31.6 ± 16.8 and 15.2 ± 8.4. The median of leukocytes in the first 24 hours was 15800. C-reactive protein levels were analyzed in 118 patients with a median of 29.55 and procalcitonine was analyzed in 74 patients with a median of 0.74. The level of procalcitonine has a positive and significative correlation with APACHE II, NISS and ISS scores. The level of leukocytes has only a weak correlation with APACHE II score. The level of C-reactive protein has no correlation with severity scores. 21 patients developed MODS, 20 of them during the first three days (12.7%) and the last one later (0.6%). 33 patients (21%) were diagnosed of nosocomial infection during ICU stay with no significative differences in leukocytes and procalcitonine levels in comparison with the non-infected patients. Nevertheless, the levels of C-reactive protein were higher in those with nosocomial infection ($p< 0.01$). 13.5% of patients died during ICU stay and 16.1% of patients after ICU discharge during hospital stay. There are no statistically significant differences in the levels of leukocytes, C-reactive protein and procalcitonine during the first 24 hours between died and alive.
CONCLUSION. CONCLUSIONS: During the first 24 hours the levels of inflammatory parametres are not specific of infection and there is no differences in mortality and nosocomial infection incidence. There is statistically significant association between these parametres and MODS. Procalcitonine could be valuable to predict the development of MODS and nosocomial infection

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000908

INTRODUCTION. Patients with spinal cord injury require long-term hospitalization and rest, so they are more likely to develop venous thromboembolism (VTE). However, the screening for VTE in spinal cord injury patients has not yet been established.
OBJECTIVES. To clarify the optimal measurement timing and threshold level of the plasma D-dimer for the screening of VTE in patients with spinal cord injury who require long-term hospitalization and rest.
METHODS. Of the patients with spinal cord injury who were transported to our center between April 2011 and March 2019, those who required at least 10 days of rest and underwent diagnostic imaging for VTE, with either ultrasonography or enhanced computed tomography of the veins of the lower extremities, were included. We retrospectively accessed their medical records to determine whether they were positive or negative for deep vein thrombosis (DVT), the changes in their plasma D-dimer levels, etc. The subjects were classified into two groups, the VTE group and non-VTE group, based on their VTE status.
RESULTS. Of the 87 patients with spinal cord injury, 26 patients were analyzed. The median age was 67 years (61–77) and 16 patients (62%) were male. VTE was detected in 12 patients (46%). Prophylactic anticoagulant administration was given to eight patients (31%). Although the VTE group and non-VTE group showed almost the same changes in their median plasma D-dimer levels until hospital day 10, a sharp upward trend was then observed in the VTE group, which peaked at hospital day 13. The area under a receiver-operator characteristic curve for positive DVT vs D-dimer level at hospital day 13 was

0.857 (p=0.042), and the optimal cutoff point for D-dimer was 19.8 µg/dL because at that level, sensitivity (80%) and specificity (86%) were well balanced.
CONCLUSION. The plasma D-dimer levels may be used to screen for VTE in spinal cord injury patients who require long-term hospitalization and rest. The optimal measurement timing is 13 days after injury, and optimal threshold level is 19.8 µg/dL.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001023

INTRODUCTION. The global burden of haemorrhagic shock (HS) is substantial and mostly caused by severe physical trauma. Essential pathophysiologic features of HS are imbalance between oxygen delivery and demand, hyper or hypocoagulatory states and compensatory anti-inflammatory response syndrome, ultimately resulting in multi-organ failure (1). Animal models of HS are essential to study underlying pathobiology and develop new treatments.
OBJECTIVES. To develop an ovine model of severe HS caused by blood loss > 30% of the estimated blood volume (EBV) and study dynamics of oxygen supply/demand imbalance systemically and at end-organ tissue level.
METHODS. Six adult female Leicester cross breed sheep (46±5 Kg) were anaesthetised, intubated and on mechanical ventilation. We cannulated the femoral artery for blood sampling and mean arterial pressure (MAP) monitoring. Swan-Ganz catheter was inserted through the right jugular vein. Animals were haemorrhaged through consecutive collections of 300 mL of blood over 90 min, up to approximately 30% of the EBV. HS was halted in case of MAP < 50 mmHg, heart rate (HR) >200 beats/min, or venous oxygen saturation (SvO2) <50%. At baseline, and every 15-min thereafter, haemodynamic parameters were recorded, and arterial blood gas analysis performed, oxygen delivery (D02) computed. Microdialysis probes were positioned into various organs to measure, at baseline and end of bleeding period, interstitial lactate and lactate/pyruvate ratio.
RESULTS. All sheep survived HS. On average, sheep were haemorrhaged 1055±193 mL of blood (33.6±5.2% of EBV). At baseline, and at the end of HS period, Hb varied from 10.3±2.1 to 7.6±10.8 g/dL (p<0.01), arterial lactate from 2.0±1.5 to 4.3±1.2 mmol/L (p<0.01), HR from 102±14 to 154±30 bpm (p=0.06), MAP from 95.6±8.8 to 51.3±15.2 mmHg (p<0.01), cardiac output from 4.4±1.4 to 2.1±0.8 L/min (p<0.01), SvO2 from 76.3±9.8 to 54.0± 24.3% (p=0.192) and D02 from 552±218 to 241±114 ml/min (p< 0.01). Table below depicts development of organ-specific oxygen debt, measured by microdialysis.
CONCLUSION. We described an ovine model of HS, characterized by significant impairment in cardiac output and oxygen delivery, resulting in multi-organ oxygen supply/demand imbalance. The model will be first used to compare the efficacy of different resuscitation fluids.

INTRODUCTION. While supportive treatment in the management of Traumatic Brain Injury (TBI) has progressed over the past 20 years, specific drug treatments are lacking [Maas *et al*]. New strategies are needed. Altering how patients are ventilated, could be an easily modifiable variable in TBI management. Data in *in vitro* and *in vivo* models of ischemic heart [Ristagno *et al*] and brain injury [Loetscher *et al*] show that the gaseous agent Argon is endowed with neuroprotective potential. Whether Inhaled Argon (iAr) is protective in experimental TBI is presently unknown.
OBJECTIVES. To test the effects of inhaled Argon administered after experimental TBI in mice on neurological functions and structural outcome by longitudinal behavioural assessments and magnetic resonance imaging (MRI) including T2W and DWI sequences.
METHODS. Severe TBI was performed in anesthetized mice (C57BL/6J, 8 weeks old, male) over the left parietotemporal cortex by controlled cortical impact as previously described [Zanier *et al*]. Immediately after TBI, mice were randomized to 24h treatment by iAr 70%-O2 30% (n=10) or air (n=10) from 10 minutes after TBI. Sensorimotor deficits were evaluated at the end of treatment (24h post TBI) and at 1 week by neuroscore and simple neuroassessment of asymmetric impairment (SNAP) tests. MRI (7 Tesla, Bruker) was performed at 3 days post TBI to evaluate contusion volume by T2W. The effect of iAr on acute brain edema, was analysed in a subset of mice (n=3 per group) by DWI-MRI. Maps of the apparent diffusion coefficient generated by DWI-MRI were used to evaluate iper/ipo intense regions as a proxy of vasogenic and cytotoxic edema, respectively. A simple random allocation was applied to assign a subject to an experimental group. Data acquisition and analysis were done blindly. Data were

normally distributed. A t-test was used to evaluate differences between iAr and air treated TBI mice.
RESULTS. Argon inhalation significantly improved neurological function at 24 hours and 7 days after TBI (Neuroscore 24h post TBI iAr 6.1±0.5 vs. Air 3.7±0.7, p=0.0102). Contusion volume was reduced by 16% in iAr than air breathing TBI mice. Vasogenic brain edema showed a reduction in iAr treated TBI mice close to significance (p= 0.056).
CONCLUSION. iAr induces an acute and persistent improvement of sensorimotor function when administered for 24h starting 10 minutes after TBI. This outcome is reinforced by preliminary MRI data showing a trend in toward a decrease in vasogenic edema in iAr treated mice. Our data support future studies to understand the potential of iAr as an accessible treatment in TBI.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001243

INTRODUCTION. Drug-drug interactions (DDIs) are considered as concerning issues for public health especially in those admitted to intensive care units (ICUs). There are many studies that show involvement of intensivists in the ICUs improves outcome and limits costs. Different types of intensivist-driven care exist. This study evaluated the effect of academic versus non-academic (therapeutic) intensivist as well as hours of coverage and attendance of intensivist on DDIs in six adult trauma ICUs of a level one trauma center
OBJECTIVES. Considering the high incidence of pDDIs in the ICU, and the importance of ADRs caused by DDIs in critically ill patients, we aimed to investigate the effect of presence of an academic versus therapeutic intensivists as well as hour of coverage of intensivist on DDIs in six adult trauma ICUs of a level one trauma center in Shiraz, Iran.
METHODS. Two hundred patients were included in this prospective study in a 6-month period. The DDIs were classified into 5 categories, including type A, B, C, D, and X. Type D and X were considered as potential DDIs (pDDIs). Effect of three different types of intensivist staffing models including type A (once daily therapeutic intensivist visit followed by 24 hour on-call), B (twice daily academic intensivist visit, 8 hours attendance in ICU and 16 hours on–call) and C (all criteria just like ICU type B except presence of therapeutic instead of academic intensivist).
RESULTS. 3735 drug orders and 3869 drugs (193 different types) were assessed and 1826 potential DDIs were identified including 1107 (60.6%) type C, 648 (35.48%) type D and 12 (0.6%) type X. The mean of DDI per patient was significantly higher (P value <0.001) in ICU type A than ICU type C and type B. The frequency of DDIs was highest in type A. There was a statistically significant relationship between the number of prescribed drugs and ICU length of stay (P value <0.001 and P=0.009, respectively).
CONCLUSION. Different types of intensivist models affect DDIs to varying degrees. In this regard, academic versus therapeutic intensivist, twice versus once daily visit and 8 hours attendance with16 hours on-call versus 24 hours on-call is associated with more reduction in DDIs in adult trauma ICUs.

Airway Management in Spinal Cord Injury: Preventing and Decreasing Tracheostomy Morbidity

R. Onders, M. Elmo
Surgery, University Hospitals Cleveland Medical Center, Cleveland, United States of America
Correspondence: R. Onders
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001291

INTRODUCTION. High level cervical spinal cord injuries (SCI) often result in respiratory failure and the need for tracheostomy mechanical ventilation. The National Trauma Data Bank reports tracheostomy rate for high cervical injuries to be over 30% and even 20% of patients with injury below C4 require a tracheostomy. The benefits of tracheostomy are documented however they do have risks and in chronic long term use, there is sub optimal management. Early complications include bleeding(2-5%), stomal infection (2-5%) and dislodgement 1%. Late complications approach 65% including tracheomalacia and stenosis.
OBJECTIVES. This is a report of tracheostomy use in all traumatic SCI patients who underwent diaphragm pacing (DP).
METHODS. This is a retrospective review of prospective IRB and or FDA approved protocols involving SCI and DP. Airway management of traumatic SCI who underwent DP was analyzed pre and post DP implant.
RESULTS. Out of over 500 implanted DP patients 99 were traumatic SCI with complete tracheostomy data on 84 patients. Fifty nine or 63% of patients had a cuffed tracheostomy at the time of DP evaluation. Average age at time of injury was 27. 8 years (1 day to 74 years). The average time spent on mechanical ventilation prior to DP was 9.7 years (6 days to 25.6 years). Within this group are 13 pediatric patients age 0 to 17 in which 54% presented with a cuffed tracheostomy tube. Post DP implant, 7 patients were decannulated, 15 patients had tracheostomy converted to cuffless tube and 2 patients went to a stoma stent. One patient required laryngectomy due to tracheal damage. Two patients went directly from Endotracheal tube mechanical ventilation to DP to extubation avoiding tracheostomy altogether. T Median survival was 22.2 years (95% CI 14.0 - not reached) with only 31 deaths. Subgroup analysis showed that earlier DP implantation leads to greater 24 hour use(72%) of DP and no need for any MV.
CONCLUSION. There continues to be a widely held belief that positive pressure ventilation must be delivered via cuffed and generally inflated cuffed tracheostomy tube. Inflated cuffed tracheostomy tubes has significant morbidity including speech difficulty, aspiration increases from difficulty swallowing, tracheal stenosis and tracheomalacia. The efficacy and benefits of the cuffless tracheotomy was first described in 1990. Publications in SCI and chronic mechanical ventilation describe the use of cuffless tracheotomy but this report confirms cuffed tube usage is dominant. The choice of tracheostomy style needs to be better scrutinized. DP implantation allowed for downsizing and decannulation. It obviated the need for tracheostomy in two patients. Early DP use may significantly alter the morbidity of tracheostomies leading to improved survival.

INTRODUCTION. Alcohol and drug abuse are potentially modifiable risk factors for critical illness. Increased knowledge regarding the impact of substance abuse on cause of admission in different ICU populations is needed.
OBJECTIVES. To describe patients with substance abuse-related admissions in a mixed intensive care (ICU) population, and to compare these patients with patients with non-substance abuse-related admissions on selected parameters.
METHODS. Cross-sectional prospective study of ICU-patients in Oslo aged ≥18 years included over a one year period from February 3rd 2014 to February 2nd 2015. Data were collected consecutively from a questionnaire, medical records and toxicology results. Substance abuse-related admissions were defined as ICU-admissions due to acute or chronic complications of alcohol or drug use, and included the following subgroups: (A) cause of admission directly associated with acute substance abuse (e.g. acute intoxication) (B) indirect influence of acute substance abuse (e.g. trauma in intoxicated patient) and (C) medical complications of chronic substance abuse (e.g. alcoholic liver disease).
RESULTS. Of the 861 patients included, 537 (62%) were medical and 324 (38%) surgical, 632 (73%) received mechanical ventilation and 279 (32%) died during the hospital stay. Overall, 168 (20%) patients had substance abuse-related admissions; 104 (12%) were alcohol-related and 64 (7%) drug-related. Of the 168 patients with substance abuse-related admissions, 59 (35%) patients were in group A, 77 (46%) in group B and 32(19%) in group C. In age groups 18-39 and 40-59 males had a much higher proportion of substance abuse-related admissions than females (47/99, 48% vs 10/40, 25%, p<0.02 and 57/167, 34% vs 11/71, 16%, p<0.01, respectively), while there were no difference between the genders in patients 60 years and older. Among the 191 trauma patients, substance abuse was predisposing factor in 69 (36%). Patients with admissions associated with acute substance abuse (subgroups A and B) were significantly younger (mean age 43 and 46 vs. 63), had lower mean Charlson comorbidity index (1.2 and 0.8 vs. 2.5) and shorter median time of mechanical ventilation (0.5 and 1.0 vs 4 days) than patients with non-substance abuse-related admissions. There were no such differences between patients in group C and patients with non-substance abuse-related admissions. Age-adjusted logistic regression analysis showed lower hospital mortality for patients in group B (OR 0.5, p< 0.04), but not in the other subgroups.
CONCLUSION. One in five ICU-admissions was associated with alcohol or drug abuse. Acute substance abuse caused the majority of the substance abuse-related admissions, and was particularly prevalent among young, male patients with otherwise few risk factors for critical illness. Nearly half of the admissions in males aged 18-39 were associated with substance abuse, and more than one third of the trauma patients were influenced by alcohol or drugs at time of injury. Routine screening for alcohol and drugs in Norwegian trauma patients should be considered implemented.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001326

INTRODUCTION. The use of albumin to resuscitate burn patients has been a controversial issue for more than 50 years. Currently the most accepted formulas use crystalloids for this purpose and colloids only as a rescue fluid in order to avoid "fluid creep". In contrast, BET formula administers albumin from the beginning of the resuscitation period using it in a progressively decreasing concentration.
OBJECTIVES. The purpose of our study was to review and analyze resuscitation related variables of all burned patients treated in our unit using BET formula
METHODS. Retrospective, observational study conducted in a 5 bed critical care unit for major burns in a tertiary hospital in Spain. BET formula estimates fluid resuscitation as a function of total burn surface area (TBSA) (ml/h = TBSA (m2) x 220) and administers it through a combination of Lactated Ringer and 20% Albumin starting at a 1:1 relationship. The proportion of albumin is decreased every 8 hours during the first 48 hours (resuscitation period) and the infusion rate is modified according to urinary output. Study period was from January 2013 to January 2018. Inclusion criteria: TBSA > 20% or > 10% plus inhalation injury, admission during the first 12 hours after the injury, who had all documentation regarding fluid resuscitation available. Data are expressed as means, medians, and proportions and analyzed using T-Test, Wilcoxon Rank Sum, Chi-Square and Fishers´ Exact Test as needed. Relationship between variables is expressed as Pearson´s correlation coefficient
RESULTS. 131 patients were admitted in the unit during the study period. 40 patients met all inclusion criteria. Patients´ characteristics: age 58 ± 19, 26 (65%), TBSA% 36 ± 17, mechanism fire 28 (70%), inhalation 8 (20%), ABSI 9 ± 2, time injury-admission 4.5h (2.7-6.1), referring hospital 24 (60%). Resuscitation volume during the first 24 hours (VOLBSi24) was 2.58 ml/kg/%BBSA, significantly less than Parkland´s estimation (4 ml/kg/%BBSA; P<0.05). Patients were successfully resuscitated showing a significant base excess and lactate clearance during the resuscitation period (base excess 135%; lactate 35%; P<0.05). A slight but significant correlation was found between time from injury to admission (admission delay) and indexed volume administered in the first 24 h (r 0.32, p<0.05). An inverse correlation was found between indexed volumes and TBSA% during the first 24h (r -0.38, p<0.05). Resuscitation related complications: mechanical ventilation 27 (67.5%), ARDS 12 (30%), renal failure (KDIGO ≥ 1) 21 (53%), continous renal replacement therapy 5 (12.5%), wound deepening 8 (20%), abdominal compartment syndrome 2 (4.5%), limb compartment syndrome 0.
CONCLUSION. BET formula is capable of resuscitating burn patients successfully, limiting fluid administration, and being able to keep burn related complications low.

Biomarkers for multiple organ dysfunction syndrome in severely injured trauma patients

D. Kleinveld[1], A. Tuip-De Boer[1], M. Hollmann[2], N. Juffermans[1]
[1]Intensive care and laboratory of experimental intensive care and anesthesiology, Amsterdam UMC - Location AMC, Amsterdam, Netherlands; [2]Anesthesiology and laboratory of experimental intensive care and anesthesiology, Amsterdam UMC - Location AMC, Amsterdam, Netherlands
Correspondence: D. Kleinveld
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001379

INTRODUCTION. Improvements in the early resuscitation phase of trauma comes at a cost of increased morbidity and mortality in later phases, including the occurrence of multiple organ dysfunction syndrome (MODS). If patients at risk for MODS could be identified early using different cytokine production profiles, preventative treatment measures could be taken.
OBJECTIVES. The aim of this study is to investigate whether specific pro- and/or anti-inflammatory biomarkers are associated with development of MODS.
METHODS. Adult (18 years or older) multiple trauma patients with an injury severity score of 16 or higher presenting to a level 1 trauma center in the Netherlands between 2008 and 2018 were included. Blood was drawn at presentation to the hospital and analyzed for 19 markers of systemic and pulmonary inflammation, endothelial activation and coagulation using a Luminex assay. MODS was defined as a SOFA score of three or more in two organ systems. Comparisons were made between patients with and without MODS. Univariate and multivariate logistic regression analysis was used to determine association between specific biomarkers and MODS. Data are presented as median with interquartile range. A p-value of less than 0.05 was considered to be statistically significant.
RESULTS. In total, 147 multiple trauma patients were included, of which, 32 patients developed MODS. Compared to patients without MODS, patients with MODS had higher injury severity scores (25 [22 – 30] vs 20 [17 – 27], p=0.010), more often had traumatic brain injury (75 vs 56 %, p=0.048), were deeper in shock with lower base excess (-2.7 [-6.1 – -0.6] vs -1.2 [-3.1 – 0.8], p=0.005) and were more coagulopathic as determined by higher prothrombin time (12.7 [11.7 – 14.7] vs 11.7 [11.3 – 12.4] seconds, p=0.001). Overall, baseline levels of both pro- as well as anti-inflammatory biomarkers were higher in MODS patients, indicative of a severe host immune reaction. In the multivariate analysis, the combination of interleukin-1 receptor antagonist (OR 1.27 [1.07 – 1.51], p=0.002) and clara cell protein 16 (1.06 [1.01 – 1.05], p=0.031) was most strongly associated with the development MODS. Receiver operating curves showed an AUC of 0.73 (IL-1RA) and 0.70 (CC-16), respectively.
CONCLUSION. In trauma, biomarkers IL-1RA and CC-16 have the potential to identify patients at risk for development of MODS. Further research is warranted to prospectively validate these results.

Identifying poisoning patients in need of intensive care in EMS: study of factors associated with intensive care admission in patients in contact with the EMS

L. Koskela[1], L. Raatiniemi[2], A. Ehrola,[3], J. Liisanantti,[1]
[1]Study group of surgery, anesthesiology and intensive care, Oulu University, Medical Research Center, Oulu, Finland, Finland; [2]Centre for pre-hospital emergency care, Oulu University Hospital, Oulu, Finland; [3]Emergency medical services, Oulu-Koillismaa Rescue Department, Oulu, Finland, Finland
Correspondence: L. Koskela
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001410

INTRODUCTION. Acute poisoned patients are a common occurrence in intensive care units (ICU). It is estimated that three to six percent of patients admitted to ICU are due to acute intoxication.(1) ICU admission rate of patients admitted to hospital in Nordic countries varies largely: from 7.3 % in Finland up to 49 % in Norway, mostly due to different poisoning treatment policies. (1–3) Majority of poisonings are presented to hospitals by ambulance operated by emergency medical services (EMS). (3)
OBJECTIVES. We set out to map out factors associated with hospitalization and intensive care admission to better recognize patient population in risk of death or other serious sequelae.
METHODS. A retrospective study was conducted in all EMS missions of poisoning patients in Oulu University Hospital (OUS) catchment area for three years, from 2015 to 2017. We combined data from Oulu-Koillismaa Emergency Medical Services database with OUS hospital discharge registry.
RESULTS. From a total of 1,336 EMS missions labeled as poisoning-related, 682 patients were included in the study after excluding patients under 16 years, those who were discharged with other diagnosis and those who were never transported to hospital. 4.8% of poisoning patients were admitted into ICU. Data for 682 patients are presented in Table 1.
CONCLUSION. Significant factors associated with intensive care admission in poisoning patients were pre-hospital intubation, negative alcohol finding and intravenous fluid resuscitation of >500 ml. Risk factors should be taken into account in further poisoning missions, and results of this study may provide support when a poisoning patient's need for intensive care is in question.

The role of computed tomography in patients admitted to the intensive care unit following overdose

J. mccarthy, C. Ward, R. Sundaram
Intensive care department, Royal Alexandra Hospital, Paisley, UK, United Kingdom
Correspondence: J. mccarthy
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001602

INTRODUCTION. Self-inflicted overdose remains the third most common reason for admission to intensive care units in Scotland. Computed tomography (CT) scanning is often performed, however its value in this patient group has been debated. CT requires intrahospital transfer of the critically ill patient, which has been associated with increased risk of respiratory and cardiovascular instability.
OBJECTIVES. We wished to ascertain the diagnostic yield of CT head in patients admitted to the intensive care unit following overdose. We hoped to identify any differences in length of stay or mortality between those patients who received a CT head and those who did not. We wished to identify clinical features which were associated with positive scan results, and to determine if a positive CT head had any impact on decision making.
METHODS. We performed a retrospective analysis of patients admitted to a single Scottish intensive care unit over a 13 year period (2005-2018). Patients presenting with "self-poisoning" were identified using the ward watcher national audit database. Descriptive statistics were used to analyse patient demographics, pre-intubation GCS, length of stay, and predicted and actual mortality. Differences between groups were analysed using unpaired t tests and p values of < 0.05 were considered statistically significant. Diagnostic yield was calculated using percentages. Where a CT head was reported as abnormal, we determined if this affected the treatment plan by reviewing all associated electronic patient records.
RESULTS. 179 patients admitted to intensive care following overdose were identified, with a median age of 39. 55% were male. 38% had a CT scan performed. 15% of these scans were reported as "abnormal" but only 6% represented an acute pathology. None required intervention or resulted in a change in management. Pre-intubation GCS was lower in those patients who had CT scans than those who did not ($p = 0.0013$). Patients with a recent history, or clinical evidence of, head injury, were more likely to receive a CT head. There was no increase in the rate of positive scan in this group. In the small group of patients with a positive CT scan, there was no history of head injury, seizures, localising neurology or anticoagulation.
CONCLUSION. The yield of CT head scanning following overdose was low. Only 6% revealed an acute intracranial pathology and non required intervention or resulted in a change in management. Mortality rates in this patient population are low compared to the general ICU population and having a CT head had no demonstrable effect on mortality. CT scans were more likely to be performed in those patients with a lower pre-intubation GCS and those with a head injury, but we did not find any increase in positive findings. We could not identify any clinical characteristics associated with increased likelihood of a positive scan. We cannot make any recommendations regarding which patients may benefit from early scanning. Any decision to proceed to intrahospital transfer to facilitate diagnostic imaging must be balanced against the very real risks of instability during transfer. Larger studies are required to provide appropriate statistical power to identify patient subgroups who may benefit from early imaging following overdose.

Risk factors of delirium in ICU patients with acute poisoning

HY. Kim, KM. Cha, BH. So
Department of emergency medicine, St. Vincent's Hospital, College of Medicine, The Catholic University of Korea, Seoul, Republic of Korea
Correspondence: B.H. So

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001659

INTRODUCTION. Delirium is a common clinical syndrome in intensive care unit, correlated with various adverse clinical outcomes.
OBJECTIVES. This study aims at estimating the incidence of delirium and investigating the associated risk factors and outcomes in ICU patients with acute poisoning.
METHODS. The data was collected from the ICU patients admitted via the emergency center over 18 years old presenting with poisoning from 2010 to 2015. Delirium was assessed retrospectively using Intensive Care Delirium Screening Checklist (ICDSC). Risk factors were evaluated with univariate and multivariate analysis.
RESULTS. 199 patients participated in this study and a total of 68 (34.2%) of the patients were diagnosed with delirium based on ICDSC score. The delirium group showed statistically significantly higher association with prolonged length of stay in the hospital and ICU in comparison with non-delirium group. The use of physical restraints and altered mental status were identified as significant risk factors for delirium with an odd ratio of 1.92 and 3.90. Pharmaceutics poisoning group was observed to develop delirium faster than non-pharmaceutics poisoning group. There was no significant difference between the two groups with respect to age, sex, past history, GCS score, vital sign, and application of ventilator care and renal replacement therapy.
CONCLUSION. In ICU patients with acute poisoning, the development of delirium was found to be common and associated with the use of physical restraints and altered mental status.

Clinical prediction score to predict massive blood transfusion in trauma patients

O. Akaraborworn[1], B. Siribumrungwong,[2], B. Sangthong[1], K. Thongkhao[1]
[1]Division of trauma and critical care, department of surgery, Prince of Songkla University, Hat Yai, Songkhla, Thailand; [2]Division of vascular and endovascular surgery, Department of Surgery, Faculty of Medicine, Thammasat University, Bangkok, Thailand
Correspondence: O. Akaraborworn

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001713

INTRODUCTION. Exsanguination is the most common cause of early trauma death. Rapid blood transfusion is crucial in trauma resuscitation. Well-performed scoring system to predict massive blood transfusion(MBT) aids resource utilization with promptly blood preparation. Previous scoring systems take long time to obtain after admission and inaccurate in Thailand with a different trauma system.
OBJECTIVES. To create a scoring system to predict MBT in trauma patients.
METHODS. All patients who met one of trauma activated criteria which were 1) Systolic blood pressure < 90mmHg 2) Gun shot wound(GSW) at the chest, abdomen or back 3) Stab wound at the chest or abdomen 4) Respiratory rate <12/min or >30/min 5) Pulse rate > 120/min 6) Glasgow coma scale score $\leq$ 8 7)Present of free fluid from focused assessment with sonography for trauma(-FAST) from January 2012 to December 2018 were included. MBT was defined as receiving packed red cell(PRC) > 10 units in 24 hours or > 4 units in the first hour. Univariable analysis was conducted on all possible predictors which included patients characteristic, mechanism of injury, and laboratory results. Factor with p value < 0.2 were included in the stepwise backward multivariable logistic regression. The score was assigned by coefficient. Sensitivity, specificity and positive likelihood ratio was estimated. Cutoff point was selected based on Receiver Operator Characteristic curve analysis then internal validation was performed with bootstrap replications.
RESULTS. Among of 878 patients, 102(11.6%) received MBT. Nine factors were significantly associated with MBT with the score of 2.5 for age $\geq$ 60 years, 1.5 for female, 2 for GSW, 3 for pelvic fracture from physical examination, 2 for femur fracture from physical examination, 1 for PR $\geq$ 105/min, 2 for base excess $\leq$ -10mEq/L, 2.5 for lactate > 4mmol/l, and 2 for present of free fluid on FAST. The area under the curve(AUC) was 0.824 (95% CI 0.778 - 0.871). At the cutoff point $\geq$ 7, this score has a positive likelihood ratio of 10.22. Internal validation demonstrated AUC 0.805 (95%CI 0.754 -0.856).

CONCLUSION. The new score has an excellence discrimination to prediction of MBT. The parameters were simple and easy to obtain a few minutes after arrival thus should be applied in clinical practice. Further, cost-effectiveness and implemental studies should be done.

Epidemiology of septic patients admitted to the Intensive Care Unit. Analysis of incidence and outcomes

AB. López Pérez, HG. Khandji Aslan, JB. López Messa
Intensive care unit, Hospital Río Carrión, Palencia, Spain
Correspondence: A.B. López Pérez
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000008

INTRODUCTION. Sepsis incidence is increasing compared to incidence for other leading causes of mortality such as acute myocardial or stroke. Estimates of sepsis incidence and trends are also essential to estimate the resources needed to care for these patients. We would like to emphasize the importance of using local data to monitor trends in results over time. This information has significant implications for health-care service planning and may be useful to estimate future care requirements.
OBJECTIVES. To examine the most recent epidemiological characteristics of sepsis and the temporal changes in its incidence and outcome.
METHODS. A retrospective study was carried out during a consecutive six years period in a polyvalent ICU of a secondary hospital from January 1, 2010 to December 31, 2016. To identify episodes of sepsis we applied the International Classification of Diseases, Ninth Revision, Clinical Modification. The statistical analysis was perfomance with IBM-SPSS-22. The hospitalization rate was defined as the yearly number of admissions per 100.000 population. Qualitative variables are expressed as frecuency and percentage, and quantitative variables as mean and standard deviation. The Student t test was used to compare means of the quantitative variables and when the hypothesis of normality was no accepted, the nonparametric Mann-Whitney U test was used. And Chi-square test for categorical variables. We performed a logistic regression analysis to identify factors associated with in-hospital mortality. Odds ratios (ORs) with 95% confidence intervals were computed.
RESULTS. Seven hundred and twenty four patients were included at ICU admission. Sepsis was present in 180 patients (24.9%) and septic shock in 544 (75.1%). The mean age was 69.2 years and 67% were male. 66.9% of all episodes of sepsis were among people aged 65 years or more. Hypertension (53%), non-metastatic cancer (30.7%) and diabetes (26.8%) were the most common categories of comorbility. Gram-negative bacteria were the most frequently involved microorganisms (42.7%). The observed mortality was 38.7%. Elderly patients (≥65 yrs) were more likely to have 3 or more organ failures (73.1% vs 61.7%). Between 2010 and 2016 there was an annualized increase in the incidence of sepsis from 35.4 per 100.000 population to 53.3 per 100.000 population. The total in-hospital mortality rate fell from 52.9% in 2010 to 34.6% in 2016. The risk of death was significantly associated with the respiratory failure, a low pH, SAPS 3 and mechanical ventilatory support.
CONCLUSION. Our analysis shows that cases of sepsis occur in older people and develop a greater number of organ failures. Sepsis incidence has risen in recent years in our region while mortality has fallen despite increase in age and severity of sepsis.

Presepsin as a predictor of sepsis outcome in comparison to procalcitonin and CRP

A. Mahmoud,[1], K. Taema[2], H. Saber,[1], H. Sherif,[2]
[1]Critical care medicine, Benisuef University Hospital, Beni Suef, Egypt; [2]Critical care medicine, Cairo University, Faculty Of Medicine, Kasr Al Ainy, Cairo, Egypt
Correspondence: K. Taema
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000014

INTRODUCTION. Identification of predicted sepsis related mortality is important for patient stratification.
OBJECTIVES. We evaluated the significance of Presepsin in predicting sepsis mortality.
METHODS. We enrolled 83 sepsis patients according to the SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference in a prospective observational study. After excluding 28 patients due to different exclusion criteria, 55 continued the study. Their age was 58(47-65) years-old with 33 (60%) males.
We measured serum Presepsin, Procalcitonin, and CRP on admission, 24 and 72 hours later. APACHE-II score and Capillary leak index (CLI) were estimated. The primary outcome was the in-hospital mortality.
RESULTS. The median(Q1-Q3) Presepsin24 and Presepsin72 levels were 1127.5(835.75-2137.5) and 883(429-1214.5)pg/ml in survivors compared to 2321(1264-3456) and 3421(1900-5432)pg/ml in non-survivors (P=0.01 and 0.000 respectively). The serum CRP24 and CRP72 were 123(76-154) and 94(42.5-127)mg/L in survivors compared to 156(101-201) and 187(139-233)mg/L in non-survivors (P= 0.02 and 0.000). PCT72 was 111.5(66-186.25)pg/ml in survivors compared to 231(187-324)pg/ml in non-survivors (P=0.000). Presepsin0, CRP0, PCT0 and PCT24 were not significantly different between survivors and non-survivors (P=0.4, 0.7, 0.5, and 0.2 respectively). The APACHE-II score was 18(15-20.8) in survivors compared to 21 (19-24) in non-survivors (P = 0.02) while the CLI was 42(27.6-57.7) and 42.4(33.3-62.3) in survivors and non-survivors respectively (P = 0.8). The AUC was the highest for Presepsin72 (0.918). Presepsin72 of 1262pg/ml was seen to be 92.3% sensitive and 81.3% specific for mortality prediction.
CONCLUSION. This study showed that the serum Presepsin could be a valuable biomarker for predicting in-hospital mortality in sepsis.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000025

INTRODUCTION. Sepsis is defined as the host's inflammatory response to a life-threatening infection potentially leading to a septic shock and the failure of organs initially not infected [1]. Currently, the most efficient weapon to fight against bacterial infections is

antibiotics. New elements suggest that some antibiotics could have an intrinsic immunomodulatory effect in addition to their antimicrobial effect [2]. Endothelial cells are able to detect danger signals from pathogens and to initiate the innate immune response, and in some specific conditions, the adaptive immunity [3].
OBJECTIVES. The aim of this study was to highlight the effects of two antibiotic classes on endothelial cells' immune properties during sepsis.
METHODS. Human Microvascular Endothelial Cells (HMEC) were stimulated by Lipopolysaccharide, Interferon γ and Tumor Necrosis Factor α (Cytomix) during 24 hours before the administration of different antibiotics. The surface expression of Inter-Cellular Adhesion Molecule 1 (CD54), Program-Death Ligand 1 (CD274), Human Leucocyte Antigen (HLA) class 1 and HLA-DR were determined using flow cytometry 24 hours after antibiotics' administration. The production of cytokines as Interkeukin (IL)-6 or IL-8 by HMEC was determined by Enzyme-Linked Immunoabsorbent Assay (ELISA). Quantitative polymerase chain reaction (qPCR) was used to analyze GAPDH (control), IL-6, HLA-A and HLA-DR gene expression. To study the effect of antibiotics on lymphocytes, the activated HMEC exposed to antibiotics were co-cultured with peripheral blood mononuclear cells obtained (PBMC) from healthy donors.
RESULTS. Compared to Cytomix alone, Clarithromycin (1 µg/mL) associated to Cytomix significantly decreased the expression of HLA-1 (fold change HLA-1 expression to Cytomix 0,67 to 1 p<0,01) and HLA-DR (0,65 to 1 p<0,01) on HMEC surface. Rovamycin and Erythromycin also significantly decreased both expressions of HLA-1 and HLA-DR. In qPCR, Clarithromycin (10 µg/mL) significantly decreased HLA-DR gene expression (1 versus 0,78 HLA-DR fold expression to GAPDH p<0,01) and IL-6 gene expression (1 versus 0,67 IL-6 fold expression to GAPDH p=0,03) compared to Cytomix. Compared to Cytomix, Amoxicillin (1 µg/mL) significantly decreased the expression of HLA-1 on HMEC surface (0,55 to 1 p<0,01) but did not affect HLA-DR expression. IL-6 and IL-8 production were not significantly different between Cytomix stimulation alone and Cytomix associated with antibiotics treatment. Co-cultures of HMEC with Rovamycin and PBMC did not change lymphocytes polarization nor regulatory or memory T cells proliferation.
CONCLUSION. Macrolides and Penicillin modulate the expression of HLA molecules on microvascular endothelial cells' surface. The use of a second endothelial cell line, co-cultures of endothelial cells with sorted CD8+ lymphocytes and *in vivo* experiments could better enlighten the potential pathophysiological implications of those results.

Right ventricular function and long-term outcome in sepsis: a retrospective cohort study

JC. Winkelhorst, SN. Voorrips, IT. Bootsma, PM. Koetsier, F. De Lange, EC. Boerma[1]
Department of intensive care, Medical Centre Leeuwarden, Leeuwarden, Netherlands
Correspondence: J.C. Winkelhorst
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000063

INTRODUCTION. Sepsis-related myocardial dysfunction is associated with impaired outcome. Traditionally, in this setting the main focus has been on left ventricular performance. As of now, specific knowledge on the prognostic importance of right ventricular dysfunction is scarce. The aim of this study was to determine whether right ventricular ejection fraction (RVEF) is predictive of long-term mortality in sepsis.
METHODS. Single-centre retrospective cohort study in adult patients admitted to the ICU with severe sepsis and septic shock, and equipped with a pulmonary artery catheter within 24 hours following admission. RVEF was recorded as an average over the first 24 hours (sample rate of 1 per minute). Patients were a priori separated into subgroups according to their RVEF: RVEF<20% (A), RVEF 20-30% (B), and RVEF>30% (C). The primary endpoint was one-year all-cause mortality; secondary endpoints included haemodynamic variables and use of norepinephrine in relation to RVEF.
RESULTS. In a 7-year period 101 patients fulfilled all entry criteria and 98 were included in the study. Demographic data, medical history, reason for admission, and source of infection did not statistically differ between groups. However, patients in group A had a significantly higher APACHE II score and signs of shock were more profound, as indicated by a lower cardiac index, SvO2, and pH, a higher lactate, and more use of norepinephrine in comparison to other groups. One-year all-cause mortality was significantly different between groups: 57.1% in group A (n=21), 18.2% in group B (n=55), and 22.7% in group C (n=22); p=0.003. Kaplan-Meier survival analysis revealed a clear separation between group A and B/C (chi square= 14,00; p=0.001). In a multivariate logistic regression analysis, RVEF, both as a categorical variable (RVEF<20%) and as a continuous variable, remained independently associated with the primary endpoint (OR 4.1; 95% CI 1.3-13.4; p=0.018 and OR 0.92; 95% CI 0.85-0.99; p= 0.018, respectively).
CONCLUSION. RVEF is independently associated with one-year all-cause mortality in a highly selected group of patients with severe sepsis and septic shock. In addition, a low RVEF was associated with an increase in signs of circulatory failure, suggesting maladaptation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000123

INTRODUCTION. The central venous-arterial carbon dioxide differences (pCO2 gap) is a marker of the adequacy of cardiac output with the global metabolic conditions that are less affected by an impairment of oxygen extraction capacities. (PCO2 gap =K. VCO2(CO2 production)/COP)(1)
OBJECTIVES. To investigate the relation between the pCO2 gap, serum lactate and cardiac index (CI) and prognostic value on admission. We also investigated the pattern of Ultrasound chest (US).
METHODS. We performed a prospective observational study and recruited 28 patients, over 6 months, with severe sepsis and septic shock in mixed ICU. We determined central venous PO2, PCO2, PCO2 gap, lactate, CI at 0 and 6 hours after critical care unit (CCU) admission. The cardiac index was measured using echocardiography (non-invasive) in a blinded fashion. The population was divided into two groups based on pCO2 gap (cut off value 0.8 kPa).
RESULTS. CI was significantly lower in the high gap group (p = 0.001). The high gap CO2 group, on admission, required more bolus fluid administration and vasopressors (P= 0.01 and 0.009 respectively) table1. The hospital mortality rate for all patients was 24.5 % (7/28). The in-hospital mortality rate was 20 % (2/12) for the low gap group and 30 % (5/16) for the high gap group; the odds ratio was 1.6 (95 % CI 0.5–5.5), p = 0.53. Patients with a persistent or rising pCO2 gap larger than 0.8 kPa at T = 6 and 12, , had a higher mortality change (n = 6; in-hospital mortality 21.4 %) compared to patients with a pCO2 gap less than 0.8 kPa at T = 6 (n = 1; in-hospital mortality 3%); this odds ratio was 5.3 (95 % CI 0.9–30.7); p = 0.08. PCO2 gap has no relation with chest ultrasound pattern.
CONCLUSION. PCO2 gap is an important hemodynamic variable in the management of sepsis-induced circulatory failure. PCO2 gap can be a marker of the adequacy of the cardiac output status in sepsis. A high-value PCO2 gap (>0.8 kPa) can identify situations where increasing cardiac output can be attempted with fluid resuscitation in severe sepsis. PCO2 gap carries an important prognostic value in severe sepsis

INTRODUCTION. Early changes in biomarker levels probably occur sometime before bloodstream infection (BSI) is diagnosed. It has clinical relevance to understand when the host inflammatory response begins. So far, this issue has not been fully addressed.
OBJECTIVES. We aimed at evaluating the kinetics of C-reactive protein (CRP) and plasma albumin (PA) in the 30 days before the community-acquired (CA) BSI.
METHODS. From a population-based BSI database we identified 658 patients with at least one measurement of CRP or PA from day −30 (D −30) through day −1 (D−1) before the day of CA-BSI (D0) and a measurement of the same biomarker at D0 or D1. Amongst these, 502 had both CRP and PA measurements which fit the above defined criteria.
RESULTS. CRP and PA concentrations began to change inversely some days before the diagnosis of CA-BSI, CRP increasing by day −3.1 and PA decreasing by day −1.3. From D−30 to D−4, CRP kinetics (expressed as slopes – rate of concentration change per day) was −1.5 mg/L/day. From D−3 to D1, CRP slope increased to 36.3 mg/L/day. For albumin, the slope between D−30 to D−2 was 0.1 g/L/day and changed to −1.8 g/L/day between D−1 and D1.
CONCLUSION. We showed that biomarker levels, used as surrogates of host inflammatory response, begin to change some days before the CA-BSI diagnosis, CRP 3.1 days and PA 1.3 days before.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000133

INTRODUCTION. The ideal study cohort should have the same number of biochemical specimens with equal time intervals between all specimens (as in well-designed prospective studies). This is a limitation of population-based studies with different numbers of samples per patient and highly variable time intervals between specimens. To date no study has assessed trajectories of C-reactive protein (CRP) and plasma albumin (PA) levels in real-life data around Community-Acquired Bloodstream Infections (CA-BSI).
OBJECTIVES. To assess trajectory patterns of CRP and PA levels before and after CA-BSI.
METHODS. Population-based study, with 2418 CA-BSI patients, CRP and PA specimens from 30 days before through 30 days after CA-BSI episode (day 0). Subgroups were established based on whether specimens were occurring or not in days -30/-1, 0, 1/7 or 8/30. Mean daily CRP and PA levels on day -30/30 were computed for each subgroup.
RESULTS. Mean CRP rose on day -5 and reached its peak on day 1. Mean steady PA on day −30/0 declined abruptly on day 1 and increased slowly thereafter. Trajectories did not differ between subgroups, in other words the course of CRP and PA around the BSI episode was independent of the number of specimens. 30-day mortality odds ratios for age, gender, co-morbidity, bacteria group, sepsis status, and albumin level did not change materially when amending 0 versus ≥1 specimen in day -30/0 to the multivariate model, though the subgroup with ≥1 specimen had 50% higher mortality.
CONCLUSION. Trajectories of CRP and PA levels around CA-BSI did not differ in relation to number of specimens from each patient. This enables longitudinal analyses of real-life data in population-based studies.

INTRODUCTION. There is wide heterogeneity in sepsis. The identification of sepsis phenotypes may lead to more precise therapy. The contribution of pathogen data to sepsis phenotypes is unknown.
OBJECTIVES. We aim to assess the effects of adding microbiological variables on clinical phenotypes determined using clinical data alone.
METHODS. We conducted a secondary analysis of data from the Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) Study. We used latent class analysis (LCA) to identify phenotypes using 24 clinical-only variables (*C*) (including demographic variables, vital signs, markers of inflammation and organ dysfunction) versus 24 clinical and 3 microbiological variables (e.g. sites of infection, type of pathogen, and drug resistance) (*CM*) using measurements collected prior to randomization. We assessed model fit using Bayesian Information Criteria (BIC), entropy, and the probability of cluster membership. We describe clinical characteristics and outcomes of phenotypes before and after adding microbiology variables. We tested for heterogeneity of treatment effect of activated protein C (APC) by phenotype using logistic regression.
RESULTS. Among 1,690 septic patients enrolled in the PROWESS study, we identified an optimal 4-class model for both *C* and *CM* variables. In clinical-only phenotypes, the α-type (N=327, 19.4%) was younger and had more pulmonary dysfunction; the β-type (N=518, 30.7%) was old and had greater comorbidity; the γ-type (N=532, 31.5%) had more pulmonary dysfunction; the δ-type (N=313, 18.5%) had more liver, renal, and hematologic dysfunction and shock. Microbiological variables rearranged 772 of 1690 (45.7%) patients (**Figure 1A**) and increased the median probability of the clustering across 4 groups from 0.952 to 0.971. When microbiology was added to clinical variables, the β-type had more abdominal infection (from 19.7 to 40.1%), while γ-type had increased lung infection (from 50.4 to 77.8%). The 28-day mortality was significantly different across phenotypes (both chi2 $P<0.001$), but was similar between *C* and *CM* models (**Figure 1B**). No heterogeneity of treatment effect by phenotype was present with either *C* (*P* value for interaction=0.25) or *CM* models ($P=0.40$). However, the treatment effect of APC in γ-type significantly changed from benefit ($P=0.04$) to neutral ($P=0.73$) when microbiological variables were added.
CONCLUSION. Compared to sepsis phenotypes determined using clinical data alone, the addition of microbiological variables such as site of infection or type of pathogen revised phenotype membership, increased the probability of cluster members, and contributed to clinically meaningful rearrangement of sepsis patients. Microbiology data are an important domain for the investigation of sepsis phenotypes.

INTRODUCTION. NP is a frequently occurring healthcare-acquired infection often caused by gram-negative pathogens and associated with high mortality rates. Rapid initiation of appropriate antibacterial therapy is key to improving survival, especially in patients (pts) with sepsis. In the recently completed, randomized double-blind, multicenter, phase 3 ASPECT-NP trial, C/T (at double the currently approved dose) was noninferior to MEM for ventilated NP in both primary and key secondary endpoints.
OBJECTIVES. Retrospectively evaluate outcomes in pts from ASPECT-NP who had greater severity of illness and organ failure, by SOFA component scores.
METHODS. Mechanically ventilated pts with NP were randomized 1:1, stratified by NP type (ventilator-associated pneumonia [VAP] vs ventilated hospital-acquired pneumonia [vHAP]) and age (<65 y vs ≥65 y), to receive 3 g C/T or 1 g MEM, by 1-h IV infusions every 8 h for 8-14 d. The primary endpoint was 28-d all-cause mortality in the intent-to-treat (ITT) population, and the key secondary endpoint was clinical response at test-of-cure (TOC; 7-14 d after end-of-therapy in the ITT population). SOFA scores were collected at baseline. We conducted a post-hoc analysis comparing outcomes by treatment arm in pts with a SOFA respiratory component score ≥2 (RS2) and in pts with a cardiovascular component score ≥2 (CVS2), regardless of their other component scores.
RESULTS. The majority of ITT pts in this trial met one or both SOFA score criteria, with distributions balanced across arms: in the C/T arm, 312/362 (86.2%) had RS2 and 84/362 (23.2%) had CVS2; in the MEM arm, 321/364 (88.2%) had RS2 and 99/364 (27.2%) had CVS2. In the CVS2 subgroup, 69 (82.1%) C/T and 91 (91.9%) MEM pts also had RS2. Baseline characteristics, including causative pneumonia pathogens (mostly Enterobacteriaceae and *Pseudomonas aeruginosa*), were generally similar between both subgroups and across treatments. Clinical outcomes in both the RS2 and CVS2 subgroups were comparable between C/T and MEM (Table). In RS2, outcomes were consistent with the previously presented overall ITT results (i.e., 28-d mortality ~25% and TOC clinical cure ~55% in both arms). As expected, mortality rates in pts with shock (i.e., CVS2) were slightly higher than in the overall ITT population.
CONCLUSION. These data confirm that ASPECT-NP enrolled a critically-ill patient population, reflected in the prevalence of acute lung injury (RS2) and shock (CVS2). In these retrospective analyses, 28-d mortality and TOC clinical cure rates were generally not affected by severity of illness. Furthermore, greater severity of illness did not affect the relative efficacy of C/T vs MEM in these high-risk patients with gram-negative ventilated NP.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000181

INTRODUCTION. In the Sepsis 3.0 definition, sepsis is only divided into 2 groups: sepsis and septic shock. Septic shock is still one of the most major causes of intensive care unit (ICU) admission and death in the world[1,2]. However, in Sepsis 3.0, it didn't tell us what the accurate mean of adequate fluid resuscitation and provide an objective and detectable indicator in septic patients.
OBJECTIVES. Our aim in the present study was to evaluate the diagnostic effect of SOFA on septic shock in septic patients.
METHODS. Firstly, we conducted a retrospective study of patients with sepsis diagnosis admitted to the ICU using the MIMIC-III database. They were divided into septic shock and non-shock based on ICD-9 and SOFA≥2. The multivariate logistic regression analysis was used to find out the independent risk factors affecting the incidence of septic shock. ROC curve was used to analyze those risk factors, SOFA, qSOFA, SAPS and SAPSII. What's more, we collected clinical data of sepsis and septic shock patients from three different hospitals within 24 hours after admission. SOFA, qSOFA, SAPS II and APACHE II were also compared with ROC curve analysis.
RESULTS. A total of 5724 patients were enrolled in MIMIC-III, with 2811 in septic shock group and 2913 in non-septic shock. The result of multivariate logistic regression analysis indicated that lactate and SOFA were the independent risk factors (p<0.05). The result of ROC analysis showed that the AUC of pH-value, lactate and BUN were 0.587, 0.553 and 0.539. SOFA had the best predictive effect with the statistical results of AUC (0.643) (95%CI 0.550–0.723, p=0.001), sensitivity (0.620), specificity (0.600); and also shown that SOFA ≥7 meant the patients have supposed to be septic shock. Secondly, SOFA, qSOFA, SAPS II and APACHE II were also compared with ROC by our multicenter data. A total 216 patients were enrolled in our data, with 80 septic shock group and 136 in sepsis. It also shown that SOFA have a higher diagnostic efficiency (AUC=0.687, 95%CI 0.550–0.723, sensitivity=0.727, specificity=0.601, p=0.002) than qSOFA (AUC=0.666, 95%CI 0.582–0.750, p<0.001), SAPS II (AUC=0.642, 95%CI 0.559–0.724, p=0.001) and APACHE II (AUC=0.642, 95%CI 0.558–0.727, p=0.001) within 24 hours after admission. It also indicated that SOFA ≥8 meant the patients have supposed to be septic shock。
CONCLUSION. SOFA score is the best choice for diagnosing the possibility of septic shock. Our findings suggest that the SOFA≥8 within 24 hours after admission in ICU provides better diagnostic effect for septic shock in septic patients.

INTRODUCTION. Prompt initiation of appropriate empiric antimicrobial therapy decreases mortality and improve clinical outcomes. However, the excessive use of antibiotics has been associated with antibiotic resistance that has been linked to increased morbidity and mortality. This study evaluated the appropriateness of empiric antimicrobial therapy in patients with severe sepsis and septic shock
OBJECTIVES. The objective of the study is to evaluate the appropriateness of empiric antimicrobial therapy in patients with severe sepsis and septic shock admitted to intensive care
METHODS. This retrospective study included adult patients admitted with severe sepsis and septic shock to a 16-bed intensive care unit (ICU) at a tertiary care facility in the eastern province, Saudi Arabia. The ICU database was utilized to identify all patients who had an admission diagnosis of severe sepsis or septic shock in 2015, which was defined based on the 2012 Surviving Sepsis Campaign guidelines. Demographic data, empiric antimicrobials, source of infection, and results of antimicrobial sensitivity testing were recorded. The primary goal was the appropriateness of empiric antimicrobial therapy in severe sepsis and septic shock patients initiated within 24 hours of ICU admission against the isolated organisms
RESULTS. A total of 98 ICU admissions were included, among whom 70 (71%) had septic shock while the remaining had severe sepsis. Among the patients, 57 were males, 53 (54%) had malignancies and the mean age was 55 years. The most common sources of infection were pneumonia (35, 36%), intra-abdominal (24, 24%), bacteremia (14, 14%), urinary tract (8, 8%), and skin/soft tissue (7, 7%). Cultures were positive in 47 episodes (48%). Empiric antimicrobial therapy was appropriate in 48 out of 55 (87%) the total isolates causing infections. Only 13% of the isolated organisms were resistant to initial empiric therapy, of which three isolates were carbapenem-resistant Pseudomonas aeuroginosa. There was a single isolate of carbapenemresistant Klebsiella pneumoniae, carbapenem-resistant Acineotbacter baummannii, methicillin-resistant Staphylococcus aureus and candida glabrata. The most frequently prescribed antibiotics were vancomycin prescribed in 66 (67%) cases, carbapenems in 59 (60%) cases followed by piperacillin/tazobactam (n=37, 38%), amikacin (n= 21, 21%), and levofloxacin (n=13, 13%). There was a variation as regard to patients type, inappropriateness of empirical antimicrobial was relatively highest among oncology patients (p= 0.025)
CONCLUSION. The majority of the patients in this study received empiric antimicrobial therapy for which the pathogens identified were susceptible to. Institutional antibiotic susceptibility profile should be considered in optimizing empirical antibiotics therapy in settings with a high rate of resistance.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000236

INTRODUCTION. Disseminated intravascular coagulation (DIC) is one of the major causes of organ dysfunction and death in sepsis; however, there are no standard criteria for DIC. Recently, sepsis-induced coagulopathy (SIC) was developed as a new criterion for coagulopathy of sepsis. It includes the sequential organ failure assessment (SOFA), similarly the new definition of sepsis revised in 2016. Previous studies suggested that SIC score might be a prognostic value for patients with sepsis and coagulopathy.
OBJECTIVES. To evaluate the generalizability of SIC score as a prognostic value generally for patients with sepsis.
METHODS. Data from a multicenter observational study (Japan Septic Disseminated Intravascular Coagulation [JSEPTIC-DIC] study), which investigated patients with sepsis in 42 intensive care units from 2011 to 2013, were analyzed. This contained information about patients' backgrounds, examination results, treatments, and mortality. Primary outcome measure was in-hospital mortality. SIC score, Japanese Association for Acute Medicine (JAAM) DIC score, and the International Society of Thrombosis and Haemostasis (ISTH) DIC score were calculated. Then, patient characteristics and other variables for survivor and non-survivor groups were compared, using $\chi 2$ test or Fisher's test. Finally, receiver operating characteristic (ROC) analysis was performed by estimating the corresponding areas under the curve (AUC).
RESULTS. This study included 2283 patients (mean age, 68.7 years; standard deviations [SD] 14.6); 1364 were males (59.7%). All-cause mortality rate was 32.1%. The mean APACHE II score was 23.4 (SD 8.8) and the mean SOFA score was 9.7 (SD 4.1). A total of 1647 patients (72.1%) were diagnosed with SIC – 1291 patients (56.5%) were positive JAAM DIC and 727 patients (31.8%) met the ISTH DIC criteria. The proportion of the JAAM DIC and ISTH DIC were significantly higher in non-survivor group (66.5% vs 51.8% $p<0.01$, 43.7% vs 26.2% $p<0.01$, respectively); however, there was no statistically significant difference in SIC score between non-survivor and survivor groups (74.2% vs 71.2%, $p=0.07$). ROC curve showed that AUC for SIC, JAAM DIC, ISTH DIC, APACHE II, and SOFA scores were 0.52 (95% confidential interval [CI], 0.49-0.54), 0.57 (95%CI, 0.55-0.60), 0.59 (95%CI, 0.56-0.61), 0.72 (95%CI, 0.70-0.74), and 0.71 (95%CI, 0.69-0.74), respectively.
CONCLUSION. Generally, SIC score might not be a good prognostic value for mortality among sepsis patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000245

INTRODUCTION. Sepsis is reported to affect more than 30 million people every year and is a priority on the global health agenda.[1,2] It is estimated that 70% of sepsis is community-onset while 30% is health care-associated (HA).[2] However, there has been only one study conducted to estimate the global sepsis burden, and specifically, the global burden of HA sepsis as compared to community-onset is still not well understood. A systematic review was conducted to assess the burden of HA sepsis and its epidemiology.
METHODS. The following electronic bibliographic databases were searched from 1 January 2000 to 31 December 2017: MEDLINE, EMBASE, Global Index Medicus, and PubMed. Epidemiological studies that described the incidence or prevalence of HA sepsis were included. Languages were restricted to English, French, Spanish, Arabic, Russian, German, Italian, Japanese, and Portuguese. Title/abstract screening, full-text screening, and data extraction were conducted by at least two reviewers. The study was registered to PROSPERO (CRD42018089554).
RESULTS. Title/abstract screening and full-text screening was performed for 8922 and 1772 studies, respectively. Among these, 4 population-based studies and 12 hospital-based studies with clear definitions of HA sepsis were identified. Studies came from 13 countries, including 38.5% from low- and middle-income settings, and 4 geographic regions. Two population-based studies focused on a pediatric population; incidence of HA sepsis ranged from 1.28-6.88 cases per 100,000 population-years. Two studies focused on an adult population including 1 study which defined only severe sepsis and septic shock; incidence of HA sepsis ranged from 12.28-13.92 cases per 100,000 population-years. The proportion of HA sepsis out of all sepsis cases ranged from 22.8% to 49.1%.
CONCLUSION. Our systematic review highlighted the important epidemiological burden of HA sepsis. HA infections leading to sepsis are preventable, and infection prevention and control measures remain important to mitigate the sepsis burden in the healthcare setting.

Immunoglobulins levels in septic shock

M. Tosi, E. Munari, S. Venturelli, E. Roat, I. Coloretti, M. Girardis
Intensive care unit, Policlinico of Modena University Hospital of Modena, Modena, Italy
Correspondence: M. Tosi
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000249

INTRODUCTION. Septic shock has growing incidence and mortality rates above 50%. Impairment of immune defences may be common among this patients and underpin the development of unfavourable outcomes1. Immunoglobulins deficit is related to higher mortality

rates in septic patient2 3. Hence immunoglobulin supplement is used as adjunctive treatment with immune-adjuvant purposes. Nonetheless it was not clarified yet if Ig baseline titers can affect the outcome in patients treated with IgGAM adjunctive treatment.
METHODS. We performed an observational retrospective study analysing a registry specifically conceived to collect information on immune system's functionality in patients undergoing septic shock. Patients admitted to polyvalent intensive care unit of the University Hospital of Modena from January 2014 to February 2019 with diagnosis of septic shock and who received adjunctive treatment with polyclonal immunoglobulins enriched in IgM and IgA (IgGAM) were included in the analysis. Patients <18 years, with an end-of-life decision or too sick to benefit and patients with no Ig titers measured at baseline were excluded. The population was splitted in tertiles of basal IgM titers. Survival ad day 30 from shock occurrence was compared among the three groups.
RESULTS. 84 patients were included. Mean age was 65, median SAPS II score at admission was 62 (IQR 48-76) and baseline SOFA score was in median 11 (IQR 8-13), more common comorbidities were neoplasm, cirrhosis and diabetes. 12 patients had a previous state of immune impairment due to haematological disease, HIV, immunosuppressant or chemotherapic drugs. Overall 30-days mortality was 47.6% (40 patients). Median length of stay in ICU was 9 days (IQR 6-19) and in hospital 22 days (IQR 11-38). IgM titers at T0 were in median 49.5 (IQR 28.5-94). Tertiles division according to IgM basal titers splitted the population using threshold values of IgM of 37 and 71 mg/dL. The three groups did not differ for age, sex, basal SAPS II and SOFA score, immune impairment state, rate of nosocomial and MDR infections and comorbidities except for cirrhosis, that was more common in 3° tertile and hematologic diseases, more frequent in 1° tertile. 30 days mortality in 1st, 2nd and 3rd tertile was 53%, 37% and 51.9% respectively (P-value 0.407).
CONCLUSION. Patients with septic shock who received adjunctive treatment with IgGAM had higher survival rates when IgM at admission had intermediate concentrations (from 37 to 71 mg/dL) compared to lower or higher IgM titers. Further studies are needed to clarify whether patients with normal or high levels of IgM at diagnosis do take advantage from Ig supplementation therapy.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000250

INTRODUCTION. Patients admitted in an intensive care unit (ICU) are at the greatest risk of acquiring nosocomial infections. Infectious diseases are associated with higher rates of morbi-mortality and hospital and ICU length of stay (LOS).
OBJECTIVES. To identify the clinical and epidemiological features of the infections registered in the ICU of Hospital Punta de Europa using ENVIN database.
METHODS. Retrospective descriptive analysis was performed using a prospective cohort of 330 patients obtained from a 12-bedsICUcollected during the year 2018. Demographic variables, ICU admission diagnoses and their origin (community, ward or another ICU), risk factors, prognosis scores, ICU LOS, mortality, microorganism isolated and antimicrobial therapy used were collected. Statistical analysis was performed: continuous variables (mean and standard deviation), categorical variables (percentages and frequencies).
RESULTS. 330 patients were included: male (63.03%), age: 64 [± 15.22], SAPS II 35.78 [±16.23], APACHE II 15.73 [±7.94]. ICU LOS (days) 6.93 [±6.02]. ICU mortality: 88 patients (26.67%).Community-acquired infections (64 patients, 19.39%): 18 non ventilator-associated pneumonias, 8 surgical infections, 8 soft tissue infections. Microbiological isolation: *E. coli*(19.51%), *H. influenzae*(7.32%) and *S. aureus*(7.32%). Antibiotic therapy: ceftriaxone (17.89%), piperacillin/tazobactam (PTZ) (12.11%). Hospital-acquired infections outside the ICU (30 patients, 9.09%): 13 surgical related infections and 3 non ventilator-associated pneumonia. Microbiological isolation: *E. faecium*(16.67%), *E. coli* (13.33%) and *Candida albicans*(13.33%). Antibiotic therapy: metronidazole(12.12%),ceftriaxone(11.11%).ICU-acquired infections (20 patients, 6.06%): 11 ventilator-associated tracheobronchitis, 5 ventilator-associated pneumonia (VAP), 5 bacteremia due to intra-abdominal infections and 3 catheter-related bloodstream infections (CRBSIs):*E. coli*(12.90%), *P. aeruginosa* (12.90%) and *S. aureus*(12.90%). Antibiotic therapy: levofloxacin (10.61%), PTZ (10.61%), linezolid (10.61%). CRBSI: 1.36 per 1000 central venous catheter days. Isolated:*E. faecalis*(33.33%), *K. penumoniae*(33.33%) and *S. aureus*(33.33%). VAP: 168 patients under invasive mechanical ventilation (50.91%), 5.17 VAP per 1000 ventilator-days. 80% of the cases had not microbiological isolation.
CONCLUSION. Most of the infections registered were community-acquired, being *E. coli*the most frequently isolated.*E. coli*and *P. aeruginosa*were the most frequently detected pathogens in ICU-acquired infections. About antibiotic therapy, ceftriaxone, PTZ, levofloxacin and meropenem were more frequently used.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000268

INTRODUCTION. Aspiration pneumonia (AP) is a frequently suspected complication of drug overdose requiring mechanical ventilation (MV) and admitted to intensive care unit (ICU) (1). In the absence of reliable biomarkers for distinguishing between aspiration pneumonia and aspiration pneumonia, antibiotic therapy is frequently prescribed (2). Latest studies suggest that a care protocol could better select patients requiring antibiotic therapy (3).
OBJECTIVES. To determine the impact of a care protocol on the antibiotic prescription among patient admitted to ICU for toxic coma with MV.
METHODS. We conducted a prospective observational cohort study in four ICU. We included all patients admitted for toxic coma with MV. In the University-affiliated ICU, a care protocol was applied. In the three others ICU, physicians declared that they did not follow formalized conduct within the service and did as usual.
RESULTS. We included 43 patients in care protocol group and 42 in control group. The mean SAPS II was 43.3 (±15.3) with a mean Glasgow Coma Scale score at 4.9 (±2.1) before intubation. Within the total population, 40 patients (47%) had a pulmonary bacteriologic sample (PBS), mostly because purulent tracheobronchial aspirate and

new infiltrates on the chest X-ray (respectively 36.4% and 29.4% of the population with a bacteriological sample). Among the patients with a bacteriological sample, 34 (85%) were culture positive. The incidence of probabilistic antibiotherapy did not differ between the care protocol group (n=16) and the control group (n=16). There was no difference for the incidence of PBS (20 in each group). The others secondary outcomes did not differ either (Table 1).

CONCLUSION. Our study does not show that a care protocol allows a reduction of antibiotic prescription among patient admitted to ICU for toxic coma with MV. Our incidence of antibiotic prescription is lower than the previous studies (4). The absence of difference can be explain by two reasons: some of physicians of control group had been trained in the university-affiliated ICU in the last years and may follow a management approach similar to that of the control group; despite our precautions, the existence of the study could have modify the practices in the control group.

INTRODUCTION. There remains no specific effective therapy for sepsis, thought to be due to heterogeneity within the syndrome. However, recent transcriptomic work has identified two distinct sepsis-response-signature (SRS) profiles; with SRS1 being associated with increased mortality compared to SRS2 [1, 2]. The genes that are differentially expressed between these two groups are involved in a range of immune processes, the functional implications of which are not yet understood, although SRS1 appears to be the relatively immunosuppressed endotype compared to SRS2. Monocytes are implicated in the pathogenesis of sepsis through direct involvement in the innate and modulation of the adaptive immune responses.

OBJECTIVES. The same SRS endotypes have been identified using transcriptomic methodology applied to samples collected from patients with septic shock from the VANISH trial [3, 4]. This aim of this study was to condition healthy monocytes in plasma taken from these patients, to model septic monocytes, and assess their functional status via surface phenotype and phagocytic activity, which may explain the some of the differences between SRS endotypes. Cell surface markers of interest included those involved with defining monocyte subsets (CD14, CD16), antigen presentation (HLA-DR), apoptosis (MerTK) and costimulation (CD86, PD-1, PDL-1).

METHODS. Healthy monocytes were obtained from fresh whole blood using a two step process of density-gradient centrifugation to isolate peripheral blood mononuclear cells, and then magnetic cell sorting to isolate CD14+ monocytes. These were conditioned overnight in complete media and either SRS-profiled or healthy volunteer plasma (previously frozen).

Fluorochrome associated antibodies were used to assess surface phenotype and fluorescent E. coli bioparticles for phagocytic activity. Results were acquired by flow cytometry, and analysed with FlowJo V10. Fluorescent activity was reported as percentage of cells positive (PP) or geometric mean fluorescence intensity (GMFI). Statistical analyses were performed using Graphpad Prism 8.0.2.

RESULTS. CD14+ monocytes were conditioned using plasma samples from 28 SRS1 and 28 SRS2 patients with septic shock recruited to the VANISH trial, and 7 healthy volunteers. There were no significant differences in baseline characteristics between the two groups. The most marked difference in monocyte function was increased expression of CD14 in SRS1 (PP 39.3% vs 23.4%, $p < 0.01$), and increased expression of PD-1 in SRS2 (PP 18.2% vs 11.7%, $p < 0.05$). No difference in phagocytic activity was seen between the two SRS groups. Serum cytokine levels were compared between the two profiles (from the same plasma samples), with increased levels of IL-6, IL-10 and MCP-1 in SRS1 ($p < 0.01$).

CONCLUSION. These results indicate that the transcriptomic differences that distinguish SRS1 and SRS2 translate to the cellular level, with the main finding being increased CD14 expression on healthy monocytes conditioned in SRS1 plasma. In this *in vitro* model, it could be assumed that this is an effect of the increased cytokine levels found in SRS1 plasma. However, *in vivo* this may instead represent a greater proportion of 'classical' monocytes, producing more cytokines. This should be validated by performing similar immunophenotyping on monocytes taken directly from patients who have been SRS-profiled.

INTRODUCTION. Organ dysfunction during sepsis or septic shock may alter antibiotic drug concentrations via changes of drug distribution and elimination. We therefore studied the pharmacokinetics of meropenem in critically ill patients with acute-on-chronic liver failure (ACLF) and without concomitant liver failure (NLF) during continuous venovenous hemodialysis (CVVHD).
METHODS. In this prospective cohort study, all patients received meropenem 1g tid. Meropenem pre- and postfilter serum and ultradialysate samples were obtained at the following time points: T0, T1, T2, T4, T8, T24, T25, T48, T49 and analyzed by high pressure liquid chromatography with diode array detection (HPLC-DAD). Nonlinear mixed-effects modelling was performed in NONMEM® 7.3.
RESULTS. 19 patients were studied. Of these, 8 patients suffered from ACLF. A two-compartment model with linear clearance (CL) from the central compartment adequately described meropenem pharmacokinetics in both patient populations. CL was 5.2 L/h with a coefficient of variation of 28%. The population estimate of the peripheral volume of distribution (Vd) was 19.7 L for critically ill patients without liver failure and 38.6 L for the ACLF-population ($p = 0.05$). Deterministic simulations of meropenem concentration over 24 hours using typical parameter values for NLF and ACLF showed differences in trough levels that decreased with consecutive doses.
CONCLUSION. Patients with ACLF receiving CVVHD have a higher Vd and may require a higher initial dose of meropenem to reach microbiological defined targets (i.e. time above minimal inhibitory concentration) compared to critically ill patients without ACLF undergoing CVVHD.

INTRODUCTION. Early mobilization prevents muscle atrophy and functional disability in critically ill patients, while its implementation is challenging due to the severity of illness and limited resources. Electrical muscle stimulation (EMS) evokes muscle contraction without input from the central nervous system, and it can be applied to critically ill patients. However there has been much debate if EMS improves functional ability of the patients.
OBJECTIVES. To investigate if early EMS on upper and lower limb muscles prevents muscle atrophy and improve physical function in critically ill patients.
METHODS. We included consecutive adult patients admitted to ICU and expected to be mechanically ventilated longer than 48 hours and to stay more than 5 days. The patients were randomly assigned to EMS or control group. EMS was applied with a low-frequency therapy equipment (Solius, Minato Medical Science Co., Ltd, Osaka, Japan). EMS group of patients received EMS sessions of bilateral upper and lower extremities daily for 30 min from day 1 to 5 in addition to the usual rehabilitation. Patients in control group received only the usual rehabilitation. The primary outcome was the change of upper and lower limb muscle thickness and cross-sectional area, measured by ultrasound from day 1 to 5. The secondary outcomes were Medical Research Council score and the incidence of ICU-acquired weakness at day 5, and ICU Mobility scale at the discharge from the ICU.
RESULTS. Thirty-seven patients were enrolled, and 4 patients were excluded (death, pain, and insufficient muscle contraction due to edema or obesity). Fourteen patients in EMS group and 19 in the control group were evaluated. Mean age was 73±3 vs. 66±3 years, ($p=0.16$), and median APACHE II score was 23(18-28) vs. 22(19-30) ($p=0.94$) in EMS and in control, respectively. The change of thickness in upper limb muscle was -1.0±2.5% vs. -11.2±2.1% ($p<0.01$), and in the lower limb was 3.2±3.7% vs. -14.7±3.2% ($p<0.01$), the change of cross-sectional area in upper limb muscle was -5.0±3.6% vs. -10.0± 2.4% ($p=0.18$), and in the lower limb was -1.0±3.4% vs. -10.4±2.9% ($p=0.046$) in EMS and in control, respectively. There was no significant difference in Medical Research Council score (54±4 vs. 46±4, $p=0.18$), ICU-acquired weakness (13% vs. 40%, $p=0.20$), and ICU Mobility scale (2.2±0.5 vs. 1.5 ±0.5, $p=0.31$) between EMS group and the control group.
CONCLUSION. In critically ill patients, EMS on upper and lower limb muscles preserved muscle mass. Further research should be done to clarify if EMS improves physical function and long-term outcomes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000084

INTRODUCTION.*Introduction*: Hyperglycemia is a compensatory metabolic response to acute stress. It reflects the development of insulin resistance to preserve life during life-threatening conditions, but is associated with worse prognosis during critical illness (1, 2).
OBJECTIVES.*Objectives*: The aim of the present study is to investigate the association of glycemic parameters at intensive care unit (ICU) admission with outcomes in critically ill patients.
METHODS.*Methods:* From September 2017 to February 2018, adult critically ill patients admitted to ICU were prospectively included in the study. Blood samples were collected at study entry for random blood glucose and glycated hemoglobin (HbA1c) and were used to calculate glycemic gap and stress hyperglycemia ratio (SHR). All patients were assessed for presence of hyperglycemia (>140 mg/dL at admission), hypoglycemia (<70 mg/dL in 24h) and glycemic variability (higher - lower capillary glucose in 24h).
RESULTS.*Results:* A total of 542 patients were enrolled (mean age 59; 30% with previous diabetes) and were followed until hospital discharge or death for 180 days. Hypoglycemia was associated with increased mortality (54.8% vs. 35.8%, $p=0.004$), need for renal

replacement therapy (RRT; 45.1% vs. 22.3%, p <0.001) mechanical ventilation (MV; 72.6% vs. 57.5%, p=0.024) and higher shock incidence (62.9% vs. 35.8%, p<0.001). Hyperglycemia was associated with higher mortality (44.3% vs.34.9%, p=0.031) and increased need for MV (66.1% vs. 55.7%, p=0.018). Patients with glycemic gap >80 mg/dL had increased need for RRT (37.7% vs. 23.7%, p=0.025) and higher shock incidence (54.7% vs. 37.4%, p=0.014), but no difference in mortality. SHR >1.1 was associated with increased need for MV (65.8% vs. 2.8%, p=0.001). Glycemic variability was associated with an increased need for RRT (28.3% vs. 14.4%, p=0.002, for variability >40 mg/dL; 31.6% vs. 16.6%, p<0.001, for variability > 60 mg/dL and 34% vs. 18%, p<0.001, for variability > 80mg/dL) and higher shock incidence (41.4% vs.31.2%, p=0.039, for variability >40 mg/dL; 42.9% vs. 34%, p=0.034, for variability >60 mg/dL; and 64.2% vs. 55.9%, p= 0.010, for variability >80 mg/dL). The associations of hypoglycemia and hyperglycemia with mortality remained after adjustments for disease severity.

CONCLUSION.*Conclusions:* In this sample of medical-surgical critically ill subjects, including patients with and without previous diagnosis of diabetes, hypoglycemia and hyperglycemia were independently associated with increased mortality, while glycemic variability, glycemic gap and SHR were associated with worse outcomes, such as shock incidence, need for RRT and need for MV, but not with mortality.

INTRODUCTION. Micronutrients included in nutritional support have a central role in maintaining human physiological functions.
OBJECTIVES. The aim of this study is to identify serum micronutrient levels in patients who are transferred from intensive care unit (ICU) towards and their relation with 90-day mortality rate and re-admission to ICU.
METHODS. This study was conducted prospectively in Erciyes University Medical ICU. Patients who are above 18 years old and stayed in the ICU more than 48 hours and then transferred to a ward were included into the study. Blood samples for micronutrient levels were taken at the time of transfer.
RESULTS. We enrolled 100 patients. Mean APACHE II score was 15.4± 7.8. Median SOFA score at the time of discharge from ICU was 3 (range 0-7). The route for nutrition was oral in 41%, enteral in 21%, oral plus parenteral in 18%, parenteral in 17% and oral plus enteral in 3% of the patients in last day ICU. Low levels rate of thiamine (98%), vitamin B6 (98%), vitamin B12 (11%), copper (21%), zinc (90%), selenium (36%), chromium (98%), and cobalt (35%) were identified in the patients. Low levels of vitamin B6 was an independent risk factor for 90 day mortality and re-admission to the ICU in multivariate analysis (OR: 0.283, CI 95%:0.099-0.812, p: 0.019 OR: 0.231 CI 95%:0.071-0.745, p: 0.014 respectively). Median duration of ICU stay was 5.5(range 3-32) days. Re-admission rate to the ICU within 90 days was 24% and 90 day mortality rate was 29%.
CONCLUSION. Vitamin B1, B6, zinc and chromium levels were very low rate in these patients. Low levels of vitamin B6 identified as an independent risk factor for 90 day mortality rate and re-admission to the ICU.

Putting the PN in PatieNts: Why are ICU patients missing their parenteral nutrition?

R. Carrington[1], J. Zekavica[2], M. Bossy[1]
[1]Intensive care, Royal Surrey County Hospital, Guildford, United Kingdom; [2]Nutrition and dietetics in critical care, Royal Surrey County Hospital, Guildford, United Kingdom
Correspondence: R. Carrington
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000260

INTRODUCTION. Critically ill patients are at risk of significant nutritional deficits leading to delayed recovery. Nutritional support has been shown to improve outcomes in these patients(1).
Parenteral nutrition (PN), intravenously administered artificial nutrition, is often thought to ensure secure delivery of the prescribed nutrition. However, studies have demonstrated a discrepancy between the amount of PN prescribed and the amount received(2). In critical illness, immobilisation and increased inflammatory and stress responses mean that the catabolic response to an energy deficit is much greater than in a healthy fasting person. If these patients miss periods of their PN prescription, they will accumulate a caloric deficit which can rapidly reach levels that contribute to skeletal muscle loss and impaired healing. This in turn leads to prolonged intensive care unit (ICU) admission and rehabilitation(3).
OBJECTIVES.

1. To identify whether the amount of PN received by patients in the Royal Surrey County Hospital (RSCH) ICU matches the number of hours prescribed
2. To identify the causal factor in instances where 100% of prescribed PN is not received
3. To identity the type of vascular access by which the PN is being administered, and whether this affects the amount of PN received

METHODS. Retrospective data collection from all patients admitted to RSCH ICU who received PN during the 6 month period between 1st April and 31st September 2018. The number of hours of PN prescribed each day and the number of hours received each day were recorded. The reason for any deficit was documented where 100% administration was not achieved. First bag prescription start time was taken as 19.00 (2 hours after routine delivery from pharmacy).
RESULTS. 637 patients were admitted to RSCH ICU during this time. 77 (12%) were prescribed PN. 9395 hours of PN were

prescribed: 9129 hours (97%) were received, and 266 hours (3%) were missed. The reasons for the missed hours are displayed in Figure 1. PN was administered via central venous catheter (CVC) in 62 patients (81%), peripherally inserted central catheter (PICC) in 10 patients (13%) and peripheral cannula (PC) in 5 patients (6%). The mean percentage delivery for each access type is shown in Table 1.

CONCLUSION. The largest reason for PN deficit was the first PN bag being started late. This was due to a combination of factors: pharmacy delivery time, time required for PN to return to room temperature, and nursing handover time. This has identified an area for an improvement initiative that we are implementing to enable the PN bags to be started earlier. Also, our results suggest PN may be received more consistently via a PICC vs other types of access, but a larger study with greater statistical power would be required to investigate this further.

Enhance caloric intake from enteral nutrition rather than parenteral nutrition decreased hospital mortality in ARDS patients with the prone position

CY. Wang[1], CH. Wang[2]

[1]Department of critical care medicine, Taichung Veterans General Hospital, Taichung, Taiwan; [2]Graduate institute of education, National Changhua University of Education Jin De Campus, Changhua City, Taiwan

Correspondence: C.Y. Wang

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000274

INTRODUCTION. Feeding intolerance is common in acute respiratory distress syndrome (ARDS) patients with the prone position. Prone position has been proved to improve mortality in ARDS patients but only a few small sample sized studies talked about the feeding adequacy in these patients. In literatures, there was no outcome difference regarding feeding amount of ARDS patients. However, the optimal amount of caloric intake for ARDS patients with the prone position is still unknown. We hypothesize adequate caloric delivery influence clinical outcomes in ARDS patients received prone position therapy.

OBJECTIVES. We retrospectively collected patients' data from Sep 2015 to Nov 2018 in medical intensive care units at a tertiary medical center. The inclusion criteria were age older than 20 years old, ARDS defined by Berlin criteria, ICU stay more than 48 hours, received mechanical ventilation and prone position therapy. Exclusion criteria were any non per os order by physicians.

METHODS. Data collection including demographic data, BMI, calories of parenteral nutrition(PN), enteral nutrition(EN) and hospital mortality, etc. Nutritional risk was evaluated by modified NUTRIC score. In addition to descriptive analysis and univarate analysis, we used cox regression modeling to control multiple variables and to calculate 95% confidence intervals.

RESULTS. There were 110 patients enrolled in the study. The hospital mortality rate was 58% (64/110). The average age was 61±17 years old and APACHE II score was 31±7. The first 7 days average EN calories intake were higher and PN calories intake were lower in survival group. (EN: 672 kcal/day vs 547 kcal/day, p=0.03; PN: 103 kcal/day vs 179 kcal/day, p=0.001). The cutoff value of average EN calories intake higher than 564 kcal/day and PN calories intake less than 79 kcal/day have the lowest mortality by receiver operating characteristic(ROC) curve analysis. (p<0.05) In cox regression model, EN calories supplement more than 564 kcal/day (HR:1.85, 95% CI:1.10-3.13, p<0.021) and PN calories supplement less than 79 kcal/day (HR:0.52, 95% CI:0.29-0.94, p<0.03) decreased hospital mortality after adjust potential confounders.

CONCLUSION. In order to decrease hospital mortality in ARDS patients with the prone position, enhance caloric intake from enteral nutrition rather than parenteral nutrition should be considered.

Impact of vitamin deficiency on septic patient's outcome

L. Bielsa Berrocal, V. Philibert, Y. Rovira, S. Triginer, A. Herraiz, E. Valls, D. Salat, L. Bordejé, P. Marcos, T. Tomasa
Intensive Care Unit, Hospital Germans Trias i Pujol, Badalona, Spain
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000304

INTRODUCTION. Our aim was to analyze plasma levels of vitamins A, B6, C, E and zinc in septic patients, and to determine their impact on patient's outcome.
METHODS. Observational and prospective study. Inclusion criteria: patients admitted to the ICU due to sepsis (January-July 2018). We analysed vitamins A, B6, C, E and zinc serum levels at ICU admission. Statistical analysis: quantitative variables in means (SD) and medians (min-max) according to their normality and qualitative variables in proportions and 95% CI. Bivariate analysis: Kruskal-Wallis and khi-square.
RESULTS. 37 patients (67.6% male). Median age was 62 years old (45-69). SOFA at admission was 7 (3.5) and the APACHE II was 27 (9.9). They remained in the ICU for 8 days (1-53) and 22 days (1-132) in the hospital. 5.4% of patients were re-admitted to the ICU. ICU mortality was 10.8% (95% CI 3.9-26.5) and in-hospital mortality was 21.6% (95% CI 10.8-38.5).
CONCLUSION. 1) We found a remarkable deficit of all micronutrients analysed, except for Vit E.
2) Septic patients with zinc deficiency had longer stays and higher mortality in the ICU.
3) Vitamin deficiency was not associated with an increased mortality, AKI or stay, in this small sample of septic patients.

INTRODUCTION. Augmented Renal Clearance (ARC) is currently defined as a Glomerular Flitration Rate (GFR) greater than 130 mL/min/1.73 m2. ARC is a phenomenon that can lead to therapeutic failure in critically ill patients. Inadequate antibiotic dose may worsen sepsis outcome and may increase resistance generation.
OBJECTIVES. To analyze clinical characteristics of patients with ARC in comparison to patients with normal GFR (nonARC, 90-130 mL/min/1.73 m2) admitted to the Intensive Care Unit (ICU), and to compare the prescribed dose of antibiotics (AB), antiepileptic (AE) and diuretic (DI) drugs between both groups.
METHODS. We set up 3 points of prevalence according to different seasonal times, November'17, February'18 and May'18, with a follow-up period of 2 months, measuring the GFR (mGFR) in 4-hour urine collection twice a week. Inclusion criteria: Adult patients admitted to the ICU with a bladder catheterization. Exclusion criteria: renal replacement therapy, bladder washings and absence of bladder catheterization. Variables: patients' features and type and dose of prescribed drugs were recorded. Statistical analysis: Pearson Chi-square Test.

RESULTS. 18 hospitals were enrolled and 561 patients were included (61% male) with a median age of 65.5 years old. At ICU admission 10.7% had already ARC. Overall, we found 31% ARC and 22% non-ARC patients. Prescribed drugs: 67% AB, 17.5% AE and 41% DI. Mechanical ventilation was required in 64% and vasopressors agents in 51%. Median SOFA was 6. ICU mortality was 14% and in-hospital mortality was 18%. Median ICU and hospital length of stay (LOS) were 15 and 29 days, respectively. Median mGFR was 176 in ARC and 106 mL/min/1.73 m2 in nonARC. ARC remained with GFR>130 for several days during their LOS. Bivariate analysis: ARC patients were younger, 56.5 vs. 66 years (P<0.001). ICU mortality was 7% in ARC vs. 14.5% in nonARC group (P=0.003) and in-hospital mortality was 10% vs. 16% (P=0.001), respectively. ICU-LOS was 13 vs. 19 days (P=0.028) and hospital-LOS was 27 vs. 33 days (P=0.022), respectively. Regarding the use of drugs, neither the number nor the delivered dose were different between ARC and nonARC groups.
CONCLUSION. 1) Up to 30% of ICU patients had ARC during ICU-LOS and 10% had already ARC when admitted.

2) ARC patients received the same dosage of AB, AE and DI, as non-ARC patients.
3) ARC patients were youger, had shorter LOS and lower mortality than nonARC patients.

Uptake of dietary amino acids into arterial blood during continuous enteral feeding in critically ill patients and healthy subjects

F. Liebau[1], E. Király[1], D. Olsson[2], O. Rooyackers[3]
[1]Perioperative Medicine and Intensive Care, Karolinska University Hospital Huddinge, Stockholm, Sweden; [2]Unit for Medical Statistics at Department of Learning, Informatics, Management and Ethics, Karolinska Institute, Stockholm, Sweden; [3]Anaesthesia and Intensive Care at Department of Clinical Science, Intervention and Technology, Karolinska Institutet, Stockholm, Sweden

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000361

INTRODUCTION. Sufficient nutrition is necessary to counteract catabolism in critical illness. Protein anabolism requires amino acid availability, one source of which is uptake from enteral nutrition. Continuous enteral feeding is a common but unphysiological approach, and little is known about its effects on amino acid uptake.
OBJECTIVES. To characterize the time course of dietary amino acid uptake into arterial plasma during continuous enteral feeding in ICU patients and healthy subjects, using a stable-isotope-labeled phenylalanine tracer as a specific indicator for dietary amino acids.
METHODS. 10 healthy subjects and 10 ICU patients were studied. Patients had invasive ventilatory support and ongoing enteral feeding at >80% of energy expenditure. All subjects were given enteral nutrition by constant continuous infusion via nasogastric tube or jejunostomy at ≥80% (patients) or 100% (healthy subjects) of energy expenditure.
After a 12-hr equilibration period, a primed constant infusion of 13C-phenylalanine (13C-Phe) was added to the enteral infusion. Arterial blood samples were then drawn every 30 minutes for 12 hrs. For isotopic analysis, plasma samples were analyzed by gas chromatography-mass spectrometry. Plasma aminograms were determined by HPLC.
RESULTS. Data are expressed as median (range). Patients' age was 64 (44-74) yrs, SAPS 3 score was 60.5 (57-85), primary diagnoses were n=3 surgical, n=3 neurological and n=4 medical, and studies were performed on ICU day 20 (5-41).
Plasma essential amino acid (EAA) concentration and 13C-Phe enrichment were largely stable in aggregate, but highly variable individually. Variability over time of 13C-Phe, expressed as coefficient of variation, was 25.8% (17.5-30.3) in healthy subjects and 20.9% (12.3-46.3) in ICU patients. Variability of EAA was 10.5% (8.5-18.3) and 10.2% (7.8-13.2), respectively. Significant co-variation between timepoint-to-timepoint changes of 13C-Phe enrichment and EAA was found in 9/10 healthy subjects and 3/10 ICU patients.
CONCLUSION. Plasma EAA concentrations and 13C-Phe enrichment reached a tentative steady state on average, but there was large intra-individual variability during 12 hours of feeding. The magnitude of variation was similar to that seen in the only previous study reporting comparable data (de Betue et al., 2017). Variation in aminoacidemia may be physiologically relevant for anabolic stimulation (Bouillanne et al., 2013), but its significance in critical illness remains unclear.
The physiological mechanism underlying the variability in aminoacidemia during continuous enteral feeding is unknown. Co-variation of changes in EAA concentrations and 13C-Phe enrichment (here a specific indicator of dietary uptake) suggests a common underlying process such as gastric emptying, but this appears less obvious in the ICU patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000423

INTRODUCTION. Acute liver failure (ALF) accounts for up to 6% of liver related deaths and is characterized by the acute onset of jaundice, coagulopathy and hepatic encephalopathy in patients without pre-existing hepatic disease. Due to multiple immunological dysfunctions, systemic inflammation and bacterial translocation, patients with ALF are at higher risk of developing sepsis. Bacterial infections have been documented in 60-80% of these patients, most commonly pneumonia (50%), urinary tract infections (22%) and spontaneous bacteraemia (15%) and are a significant cause of mortality.
METHODS. We assessed a retrospective cohort of 39 patients with ALF admitted to an Intensive Care Unit (ICU) of a Liver Transplant Center from January 2015 until December 2018. Baseline characteristics, admission respiratory, kidney and hemodynamic support and culture samples were recorded.
RESULTS. The median age (IQR) was 40 (28-52) years; 17 were male (43,6%). Paracetamol etiology was found in 7 patients (17,9%). On ICU admission, median SAPS II score was 49 (30,8-59,5) with an associated risk of mortality of 43,85% (12-71). Paracetamol overdose or others drugs-related toxicity and unknown causes represented more than 50% of the ALF aetiologies. Invasive mechanical ventilation, vasopressor support and renal replacement therapy on admission were required in 10 (27%), 11 (28%) and 8 (21%), respectively. Admission hepatic encephalopathy higher than grade 3 was present in 10 patients (27%) with a median arterial ammonia of 248 (161-316) mg/dL. Median INR, total bilirubin and lactate levels were 2,7 (2,3-3,4), 9,90 (2,52-19,57) mg/dL and 2,6 (1,6-6,0) mmol/L, respectively. King's College (KCC) and Clichy's Criterias were fulfilled by 14 (36%) and 5 (13%) patients. Eleven patients (28%) received liver transplant. Infection was present in 17 patients (43,6%), predominantly gram-negative organisms. Median day of infection diagnostic was 3 (2-5). Time-to-event analysis (Cox regression) with Kaplan-Meyer curves adapted for the presence of infection revealed a worst 30 day survival for those patients who developed infection (67% *versus*50%, p = 0,08). Hospital mortality rate was 36%.
CONCLUSION. In a Portuguese cohort, bacterial infection was present in almost half of the patients admitted with ALF. As the diagnosis is difficult, a high level of clinical suspicion, particularly in patients who have signs of SIRS, refractory hypotension or unexplained progression to higher grades of hepatic encephalopathy may indicate the presence of infection. So, careful assessment for ongoing infections should be performed and treated in order to optimize patient's outcome.

INTRODUCTION. Previous research has demonstrated that high Glycemic Variability (GV) is associated with increased mortality among critically ill patients, but its relationship with other factors such as nosocomial infections has not yet been determined.
METHODS. Observational prospective study of critically ill patients receiving artificial nutrition (first 48h). Our exclusive criteria were diabetic ketoacidosis or those not receiving artificial nutrition. The study was carried out at a Medical ICU, from November 2015 until December 2018.
Admission data: demographic data, clinical characteristics,APACHEII,-SOFA, nutritional parameters during the 1st&7th day, GV during first 7 days, infectious complications, days of mechanical ventilation (MV), ICU length of stay (LOS) and mortality.
We calculated GV as VC= SD/Mx100. We performed univariate statistical analysis considering the significance p<0.05, T-test [LP1] for quantitative independent group variables and χ2 for qualitative variables. We also employed linear regression for continuous dependent variables and binary logistic regression for dichotomous dependent variables.
RESULTS. The sample consists of 118 patients, 67% men with a mean age of 62±14 years, BMI 29±16, diabetics (DM) 24%, dyslipidemics 38%, Arterial hypertension 54% and 38% were smokers. From the sample 86% presented stress hyperglycemia, 70% needed vasoactive drugs, 90.5% enteral nutrition (EN) and 20.5% parenteral nutrition (PN). Mechanical ventilation median 8 days (min 0 – max60), ICU length of stay (LOS) 10 days (min 2 - max 69), hospital LOS 23 days (min 3 – max 123) and 32% of mortality.
APACHE II 19.9±8 and SOFA on admission 8±3.
35% suffered nosocomial infections: ventilated-associated pneumonia (VAP) 26%, tracheobronchitis48%, bacteraemia 1% and catheter related bacteraemia 4.7%, urinary tract infection7%, ventriculitis 2.3% and others 4.7%). We divided our sample into quartiles depending on the level of GV: (1) 8.7–15.49; (2) 15.5–20.37; (3) 20.38–26.48; (4) 26.49–43.9. Mean GV 21.8±8. Table 1 with Results:
CONCLUSION.

- Patients with higher illness severity scores (APACHE II) show higher GV.
- We observe higher GV among patients receiving PN.
- It is observed that patients with DM present higher rates of GV.

Table 1 (abstract 000453). See text for description

INTRODUCTION. Recent guidelines suggest using the Nutritional Risk in Critically ill (NUTRIC) score to detect those patients who would benefit the most of nutritional therapy by giving them a category of high (≥5 points) or low (<5 points) nutritional risk.(1) To obtain this score the clinician most calculate the Acute Physiology and Chronic Health Evaluation score II (APACHE II) and the Sepsis Related Organ Failure Assessment score (SOFA) to assign them specific points, finally adding the obtained points from the age, number of comorbidities and days of hospitalization before admission to the intensive care unit (ICU).(2,3)To our consideration some collinearity is given by using two severity scores in the same calculation, implying a high probability of obtaining similar results if either one of the severity scores is omitted from the original model.(4)
OBJECTIVES. To assess the practical validity of using the NUTRIC score omitting the calculation of either the APACHE II or SOFA scores given their collinearity.
METHODS. Retrospective observational study including every adult patient with nutritional assessment (NUTRIC score included) admitted to the ICU excluding obstetric patients, in a period of 9 months. The population was divided in two groups: 1) generation sample (first 50% of the population) 2) validation sample (second 50% of the population). In the generation group two receiver operating characteristics (ROC) curves were generated: 1) NUTRIC score without APACHE II points (model 1) 2) NUTRIC score without SOFA score points (model 2) and a cutoff point for every curve was assigned to detect high nutritional risk according to the original NUTRIC score. In the validation group, 2x2 tables were generated and sensitivity (Se), specificity (Sp), positive predictive value (PPV) and negative predicted value (NPV) were calculated for the detection of high nutritional risk according to the original NUTRIC score using the new cutoff points previously generated (model 1 and model 2). Comparisons between groups were also made.
RESULTS. 174 and 173 patients were included in the generation and validation groups respectively. The generation model had higher

SOFA score and higher proportion of patients with 2 or more comorbidities: 3 (2-6) vs 2 (1-4) points (p<0.05) and 70.7% vs 52.6% (p< 0.05). In the generation phase the model 1 obtained an area under the curve (ABC) of 0.929 (p<0.05, confidence interval at 95% (CI95%) 0.892-0.966) selecting a cutoff value of ≥3 points (Se 93.7% and Sp 78.4%), the model 2 obtained an ABC of 0.973 (p<0.05, CI9%% 0.953-0.993) selecting a cutoff value of ≥4 points (Se 98.4% and Sp 77.5%). In the validation phase, the model 1 obtained a Se 98.18%, Sp 81.36%, PPV 71.05% and NPV 98.97% and the model 2 obtained a Se 100%, Sp 70.34%, PPV 61.11% and NPV 100%.
CONCLUSION. Using the NUTRIC score omitting the calculation of either SOFA or APACHE II scores could be a practical way to detect patients with low nutritional risk; this does not imply that both obtained scores detect high nutritional risk according to the original NUTRIC in a reliable manner. This could translate to a faster assessment that excludes only low risk patients leaving more time for complete calculation for patients with a high score.

INTRODUCTION. Glycosylated hemoglobin (HbA1c), is currently the best existing parameter of metabolic control in patients with diabetes mellitus. Cardiovascular disease is the main cause of morbidity and mortality in this group of patients
OBJECTIVES. To determinate the association between Hb1Ac and multivessel coronary disease in patient with ST elevated myocardial infarction (STEMI)
METHODS. We included 246 patients with STEMI admitted in our center. Patients were classified according to their Hb1Ac levels at admission (elevated ≥6.5%; normal < 6.5%).Multivessel coronary disease was assessed by invasive coronary angiography. The association between Hb1Ac and multivessel coronary disease was evaluated using logistic regression.
RESULTS. 36% of patients had elevated Hb1Ac. 91,6% of patients with known diabetes had Hb1Ac ≥6.5%. Those with Hb1Ac ≥ 6.5% had increased odds of having multivessel disease as compared with those with hb1Ac < 6.5% (OR: 2.15, 95% CI: 1.01, 4.55, p 0.02)
CONCLUSION. Hb1Ac was positively associated with multivessel coronary disease in patients with STEMI

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000574

INTRODUCTION. According to several studies one third (31-38%) of ICU patients have a low plasma glutamine concentration (<420 μmol/L) at admission. Moreover, this hypoglutaminemia has been shown to be associated with an increased morbidity and mortality. It has been hypothesized that an increased utilization of glutamine cannot be met by the production in spite of an increased net efflux from skeletal muscle to plasma resulting in the low concentrations. However, glutamine kinetics in ICU patients has only been studied scarcely and data to relate endogenous production to glutamine levels has not been available. It remains important to understand the mechanisms behind the low glutamine concentrations in order to determine when, how and if glutamine should be supplemented in the ICU setting.
OBJECTIVES. To elucidate the relationship between plasma glutamine levels and the endogenous glutamine production in ICU patients.
METHODS. Glutamine kinetics was studied in ICU patients. A tracer bolus injection method employing 13C-glutamine was used. It has been validated to give minimum effect on plasma glutamine and insulin concentrations. After bolus injection 18 plasma samples during 90 minutes were taken and the area under the curve for C13-glutamine calculated.
RESULTS. There was a weak statistical correlation between de novo endogenous production of glutamine (not emanating directly from protein breakdown) and plasma glutamine concentration in stabilized ICU patients (n=11), with R2 = 0,308. Two sided P=0,0764 with a power of 41%, which was not statistically significant.
CONCLUSION. Plasma concentration of glutamine did not directly reflect the de novo production of glutamine, although a statistical correlation was at hand. A larger cohort of ICU patients representing a wider concentration interval will be needed to fully explore the relationship.

Nutritional Goals and time of Pressure Injury development in Intensive Care Unit patients

F. Wenzel, I. Whitaker
Escola paulista de enfermagem, UNIFESP, São Paulo, Brazil
Correspondence: F. Wenzel
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000609

INTRODUCTION. Pressure Injuries (PI) are characterized by damage to the skin and either soft tissues resulting from compression of the bony prominence against a hard surface or related to the use of some medical device. The time until PI development can be related to several factors present in critically ill patients, such as their clinical condition and nutritional status.
Nutritional support is essential for wound healing and it is important for patients at risk of developing PI. Inadequate nutrition and negative energy balance combined with catabolic stress and inflammation caused by severe disease increase the risk of complications, including PI and bad wound healing.
OBJECTIVES. To compare the time until PI development between groups of critical care patients with enteral nutrition which achieved or not the nutritional goals and verify the risks associated with the PI development over time.
METHODS. Observational, prospective study conducted at the Intensive Care Center of a University Hospital in São Paulo (Brazil) during 2016. Patients admitted to ICU without PI and which received exclusive Enteral Nutrition were selected for the sample. The PI development and time to PI were considered dependent variables. The statistical analysis was performed by applying the survival curve with the Kaplan-Meier method and the Cox regression model was used to verify the risks associated with the PI development over time, observing a significance level of < 5% and confidence interval of 95%.
RESULTS. The sample included 181 patients, 56.4% was male, the mean age was 55.1 years, the mainly location before ICU admission was operating room (84.0%) and the main reason for hospitalization was the neurological causes (44.8%). The mean of ICU stay was 17.5 days and mortality was 30.4%. The mean of the SAPS3 was 59.9 and the SOFA was 6.7. The incidence of PI was 31.5%. The survival curves did not show difference in time until PI development, considering the patients who achieved caloric goal (p = 0.532) or protein goal (p = 0.694) or caloric + protein goals (p = 0.648). The nutritional goals were not observed among the risks associated with the time of PI development. The identified risks were location before ICU admission (emergency department - HR = 2.05 and ward - HR = 2.40), length of ICU stay (HR = 1.01), Braden scores (HR = 0.63) and EVARUCI scores (HR = 1.33).
CONCLUSION. The time of PI development in critically ill patients with enteral nutrition was not influenced by the achievement of nutritional goals. Moreover, the nutritional goals were not included among the risks associated with the development of PI over time. Considering that the occurrence of PI is multifactorial, the early identification of patients at risk is essential for preventive measures to be adopted immediately.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000690

INTRODUCTION. The correlation between elevated plasma lactate concentration and increased mortality has been firmly established in ICU patients. Although plasma lactate is heavily relied upon for clinical decision making, the kinetics of lactate in critically ill patients is still sparsely studied.
OBJECTIVES. To establish and validate a feasible method to study whole body lactate kinetics in critically ill patients.
METHODS. Healthy volunteers (n=6) received a bolus dose of 13C-labeled lactate (20µmol/kg body weight) and 43 blood samples were drawn over two hours to determine the decay in labeled lactate. Data was analyzed using non-compartmental modeling, calculating rates of appearance (Ra) as an estimate of lactate production, and clearance of lactate. The area under the curve (AUC) was calculated using a linear-up log-down trapezoidal approach with extrapolation beyond 120 minutes using the terminal slope to obtain the whole AUC. After evaluation, the same protocol was used in an unselected group of critically ill patients (n=10).
RESULTS. Ra for healthy volunteers and ICU patients were 12.8 ± 3.9 vs 22.7 ± 11.2 µmol/kg/min (p=0.026) and clearance 1.57 ± 0.39 vs 1.10 ± 0.43 L/min (p=0.047), respectively. ICU patients (n=6) with normal lactate concentrations showed kinetics very similar to healthy volunteers (Ra 14.5 (range 12.3 – 18.3) µmol/kg/min, lactate clearance 1.3 (range 0.77 – 1.77) L/min). For ICU patients, there were statistically significant correlations between plasma concentration and Ra of lactate, r2=0.85 (p<0.0002) and lactate clearance, r2= 0.50 (p=0.023). Simulations showed that reducing the number of samples from 43 to 14 gave the same results. Our protocol yielded results on lactate kinetics very similar to previously published data.

CONCLUSION. This minimally invasive protocol using an isotopically labeled bolus dose of lactate was accurate and feasible for studying lactate kinetics in critically ill ICU patients.

INTRODUCTION. Subglottic secretion drainage (SSD) is one of the recommended strategies to prevent ventilator-associated pneumonia (VAP) with a high level of evidence, especially regarding early-onset pneumonia. Despite published recommendations, SSD has not been widely implemented in ICUs and remains underused. Several factors could account for this: the uncertainty regarding the safety of SSD, the lack of evidence of benefits in other clinical outcomes than prevention of VAP and the extra cost of the specific endotracheal tubes (ETs) allowing SSD compared with usual endotracheal tube. To assess the medico-economic impact of SSD implementation, we performed a multicenter, pragmatic trial: the DEMETER study (ClinicalTrials.gov, identifier NCT02515617).
OBJECTIVES. To assess the cost utility of the implementation of SSD in a VAP prevention bundle with a time horizon of one year.
METHODS. It is a multicenter cluster-randomized and cross-over study. 26 ICUs were involved (25 located in France and 1 in Belgium). Two periods of 10 months (period A and B) were planned to include patients. During the period A, the ICU's team used endotracheal tubes not allowing SSD and during the period B, specific endotracheal tubes allowing SSD were used. A 2-month interval between the two periods was planned to allow the switch of ET type. Both inclusion periods correspond to the same seasonal period. Moreover, during period B, specific endotracheal tubes allowing SSD were also available in the emergency rooms and the prehospital emergency units of hospitals located around the ICUs involved in the study. Regardless of the period (A or B), mechanically ventilated patients benefited from the regular VAP prevention policy which included: measures to reduce the duration on mechanical ventilation (MV) as well as the exposure to the medical device (sedation algorithm, standardization procedure for weaning of the MV) and specific measures to prevent VAP (maintaining a cuff pressure between 25 and 30 cm H20, semi-recumbent positioning of the patient, oropharyngeal care). During period B, in addition, SSD was performed intermittently every 2 hours by using a 10ml syringe.
The economic evaluation was performed in accordance with the CHEERS statement. The prospective analysis was conducted from the health care perspective to determine the cost per quality-adjusted life year (QALY) gained with the SSD implementation over a 1-year period. Hospital resources were considered as well as the cost of the medical device and the cost of the nursing time required to perform the SSD procedure during the mechanical ventilation period. Health-related quality of life was assessed using the EuroQol 5 Dimensions at baseline, 3-month, 6-month, and 1-year. The utility values are based on French tariffs for the corresponding EQ5D scores.
RESULTS. During the periods of inclusion (nov 2015-aug 2016 and nov 2016-aug 2017), 2600 patients were included. Patient's follow-up ended in August 2018. The analyses are currently ongoing. The results will be available and presented in exclusivity at LIVES 2019.
CONCLUSION. The DEMETER study is the first prospective and large study assessing the medico-economic impact on the SSD use and could afford new insights on this VAP prevention strategy.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000478

INTRODUCTION. Morbidity and mortality of *Staphylococcus aureus* (SA) pneumonia remain high in mechanically ventilated, intensive care unit (MV ICU) patients despite best clinical care. Suvratoxumab (MEDI4893) is an extended half-life, SA alpha toxin-neutralizing

human monoclonal antibody that may reduce incidence of SA pneumonia in MV ICU patients.
OBJECTIVES. To assess efficacy, safety, pharmacokinetics (PK), population PK modeling, anti-drug antibody (ADA) responses, and healthcare resource utilization (HRU) benefits of suvratoxumab in MV ICU patients at risk for SA pneumonia.
METHODS. MV ICU subjects with PCR-confirmed SA colonization of the lower respiratory tract were randomized to either a single intravenous infusion of 5000 mg suvratoxumab (n=96) or placebo (n=100) and followed for 190 days post dose. Efficacy endpoints included relative risk reduction (RRR) vs. placebo within 30 days post dose in: incidence of SA pneumonia (primary endpoint; tested at 2-sided α=0.1), all-cause pneumonia, and all-cause pneumonia or death (all events determined by the Endpoint Adjudication Committee). HRUs, PK and ADA were measured through 90 days post dose and TEAEs and serious TEAEs through 190 days.
RESULTS. Baseline characteristics were similar between groups. Suvratoxumab provided 31.9% RRR in incidence of SA pneumonia vs. placebo (17.7% vs 26%; *P*=0.166), 30% RRR (*P*=0.146) in incidence of all-cause pneumonia, and 23% RRR (*P*=0.164) in incidence of all-cause pneumonia or death. Suvratoxumab provided 38% RRR in incidence of SA pneumonia vs. placebo, when adjusted for duration of initial MV. Suvratoxumab provided greater prevention of SA pneumonia in subjects aged ≤65 years (RRR=47.4%), low SA colonization status (RRR=66.7%), and 5 VAP bundles (RRR=46.3%) vs. placebo. Suvratoxumab was associated with 3.0 fewer hospital days and 2.4 fewer ICU days for every 90 days patient follow-up and greater HRU reductions in subjects aged ≤65 years (10.1 fewer hospital days, 3.7 fewer ICU days). Over 190 days, proportions of subjects with TEAEs and serious TEAEs were similar between suvratoxumab and placebo groups: ≥1 TEAE (90.6% vs 90.0%); ≥1 serious and/or ≥grade 3 severity TEAE (55.2% vs 52.0%). Mean serum suvratoxumab concentrations were above the target serum level of 211 μg/mL through day 31 (mean±SD concentration 296±131 μg/mL). Population PK model estimated mean±SD terminal half-life of 72±33 days. No ADA responses were detected post-dose through 90 days.
CONCLUSION. A single intravenous dose of suvratoxumab produced a trend toward reduced incidence of SA pneumonia and reduced HRU in high-risk ICU patients compared with placebo. Greater clinical benefits were observed in certain subgroups. Suvratoxumab demonstrated acceptable safety, PK and ADA profiles. These results support continued development of suvratoxumab in MV ICU patients.

INTRODUCTION. To test the interest to monitor the expression of human monocytic Human Leukocyte Antigen-D Related (mHLA-DR) to predict mortality and the occurrence of secondary infections in a large single-center Intensive Care Unit (ICU) population.
METHODS. We conducted a single-center, prospective, observational study in a tertiary hospital in France. All patients admitted from 2013 to 2015 in our ICU were included from our data base if mHLA-DR measurement was performed within the first days (< 4 days) post admission. Collected parameters were severity score on admission (SAPS II and SOFA), sex, age, mortality and secondary infections. The association between mHLA-DR expression and outcomes was tested by the adjusted Fine and Gray sub-distribution competing risk models.
RESULTS. 1053 patients having an early mHLA-DR measurement were included and analyzed: 151 patients (14.3%) died in the ICU; based on the logarithm cutoff value for median (mHLA-DR < 9.2 log), a low mHLA-DR was independently associated with mortality (HR = 0.71 [0.57; 0.95], p < 0.01). The performance of mHLA-DR to predict ICU death was inferior to the gravity scores (mHLA-DR: AUC = 0.65 [0.6-0.69], SAPS II: 0.8 [0.77-0.84], p<0.01) and the performance of the combination of mHLA-DR and SAPS II was similar to SAPS II alone (p = 0.81). Two successive mHLA-DR measurements within the first week were performed in 543 patients allowing to test the 2nd value or the slope between the 2 values (positive, negative or stable). Among these patients, 223 patients
(37.7%) had a secondary infection with a sustained lower mHLA-DR than other patients (mHLA-DR = 9.0 log vs. 9.3 log, p < 0.01). The second mHLA-DR value was independently associated with the development of subsequent secondary infection, regardless of initial severity (HR = 0.66 [0.51 ; 0.84], p = 0.001). A negative slope between mHLA-DR 1 and 2 was strongly associated with later occurrence of a secondary infection (HR = 0.62 [0.43; 0.89], p = 0.009).
CONCLUSION. mHLA-DR expression is early decreased in ICU patients and is associated with ICU
mortality (the higher mortality, the lower mHLA-DR), but with no superiority to severity scores even in combination. For a given severity, persisting low mHLA-DR expression or decreasing mHLA-DR, are independent and reliable predictors of secondary infection occurrence. This large survey may then be used to design clinical trials testing immune-stimulating drugs based on mHLA-DR monitoring to prevent or cure secondary infections.

INTRODUCTION. Patients suspected of ventilator-associated lower respiratory tract infections (VA-LRTI) receive antimicrobial therapy, even though subsequent bronchoalveolar lavage (BAL) microbiological culture results deem this inappropriate in almost half of these patients [1]. Breath contains volatile organic compounds (VOCs) produced by host response or pathogen metabolism, which may be used to diagnose pneumonia [2].
OBJECTIVES. We hypothesize that exhaled breath analysis can discriminate between patients suspected of VA-LRTI with positive respiratory tract cultures (confirmed) and those who are negative (nonconfirmed).
METHODS. This was an international European multicentre observational cohort study in intubated and ventilated ICU patients who received antibiotics for suspected VA-LRTI [3]. Gas-chromatography mass-spectrometry was used to detect and identify VOCs. A (mini-)BAL semi-quantitative culture ≥10^4 CFU was considered positive for VA-LRTI. Comparison of all measured VOCs was performed using the "limma" function in *R statistics*, resulting in *p*-values adjusted for multiple testing and fold changes.
RESULTS. 108 patients were included consecutively: 52 (48%) had positive cultures, most commonly *Pseudomonas aeruginosa* (N=9, 17%) and *Staphylococcus aureus* (N=15, 29%). The clinical pulmonary infection score (CPIS) was higher in confirmed VA-LRTI patients ($p<0.001$). 5 out of 184
VOCs were significantly higher in culture positive patients ($p<0.05$). The AUROCC for the 5 VOCs combined was 0.82 and increased to 0.85 when added to the CPIS.
CONCLUSION. Exhaled breath analysis can be used to discriminate between patients with suspected VA-LRTI who had confirmed positive or negative respiratory cultures, with the potential to reduce delays in diagnosis. Further analysis will result in the identification of the molecules and further validation of the diagnostic algorithm.

INTRODUCTION. The effectiveness of decontamination strategies for eradication of antibiotic resistant GNB in ICU patients remains controversial and has not been studied extensively in ICUs with higher levels of antibiotic resistance than Dutch ICUs (1). We, therefore, aimed to determine the efficacy SDD, SOD and CHX 1-2% mouthwash on eradication of 3GCR-E and CR-GNB from the rectum and respiratory tract and on acquisition of these bacteria during ICU stay.
OBJECTIVES. To quantify the effects of selective digestive tract decontamination (SDD), selective oropharyngeal decontamination (SOD) and 1-2% chlorhexidine (CHX) mouthwash on eradication and acquisition of carriage of third generation cephalosporin resistant Enterobacteriaceae (3GCR-E) and carbapenem resistant Gram-negative bacteria (CR-GNB) in ICU patients.
METHODS. Nested cohorts study within a European cluster-randomized cross-over trial (2) with 8,665 patients. Eradication and acquisition of 3GCR-E and CR-GNB were investigated separately in the rectum and respiratory tract for the three interventions and compared to standard care (SC) using Cox-regression competing events analyses.
RESULTS. Adjusted cause specific hazard ratios (CSHR) for eradication of rectal carriage for SDD were 1.76 (95%CI 1.31-2.36) for 3GCR-E and

3.17 (95% CI 1.60-6.29) for CR-GNB, compared to SC. Adjusted CSHR for eradication of 3GCR-E from the respiratory tract were, compared to SC, 1.47 (95% CI 0.98-2.20) for SDD and 1.38 (95%CI 0.92-2.06) for SOD. Adjusted CSHRs for acquisition of rectal carriage during SDD (compared to SC) were 0.51 (95%CI 0.40-0.64) for 3GCR-E and of 0.56 (95%CI 0.40-0.78) for CR-GNB. Adjusted CSHRs for acquiring respiratory tract carriage with 3GCR-E, compared to SC, were 0.55 (95%CI 0.42-0.71) for SOD and 0.38 (95%CI 0.28-0.50) for SDD, and 0.60 (95%CI 0.44-0.81) and 0.46 (95%CI 0.33 - 0.64) for CR-GNB during SOD and SDD, respectively.

CONCLUSION. SDD was associated with faster eradication of 3GCR-E and CR-GNB from the rectum than SC, and SDD and SOD were associated with less acquisition of both 3GCR-E and CR-GNB, compared to SC, in the respiratory tract.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000023

INTRODUCTION. The timing of initiation of Norepinephrine (NEP) in septic shock is still controversial. The most recent guidelines recommend its use after failed trial of fluid resuscitation.

OBJECTIVES. We intended in this study to evaluate the impact of early starting NEP simultaneously with fluids resuscitation immediately after diagnosis of septic shock.

METHODS. We recruited 101 patients admitted to the emergency department (ED) with septic shock who were randomized in 1:1 ratio to early initiation of NEP simultaneously with IV fluids (early NEP group) and starting NEP after failed fluid resuscitation trial (late NEP group). Our primary outcome was the in-hospital survival while the secondary outcomes were the time of restoring a mean arterial pressure (MAP) of 65 mmHg, lactate clearance and volume of fluids used in resuscitation.

RESULTS. There was no statistically significant difference between the two groups regarding the baseline hemodynamics, laboratory findings and the source of infection. NEP infusion started after 25 (20-30) minutes from ED admission in the early group compared to 120 (120-180) minutes in the late group [P=0.000,95% CI:-100(-140,-100)]. Target MAP of 65mmHg was achieved faster in the early group [2 (1-3.5)hours Vs 3(2-4.75)hours in the late group][P=0.003,95% CI:-1(-1,0)]. The post resuscitation serum lactate was decreased by 37.8(24-49)% and 22.2(3.3-38)% in the early and late groups respectively [P=0.005,95% CI:13.96(4,24.2)]. Serum lactate less than 2mmol/L after resuscitation was achieved in 29 patients (50.9%) in the early group compared to 12 (27.3%) in the late group (P=0.017). Patients with early NEP were resuscitated by significantly lower volume of fluids [25(18.8-28.7)mL/Kg Vs 32.5(24.4-34.6)mL/Kg in the early&late groups] [P=0.000,95% CI:-5.5(-8.2,-2.8)]. The early group had survival rate of 71.9 % (41 patients) compared to 45.5 % (20 patients) in the late group (P = 0.007). The survivors had NEP started after 30(20-120) minutes Vs 120(30-165) minutes in the non-survivors [P= 0.013,95%CI:-15(-60,0)].

CONCLUSION. We concluded that the early use of Norepinephrine at the onset of diagnosis of septic shock might cause earlier restoration of blood pressure, better lactate clearance and consequently better in-hospital survival

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000660

INTRODUCTION. Mortality of old intensive Patients (80 years and older; VIP) admitted to an intensive care unit (ICU) for various admission diagnoses is high, and morbidity causes significant health costs and leads to human suffering in survivors. Risk stratification is crucial in VIPs to optimize outcomes. Established clinical scores including Sequential Organ Failure Assessment score (SOFA) score are available to stratify risk. However, these scores were not developed for VIPs. Assessing frailty through clinical assessment might help, and the Clinical Frailty Scale (CFS) has been successfully used to risk-stratify elderly patients. However, patients after elective intervention versus after acute intervention might differ significantly with regards to characteristics, outcomes, and predictors of outcomes.

OBJECTIVES. We evaluated differences between patients admitted to intensive care unit (ICU) after elective versus acute intervention in a multinational cohort of very old patients (≥80 years; VIP; NCT03134807). Differences in baseline characteristics, outcomes, and predictors of mortality, with particular emphasis on frailty, were assessed.

METHODS. In total, 5063 VIPs were included in this analysis, 922 were admitted after elective surgery or intervention, 4141 acutely, with 402 after acute surgery. Differences were assessed using Mann-Whitney-U test and Wilcoxon test in continuous variables. Associations with mortality were determined by univariate and multivariable logistic regression. We further matched 296 patients admitted after acute intervention for age, sex, frailty and SOFA score to 296 patients admitted after elective intervention.

RESULTS. Compared to patients admitted after acute intervention, patients admitted after elective intervention suffered less often from frailty as defined as CFS (28% vs. 46%; p<0.001), evidenced lower SOFA scores (4±5 vs. 7±7; p<0.001). Presence of frailty (CFS >4) was associated with significantly increased mortality both in elective surgery patients (7% vs 12%; p=0.01), in acute surgery (7% vs 12%; p= 0.02).

In the matched cohorts both ICU mortality (mean difference 5.07%; 9.37-0.76%; p=0.03) and 30-day mortality (mean difference 10.12%; 3.58-16.65%; p<0.01) was lower in patients admitted after elective internvention.

CONCLUSION. In VIPs, patients admitted after acute intervention were compared to patients admitted after elective intervention clinically less sick, younger and less frail as assessed by CFS. Admission after acute intervention was an independent predictor of mortality even after correction for relevant confounders and in a matched-pair analysis. Frailty assessed by CFS was useful for risk prediction and

independently associated with 30-day mortality both in VIPs admitted after elective and acute intervention.

INTRODUCTION. In patients resuscitated from cardiac arrest (CA) with acute myocardial infarction (AMI), the optimal level of inotropic and vasopressor support is unknown. While overuse may increase myocardial oxygen consumption and induce arrhythmias, diastolic hypotension may reduce coronary perfusion and increase infarct size.
OBJECTIVES. We aimed to determine the optimal mean arterial pressure (MAP) in AMI patients after CA.
METHODS. We performed a pooled analysis of post-CA AMI patients randomised in the Neuroprotect (NCT02541591) [1] and COMACARE (NCT02698917) [2] trials to either MAP 65 mmHg or MAP 80/85-100 mmHg targets for the first 36 hours after ICU admission. AMI was defined as either ST-elevations in the electrocardiogram at hospital admission or identification of a clear culprit lesion (a coronary lesion with at least 70% stenosis and the presence of characteristics of plaque disruption) in coronary angiography performed within 2 hours after admission.
RESULTS. Out of 235 patients originally included in both trials, 120 patients qualified for our definition of AMI. Of these, 58 patients were randomised to the MAP 80/85-100 mmHg group and 62 patients to the MAP 65 mmHg group. Patients assigned to the higher MAP target received significantly higher doses of norepinephrine (p=0.004) and dobutamine (p=0.01) and had significantly higher MAP (p<0.001) and diastolic blood pressure (p<0.001) levels. Myocardial infarct size, as quantified by the area under the 72-hour high-sensitivity troponin T (HS-TnT) curve, was significantly lower in patients assigned to the higher MAP target (median [IQR] 73 µg [24-136 µg] vs 109 µg [46-317 µg], p=0.01). Additional inotropic and vasopressor support did not increase the risk of a new CA (8/58 [14%] in the higher MAP group vs. 9/61 [15%] in the lower MAP group, OR 0.92 [95% CI 0.33-2.58], p=0.88) or new onset atrial fibrillation (4/58 [7%] in the higher MAP group vs. 4/61 [7%] in the lower MAP group, OR 1.05 [95% CI 0.25-4.43], p=0.94).
CONCLUSION. Myocardial infarct size, as measured with HS-TnT, remained significantly smaller in the group targeting MAP between 80/85-100mmHg. The risk for re-arrest or arrhythmia was not increased.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000436

INTRODUCTION. Hyperbaric oxygen (HBO2) therapy is thought to be essential for preventing delayed neurological sequelae (DNS) in patients with carbon monoxide (CO) poisoning, based on the results of a randomized controlled trial (RCT) reported by Weaver et al. [1]. However, the beneficial effect of HBO2 therapy remains debated because subsequent reports have been contradictory [2].
OBJECTIVES. To identify the appropriate clinical treatment for acute CO poisoning in Japan and to clarify the effects of HBO2 therapy in the acute phase of CO poisoning.
METHODS. We conducted a multicenter, prospective, observational study of acute CO poisoning in Japan, the "COP-J Study". Patients with acute CO poisoning were enrolled in the study. The treatments, including HBO2 therapy, were performed according with each institution's policy, and about 30% of institutions did not administer HBO2 therapy [3]. The primary endpoint was the onset of DNS within 2 months of CO exposure. DNS was defined as cognitive dysfunction after an improvement in disturbed consciousness.
RESULTS. A total of 311 patients were registered form 57 institutions and 255 were analyzed in this study. Of these patients, 171 received HBO2 therapy (HBO2 group) and 84 did not (NBO2 group). The mean ages were 49 ± 19 and 54 ± 22 years in the HBO2 and NBO2 groups, respectively (P = 0.063). There were no significant differences between the HBO2 and NBO2 groups in the estimated exposure time (202 ± 256 and 181 ± 376 min, respectively; P = 0.605) or the time between exposure and arrival at hospital (279 ± 350 and 240 ± 382 min, respectively, P = 0.420). The carboxyl hemoglobin concentration upon arrival did not differ between the HBO2 and NBO2 groups (18.6 ± 11.3% and 18.9 ± 10.1%, respectively; P = 0.831). HBO2 therapy was performed once, twice, or three times within the first 24 h in 11.1%, 30.4%, and 56.1% of patients in the HBO2 group, respectively. The treatment pressure in the first HBO2 session was 2.8

ATA (51.6% of patients), 2.0 ATA (37.3%), 2.5 ATA (8.5%), or other (2.6%). The number of patients with DNS was 13 (7.6%) in the HBO2 group and three (3.6%) in the NBO2 group (P = 0.212).
CONCLUSION. In this study, the total incidence of DNS was 6.3% in patients with acute CO poisoning, which is lower than in previous reports [1,2]. The superiority of HBO2 therapy over NBO2 therapy in terms of the prevention of DNS was not demonstrated. Furthernore, the clinical practice of HBO2 therapy varied in this study. Further investigations are required to clarify the effect of HBO2 therapy on the prevention of DNS after CO poisoning.

SAPS 3 performance in cancer patients admitted to an intensive care unit in Brazil

L. Taniguchi, E. Siqueira
Intensive care unit, Hospital Sirio Libanes, Sao Paulo, Brazil
Correspondence: L. Taniguchi
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001246

INTRODUCTION. Simplified Acute Physiology Score 3 (SAPS 3) is the most accurate prognostic model for Brazil [1]. However, recent evaluation of its performance in solid cancer patients has not been performed in our country.
OBJECTIVES. To compare the performance of SAPS 3 in patients with and without solid cancer admitted to the intensive care unit (ICU) of a comprehensive oncological hospital in Brazil.
METHODS. Retrospective cohort analysis of Epimed® administrative database of adult patients (>18 years) first admission to the intensive care unit (ICU) of Hospital Sírio Libanês (São Paulo, Brazil) from 2012 to 2016. Patients were categorized according to the presence of solid cancer at ICU admission. Hematological patients were excluded. We evaluated discrimination using the area under the receiver operating characteristic curve (AUROC) and the agreement between observed and expected mortality rates (calibration) using the calibration belt.
RESULTS. We studied 7,390 patients (age 66.1±18.4 years, 54.1% male, SAPS 3 score 41.6± 13.3, 41.6% had cancer, 12.1% died during hospitalization). Cancer patients were younger compared to non-cancer patients (62.6±16.5 years vs 68.7±19.3 years respectively, p<0.001), had lower SAPS 3 (40.9±14 vs 42.1±12.8 respectively, p<0.001), were admitted more frequently after elective surgery (60.6% vs 24.9%, p<0.001), but had higher hospital mortality (14.1% vs 10.6%, p<0.001). SAPS 3 discrimination was better for cancer patients (AUROC = 0.85) than for non-cancer patients (AUROC = 0.79) (p < 0.001). After we applied the calibration belt, we observed that in cancer patients the SAPS 3 match the average observed rates for the confidence level of 95%. In non-cancer patients the SAPS 3 overestimated mortality in those with low-middle risk (figure).
CONCLUSION. SAPS 3 has different performances in cancer and non-cancer patients in our single-center cohort.

INTRODUCTION. Organophosphates (OP) have been used commonly worldwide as insecticides. OP intoxication is almost a public health problem in some countries leading to significant morbidity and mortality. Diagnosis and treatment have many difficulties.
OBJECTIVES. The aim of the study was to determine the effect of standard therapy plus plasmapheresis or only standard therapy on serum pseudo-cholinesterase (PChE) and plasma erythrocyte cholinesterase (AChE) levels in critically ill patients with OP poisoning.
METHODS. This study was performed prospectively Medical Intensive Care Unit (ICU). OP poisoning patients above 18 years of age were included into the study. Patients were randomized into two groups; Study (intervention) group received standard therapy plus plasmapheresis and control (standard) group received only standard therapy.
RESULTS. We enrolled 40 patients (Intervention group: 21, standard group: 19 patients). The mean age was 37±16 years. The mean APACHE II score was 9±5. The most common cause OP intoxication compound was dichlorvos. Serum PChE values of all patients included in the study were 482.5 (177-3883) u / L at baseline, 3723 (227-7078) u / L after plasmapheresis, 1529 (174-7078) u / L on 2nd day, 1956 (181-10918) u / L on 3rd day, 2206 (161-9993) u / L on 4th day, 1258 (178-8464) u / L on 5th day, and 2590 (121-10597.00) u / L at the time of ICU discharge.Serum PChE values of the intervention group and standard group patients were compared in the first 5 days and the last day of intensive care hospitalization. No statistically significant difference was found between the two groups (p> 0.05).
Plasma erythrocyte AChE values of all patients included in the study were 1.9050 (0.12- 4.85) u / mL on admission, 2.5300 (0.06-4.47) u / mL after plasmapheresis, 2.18 (0.01-4.27) u / mL on day 2, 2.13 (0.07-4.30) u / mL on day 3, 2.015 (0.07-4.24) u / mL on day 4, 2.18 (0.12-4.19) u / mL on day 5 and 1.90 (0.09-4.37) u / mL at the time of ICU discharge. Plasma erythrocyte AChE values of the intervention group and standard group patients were compared on the daily from the admission to intensive care of patients, the first 5 days and the last day of the intensive care unit stay. No statistically significant difference was found between the two groups (p > 0.05).
CONCLUSION. As a result of this study, in addition to standard treatment, plasmapheresis therapy did not show any additional effect on serum PChE and erythrocyte AChE levels compared to standard treatment.

INTRODUCTION. Prognostication after cardiac arrest (CA) remains challenging (Rossetti 2016). Traditionally, most emphasis was put on prediction of poor outcome, but with the introduction of advanced supportive therapies, such as extra corporeal membrane oxygenation, it becomes increasingly important to identify patients with a chance of good neurological recovery. For prediction of good outcome after CA, presence of EEG reactivity (EEG-R) has been proposed as a valuable marker, but the relation to EEG background pattern has not been described. The EEG background pattern itself between 12 and 24h post CA is already a reliable predictor of good outcome (Hofmeijer 2015).
OBJECTIVES. In this study, the primary aim was to define the *additional* prognostic value of EEG-R per EEG background pattern. Secondary aims were to explore whether time after CA and sedative medication influence the prognostic value of EEG-R and to determine optimal methods of EEG-R testing
METHODS. A post-hoc analysis of a prospective cohort study. EEG-R was tested twice a day, using a strict protocol of different stimuli. Good outcome was defined as a Cerebral Performance Category of 1-2 within 6 months. The additional value of EEG-R per EEG background pattern was evaluated using the diagnostic odds ratio (DOR). Furthermore, prognostic value (sensitivity and specificity) of EEG-R was investigated in relation to the timing after CA, sedative medication, different stimuli, and repeated testing.
RESULTS. Patients with a discontinuous (< 50% suppression) normal voltage (> 20 uV) background pattern and reactivity were eight times more likely to have a good outcome (DOR 8.0, 95%-CI 1-64, p-value < 0.05). In continuous normal voltage background patterns, DOR of EEG-R was 3.4 (95%-CI 1-12, p-value 0.06). (108 patients, with and without sedation, 12-24h after CA). EEG-R was not observed in other background patterns. In 119 patients with (dis)continuous normal voltage background, prognostic value was highest in sedated patients (sensitivity 81.3% (95%-CI 70.7-89.4), specificity 59.5% (95%-CI 42.1-75.2)), irrespective of time after CA. EEG-R induced by handclapping and sternal rubbing, especially when combined, had highest prognostic value for good outcome. Repeated EEG-R testing increased sensitivity from 65% to 89% with a decrease in specificity from 71% to 46%.
CONCLUSION. These results suggest that EEG-R testing is of additional value for prediction of good outcome in patients with a (dis)continuous normal voltage background pattern. The best stimuli were clapping and sternal rubbing.

INTRODUCTION. Normal saline is routinely used in post-cardiac arrest patients based on the belief that management in sepsis setting will be similarly beneficial in cardiac arrest setting. (1) However, there is no established evidence supporting such management in cardiac arrest patients. It is known that brain edema is a key prognostic factor in post-cardiac arrest syndrome (PCAS). (2-5, 7, 8) A clinical study have shown that hypertonic saline use during cardiopulmonary resuscitation might be beneficial to patients with PCAS. (6) But hypertonic fluid could be harmful to those patients after vasogenic edema occurs. (2, 3)
OBJECTIVES. Therefore, the aim of this study is to evaluate the correlation between electrolyte or osmolality alteration and neurologic outcome of PCAS patients, thereby providing evidence to the optimal fluid management in post-cardiac arrest care.
METHODS. This is a retrospective observational study based on a multicenter prospective cohort registry of out-of-hospital cardiac arrest patients from December 2013 to February 2018. 653 patients were finally included in this study, excluding those with poor baseline cerebral performance category (CPC 3, 4, or 5) and those with incomplete data. Outcome variables were defined as 28-day CPC, 6-month CPC, and 1-year CPC after discharge. We conducted univariate and multivariate logistic regression analyses to find the relationship between serum electrolyte at 0, 24 hours after return of spontaneous circulation (ROSC), calculated osmolality, and main outcomes. The final multivariate logistic regression model included osmolality at 24 hours after ROSC, total low-flow time, total no-flow time, witnessed arrest, bystander CPR, ROSC achieved by prehospital emergency medical service, sequential organ failure assessment (SOFA) score, initial ECG rhythm after ROSC and initial light reflex after ROSC.
RESULTS. 139 [35%] patients had good CPC (1 or 2) at 28-day after discharge otherwise, 514 [65%] patients had poor CPC (3, 4 or 5). Multivariate logistic regression analysis showed that high serum osmolality at 24 hours after ROSC had significant correlation with poor neurologic outcome at 28-day after discharge (adjusted odds ratio [OR], 1.04; 95% confidence intervals [CI], 1.00-1.07; p value, 0.03). Similar results were obtained in the multivariate model using neurologic outcome at 6 months and 1 year.
CONCLUSION. High serum osmolality at 24 hours after ROSC was independently associated with short-term and long-term poor neurologic outcome in patients with post-cardiac arrest syndrome.

INTRODUCTION. Neurological prognostication after cardiac arrest (CA) is a complex challenge for physicians and requires a multimodal approach. Neurological Pupil Index (NPI) derived from automated pupillometry and assessed at 24 hours after the event has been recently shown a high sensitivity to predict unfavorable neurological outcome after CA. Nevertheless, it is unclear how NPI correlates with other predictors of brain injury in this setting.
OBJECTIVES. To assess the correlation of NPI with electroencephalography (EEG) background, serum neuron-specific enolase (NSE) and cortical response to somatosensory evoked potentials (SSEPs).
METHODS. Post hoc analysis of an international multicenter (n=10; n=456 patients) prognostic study on automated pupillometry in comatose post-CA patients. The primary study endpoint was the accuracy of NPI in predicting 3-month unfavorable neurological outcome, defined as Cerebral Performance Category (CPC) of 3-5 (severe disability, unresponsive wakefulness or death). The worst finding over the first 3 days after CA among EEG background (dichotomized as "continuous" vs. "'discontinuous"), cortical response to SSEPs (dichotomized as bilaterally absent (N20ABS) vs. "other"), and the highest NSE value were evaluated.
RESULTS. On a total of 456 included patients, 398 (87%) had at least one other prognostic tool assessed along with NPI. NPI were inversely correlated with NSE levels (n=228; r2=0.20; p<0.001). Furthermore, NSE values were significantly higher in patients with NPI ≤ 2 vs. those with NPI $\geq$ 4.0 (152 [113-415] vs. 31 [18-46] mg/L, respectively; p<0.001). NPI values were significantly lower in patients with a discontinuous EEG (n=137) (n=234 - 3.5 [1.4-4.0] vs. 3.8 [3.3-4.2]; p< 0.001) and in patients with N20ABS (n=63) than others (n=123 - 3.3 [1.0-3.7] vs. 3.6 [3.3-4.1]; p<0.001).
CONCLUSION. Our data corroborate previous findings indicating that impaired NPI is strongly associated with severe hypoxic-ischemic brain injury and unfavorable neurological outcome after CA.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001288

INTRODUCTION. Following severe hemorrhage, proper response to circulatory dysfunction is essential to immediate survival and long-term outcome. Standard approach is replacement fluids and vasopressors to treat hypotension. No firm consensus as to type and volume of fluids exists, and hemodilution, clotting disruption, and increased bleeding may result. Vasopressor use also varies clinically with some reports documenting increased risk of mortality with use. The CirQPOD (Zoll Medical) is an active intrathoracic pressure regulation (a-IPR) device placed between the endotracheal tube and a ventilation source that generates negative intrathoracic pressure. It has previously been shown to improve systemic and cerebral hemodynamics.
OBJECTIVES. This study tested the hypothesis that post-hemorrhage a-IPR use would enhance hemodynamics while reducing vasopressor demand.
METHODS. 14 female farm pigs (38.8±1.3 kg) were bled 40% of circulating blood volume from a central arterial line over 15 minutes, followed by a 15-minute stabilization period. Animals were randomized to one of two treatment groups, one with continuous a-IPR therapy, the other without a-IPR therapy. In the a-IPR group, the CirQPOD was started at -5cmH2O and stepwise increased to a maintenance level of -10cmH2O over a 30-minute ramp-up period. At this point, a target mean arterial pressure (MAP) of 65 mmHg was achieved in both groups through controlled infusion of norepinephrine (NE), delivered to effect as needed, to the end of the 3-hour study. After 2 hours of device use, the device was ramped down for 30 minutes. Vasopressor demand and hemodynamic data were recorded throughout the study. All animals were anesthetized with 1.0% isofluorane throughout the study and ventilated with an FiO2 of 0.4 and a tidal volume of 8 ml/kg. Student's t-tests were used for statistical comparisons. Data are expressed as mean±SD.
RESULTS. MAP during the study was matched between groups (64.8±6.3 for NE only vs 67.8±4.5 mmHg for a-IPR) through careful dosing of vasopressor. Mean NE demand during the post-bleed period was significantly lower in the a-IPR group compared to NE only group (0.17±0.1 vs 0.04±0.04 ug/kg/min, p<0.05). Pulse pressure variation (PPV) was matched between groups at the end of the post-bleed stabilization period (27.6±6.0 vs 27.7±6.8%) but was lower in the a-IPR group throughout the study, significantly during a-IPR ramp-up from 0-30 minutes (30.1±8.2 vs 17.5±4.9%, p<0.001) and from 60-120 minutes (25.7±2.7 vs 17.7±2.7%, p<0.001). Cerebral perfusion pressure was also consistently higher in the a-IPR group throughout the study (49.4±6.8 vs 54.3±6.3mmHg), significantly during ramp-up from 0-30 minutes (41.2±4.9 vs 50.3±7.2mmHg, p<0.01).
CONCLUSION. Addition of a-IPR therapy post-hemorrhage reduced vasopressor demand, decreased PPV, and improved cerebral hemodynamics. Use of a-IPR has the potential to treat the

hypotension and systemic circulatory disturbances associated with hemorrhagic shock without risk of hemodilution associated with fluid therapy and the complications associated with high dose norepinephrine use.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000118

INTRODUCTION. Microcirculatory impairment has an impact on outcome in a variety of disease states (1,2)and has been proposed as a therapeutic target, however interventional studies are hindered by time consuming off-line analysis. We recently described a 5-point ordinal scoring system, the Point Of carEassessment of the Microcirculation (POEM) score (3).
OBJECTIVES. To determine the reliability of the Point of Care Microcirculation tool when used at the bedside in critically ill patients.
METHODS. All adult intubated patients in critical care were eligible for inclusion using an emergency waiver of consent. A minimum of four standardized video clips were taken by an investigator using an incident dark field (IDF) video-microscope (Cytocam, Braedius Medical, NL) who subsequently calculated a POEM score and recorded the time taken. On completion a second investigator blinded to the results of the first repeated this process. At a later stage (>1 month) investigators re-scored their own and their co-investigators images. Scores were analysed using Cohens weighted Kappa score to provide intra-user, inter-user and test-retest reliability. A kappa statistic was also calculated for test-retest reliability for POEM score 1-3 against POEM score 4-5 which is the threshold for fluid administration used in an ongoing interventional study (Clinical Trials.gov ID).
RESULTS. 80 patients were recruited at 3 sites in 3 countries. Poor quality video assessments (cumulative Massey score >10) were excluded resulting in a loss of 15 (18%) of patients. Weighted kappa analysis showed good agreement ((0.4-0.6 moderate, 0.61-0.8 substantial, 0.8-1 excellent(4)) in all circumstances: Intra-User 0.801 (95% CI 0.722-0.879), Inter-User 0.792(95% CI 0.719-0.861) and Test-Retest reliability 0.701(95% CI 0.589-0.812). Mean time to record videos and assess POEM scores was 7 min. (std deviation 03:38) Reliability of the POEM score used to potentially dichotomise a decision on fluid administration (POEM 1-3 vs 4,5) was also good, 0.726 (95% CI 0.637-0.815)
CONCLUSION. Point-of-care assessment of the microcirculation using IDF video microscopy and POEM scoring appears to be both quick and have good agreement within and between investigators in a real life clinical setting. This opens the possibility of using the score as a resuscitation end-point.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000829

INTRODUCTION. Atrial fibrillation (AF) is the most common arrythmia in intensive care unit (ICU). Previous studies reported that development of new-onset AF was associated with poor outcomes. However, information of the clinical course after the AF onset is scarce. Moreover, it is unknown whether sustained new-onset AF contributes to poor outcomes.
OBJECTIVES. The primary goal is to describe the clinical course after the AF onset. The secondary goal is to determine whether the duration of sustained AF contributes to poor outcome.
METHODS. In a prospective cohort study in 32 ICUs in Japan, we enrolled patients who were admitted to the participating ICUs from 2017 to 2018 and developed new-onset AF during their ICU stay. Following information was collected for the study patients: demographics, medical history, physiological variables before and after the AF onset, AF duration, treatment for AF, mortality and the incidence of ischemic stroke.
RESULTS. Of the 14,348 adult ICU patients excluding post-cardiac surgery, 423 patients (2.9%) with new onset AF were enrolled. Medication for rhythm control, rate control and anticoagulation were administered to 30%, 61% and 41% of all the new-onset AF patients, respectively, during the initial episode of AF. Eighty-six patients (20%) died within 30 days after the AF onset and 19 patients (4.5%) experienced in-hospital ischemic stroke. Patients with initial sustained AF longer than 48 hours (long AF) had increased 30-day mortality compared with those with initial sustained AF shorter than 48 hours (15% vs. 28%, p=0.009). Long AF was independently associated with 30-day mortality (adjusted OR 2.13; 95% CI, 1.17–3.85; p = 0.013) in multivariable regression analysis. Repeating multivariable regression analysis for different duration of the new on-set AF (6,12, 18, 24, 30, 36, 42, 48, 72, 96, 120, 144, 168 hours), the longer initial AF duration had greater odds ratios for 30-day mortality. Restricted cubic spline function analysis also showed a dose-response relationship between the initial AF duration and 30-day mortality.
CONCLUSION. The duration of initial sustained AF was associated with 30-day mortality by various statistical analyses. Our findings provide strong rationale for further research assessing treatment for new-onset AF in critically ill patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000851

INTRODUCTION. Early detection of occult hemorrhage is important for timely treatment. Yet, availability of sensing modalities may be minimal and knowledge of physiologic baseline often unknown.

OBJECTIVES. To characterize the differences in bleeding detection performance of predictive models trained with vital sign waveform data derived from different monitoring modalities, referenced with a personalized baseline or not.
METHODS. Waveform data (250Hz) from non-invasive monitoring (NIM), arterial (ART), central venous (CVC) and pulmonary artery (PAC) catheters were collected from 38 Yorkshire pigs during a stable 30-min period followed by bleeding at 20 mL/min until a mean arterial pressure of 30 mmHg. Waveform data as well as beat-to-beat (B2B) parameters were used to compute various secondary measures (features) in a rolling window including basic statistics, entropy, power spectral density, and others. Time series data were either referenced to a personalized stable baseline or not (universal baseline). Classification models were trained to discriminate between stable and bleeding states, and the Activity Monitoring Operating Characteristic (AMOC) curve was used to characterize the tradeoff between time to detection (TTD) of bleeding and false positive rate (FPR). Nested models were trained to evaluate an increasingly rich sensor data, starting from NIM, then adding ART, CVC, PAC, ART+CVC and ART+PAC. The models were optimized and validated in a leave-one-out cross validation framework.
RESULTS. Increasing availability of sensing modalities and referencing to personalized baseline decreased TTD of bleeding at lower FPR (Fig. 1). Without personalized baseline all but NIM and CVC based models detected bleed <10min at a 1 in 100 FPR. With a personalized baseline, all models detect bleed <10min. PAC and ART+-PAC detect bleed at 3min.
CONCLUSION. The ability of hemodynamic monitoring to detect bleed onset improves with the availability of a personalized baseline and more intense monitoring. Excellent bleed detection can be achieved by all invasive monitors if referenced to personalized baselines whereas NIM performs less well.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000880

INTRODUCTION. Atrial fibrillation is the most common arrhythmia following cardiac surgery, with a percentage up to 50%. It is associated with increased morbidity and mortality. Dexmedetomidine is a highly selective a2 adrenergic agonist. Considering its sympathoinhibitory action, dexmedetomidine could be associated with postoperative atrial fibrillation reduction.
OBJECTIVES. The present study aims to evaluate the effect of postoperative dexmedetomidine on the incidence of atrial fibrillation after cardiac surgery.
METHODS. This prospective, randomized, controlled, clinical trial was carried out at the cardiac surgery unit of a tertiary care university hospital. 164 patients, undergoing on pump cardiac surgery, were evaluated. 21 were excluded due to preoperative atrial fibrillation or flutter. 143 patients were enrolled. After arrival to the cardiac intensive care unit, patients were randomized in two groups, dexmedetomidine and control group. Patients in dexmedetomidine group received an infusion of dexmedetomidine (0.7 mg/kg/h) during the early postoperative period. Primary endpoint was the incidence of postoperative atrial fibrillation within the first three postoperative days.
RESULTS. There were no differences in atrial fibrillation risk factors between the two groups. There were also no differences in postoperative parameters except for catecholamine (44.4% vs 55.6%, p=0.675) and beta-blocker use (45.2% vs 54.8%, p=0.967) in dexmedetomidine and non-dexmedetomidine group respectively. Our results revealed that the dexmedetomidine group was associated with an increased incidence of atrial fibrillation compared to the control. Prevalence of atrial fibrillation in dexmedetomidine group (n=70) was 26 patients (37.1%) and non-dexmedetomidine group (n=73) 16 patients (21.9%). Subgroup analysis indicated that postoperative augmented diuresis and low potassium levels (p<0.001) have an increased influence on occurrence of atrial fibrillation in patients after cardiac surgery.
CONCLUSION. In our study, dexmedetomidine use after cardiac surgery was associated with a higher incidence of postoperative atrial fibrillation. More studies are required to determine the dexmedetomidine effect on atrial fibrillation after cardiac surgery.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000895

INTRODUCTION. Invasive blood pressure monitoring is recommended in patients admitted to the ICU with shock (1). Non-invasive blood pressure measurements are still often used but may be inaccurate and may lead to erroneous interpretations in patients receiving vasoactive medication in the ICU (2).
OBJECTIVES. We aimed to compare mean arterial pressure (MAP) measurements of blood pressure using non-invasive (MAPNi) and invasive (MAPi) methods in a prospective cohort of critically ill patients, both with and without vasoactive medication.
METHODS. This was a post-hoc analysis of the SICS-I study, in which all patients acutely admitted to the ICU were included (3). The invasive blood pressure, preferably via an indwelling radial artery catheter, and non-invasive blood pressure, via oscillometric brachial cuff, was measured within 24 hours of ICU admission. Linear correlation was assessed by Pearson coefficient and precision and agreement by Bland-Altman analysis. A difference of more than 10 mmHg was considered clinically inaccurate.
RESULTS. Of 1075 patients, 734 patients (68%) had both invasive and non-invasive blood pressure measurements. Overall, MAPi and MAPNi had strong positive linear correlation (r2=0.62, $p < 0.001$) (fig 1) which decreased if patients were on vasoactive medication (n = 361, r2= 0.44, $p < 0.001$) compared to patients not on vasoactive medication (n = 373, r2=0.64, $p < 0.001$). Bias was 1.0 (95% CI 0.2–1.7) and limits of agreement of all measurements ranged from -19.5 (95% CI -20.8– -18.2) to 21.4 (95%CI 20.1–22.7) (fig 2). The difference in MAP was acceptable in 69.1% of all measurements, in 71.7% of

measurements in patients on vasopressors, and in 66.5% of measurements in patients not on vasopressors (table 1).
CONCLUSION. Non-invasive blood pressure measurements are not a reliable alternative for invasive intra-arterial measurements in critically ill patients, regardless of receiving vasoactive medication.

INTRODUCTION. The amino acid citrulline (CIT) is of interest in various conditions characterized by reduced enterocyte mass or function. Decreased CIT levels have been shown in critical illness, sepsis and shock [1,2]. Less is known about daily dynamics of CIT values in a general ICU patient population.
OBJECTIVES. To describe CIT in ICU patients during their first week of stay.
METHODS. Consecutive adult patients in 5 ICUs were studied. Plasma was collected immediately after ICU admission and thereafter daily. Following storage at -80 °C, samples were deproteinized and analyzed for CIT, using liquid chromatography-mass spectrometry. Citrulline values between groups were compared using the SPSS Median Test for each day separately.
RESULTS. CIT was measured in 224 patients (median age 66.5, range 29-94 years; median APACHE II 18, IQR 11-23; 28 d mortality 10.3%). Median CIT value of all measurements was 19.5 (IQR 14.0-25.8) µmol/L, being higher in 28 d survivors [19.9 (IQR 14.7-26.2)] *vs* nonsurvivors [14.4 (IQR 11.8-22.9) µmol/L] independent of renal dysfunction. Median of the lowest individual CIT value was 16.3 (12.6-22.4) µmol/L and occurred on day 2 in 54% of patients. CIT values were lower in patients with sepsis (significant on days 1-4), emergency surgical patients (days 1 and 2) and those admitted after gastrointestinal surgery (days 1-4). CIT dynamics in all patients, in comparison of 28 d survivors *vs* nonsurvivors and related to early enteral/oral nutrition (within 48 h) and its success are shown in Figures 1-4.
CONCLUSION. A majority of patients had normal CIT values on admission to ICU, rapidly decreasing to marginally low normal levels that persisted over the first week. Lowest individual CIT value was reached most often on day 2. CIT increased with early and successful enteral or oral nutrition.

INTRODUCTION. Fish oil-containing lipid emulsions (LE), a type of LE that is high in omega-3 (ω-3) polyunsaturated fatty acids, have been used over the last years as a long-chain triglycerides source. Evidence on their effectiveness is accumulating, but an updated pooled estimate is currently unavailable.
OBJECTIVES. We conducted a meta-analysis (MA), asking if ω-3 fatty-acid enriched PN improves clinical and laboratory outcomes in patients treated in the ICU, and in a subgroup of critically ill patients, with trial sequential analysis (TSA) to evaluate the robustness of the estimates. TSA assesses the conclusiveness of pooled estimates by controlling for type I errors given heterogeneity of the single estimates.
METHODS. We searched public databases using keywords "PN", "fish oil", "lipids", "emulsion" and "randomised controlled trial (RCT)". Publications eligible for inclusion were RCTs in hospitalised adults given PN (at least 70% of total caloric delivery) in ICU settings. Intervention and control groups received ω-3 fatty acids-containing and ω-3 fatty acids-free LEs, respectively, both as part of PN. A critically ill (defined by the condition or by ICU stay >48h) subgroup analysis was pre-specified.
RESULTS. 24 publications were included. Pooled treatment effect estimates for clinical outcomes are shown in Table 1.
TSA results indicate statistically significant robustness of the estimates on the effect of ω-3-enriched PN regimen compared to standard PN regimen in reducing infection rate, hospital stay and ICU stay, which can be considered conclusive.
CONCLUSION. This is the largest MA conducted on this topic. Both in the ICU and in the critically ill subgroup, risk of infection and lengths of stay in hospital and ICU were impressively reduced with ω-3 fatty-acid enriched PN; all effects were confirmed to be conclusive by TSA.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000663

INTRODUCTION. The importance of early recognition, prevention and treatment of refeeding syndrome (RFS) has been emphasized recently[1]. Based on the criteria for high risk of developing RFS proposed by National Institute for Health and Clinical Excellence (NICE)[2], the new risk classification criteria of developing RFS were recently published in 2018[3]. However, the frequency of each applied risk category and the association between the risks and patients' prognosis have not yet been investigated.

OBJECTIVES. To describe the frequency of new classification groups of RFS risk in the ICU and to investigate the association between the risks and 30-day mortality.

METHODS. This cohort study was conducted at the tertiary-care university hospital located in the metropolitan area in Japan from December 2016 to December 2018. We included critically ill patients who were aged 18 or older, who were admitted to the ICU via the emergency department, and who stayed in the ICU for 24 hours or longer. The registered nurses and dieticians well-trained for this study prospectively evaluated the NICE RFS risk factors at ICU admission for all critically ill patients. NICE RFS risk factors consisted of weight loss, the period of little or no nutritional intake prior to the ICU admission, and so on. The main exposure was risk classification of RFS: no risk, low risk, high risk or very high risk, according to the recently published criteria. The primary outcome was in-hospital mortality censored at 30 day after ICU admission. We performed multivariable analysis using Cox proportional hazard regression. As the primary analysis, the hazard ratio was adjusted for age, sex and presence of chronic illness.

RESULTS. We analyzed 541 patients who met the eligibility criteria. The prevalence of four risk classification groups of RFS was 24.4% in no risk, 24.6% in low risk, 48.8% in high risk, and 2.2% in very high risk. The 30-day mortality was 5.3%, 6.8%, 14.8%, and 25.0%, respectively (log-rank trend test: p<0.001) (Figure). In multivariable Cox regression, adjusted hazard ratios as compared to no risk group were 1.19 (95% CI 0.44–3.23) with low risk group, 2.94 (95% CI 1.31–6.60) with high risk group, 5.33 (95% CI 1.35–21.1) with very high-risk group.

CONCLUSION. More than half the critically ill patients had high or very high risk of developing RFS according to the recently published risk classification criteria. Patients with high or very high risk had higher 30-day mortality. Early recognition, prevention and treatment might be required for these patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000807

INTRODUCTION. A polymeric solution is recommended in first intention for enteral nutrition in critically ill patients. The efficacy to provide optimal amount of calories is often limited by digestive tolerance. Gastroparesis is frequent in neurocritically ill patients, explaining the difficulties to achieve optimal enteral nutrition in the early days after acute brain injury. A semi-elemental solution with hydrolyzed nutrients could facilitate digestive absorption and tolerance. Efficacy has never been evaluated in this specific condition.

OBJECTIVES. To evaluate efficacy and tolerance of a semi-elemental versus a polymeric solution for enteral nutrition in neurocritically ill patients.
METHODS. Randomized open-label trial (NCT01833624) including adult (age > 18), comatose (Glasgow Coma Scale (GCS) ≤ 8) patients, admitted in our ICU after severe acute brain injury. Next-of-kin's consent was obtained, or inclusion was done accordingly to an emergency procedure, as allowed by local ethic committee. Patients in the SE group received a semi-elemental solution (Peptamen AF®, Nestlé®, 1.5 kcal/ml, 9.4 g of proteins per 100 ml), patients in the PM group received a polymeric solution (Sondalis HP®, Nestlé, 1.5 kcal/ml, 7.5 g of proteins per 100 ml). Protocol considered twice daily residual gastric volume (RGV) to increase enteral nutrition delivering until objective was achieved, before 36th hour in case of good tolerance[1]. Primary judgement criterion was the daily amount of delivered calories. Intervention period lasted 10 days maximum. Secondary judgement criteria were incidence of gastroparesis (defined as RGV > 500 ml/12h) and diarrhea, the need for prokinetic drugs use, daily amount of delivered proteins, 10th day plasma levels of albumin and prealbumin, and 28-day mortality. Results are expressed as mean ± standard deviation, or as number(percent).
RESULTS. 205 patients (128 men, age 53 ± 17, admitted for traumatic brain injury (34%), subarachnoid hemorrhage (24%) or polytrauma (15%) – GCS 5 ± 2, IGS2 49 ± 12), respectively 107 and 98 in the SE and PM groups. Mean daily amount of delivered calories did not differ between groups (1501 ± 496 vs. 1539 ± 463 kcal/d, p=0.60). Secondary criteria are presented in table. Mean daily amount of delivered proteins was significantly higher in the SE group (1.24 ± 0.04 vs. 1.05 ± 0.04 g/kg/d, p=0.0006).
CONCLUSION. The use of a semi-elemental solution did not increase the daily amount of delivered calories in the first 10 days in neurocritically ill patients, compared to a polymeric solution. The daily amount of delivered proteins was increased, its interest could be evaluated in further studies.

Long-stayer patients in the ICU: the nutrition and blood glucose pattern change through the stay
M. Viana, G. Bagnoud, A. Martinez, O. Pantet, E. Favre, P. Eckert, M. Berger
Service of adult intensive care & burns, Lausanne University Hospital, Lausanne, Switzerland
Correspondence: M. Berger
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000947

INTRODUCTION. The intensive care (ICU) patient population has increasing number of very long ICU stays. Long-stayers are usually defined as requiring more than 1 weeks of mechanical ventilation and of ICU therapy. Little is known about their nutritional and metabolic characteristics. In an attempt to better coordinate their treatment and reduce their length of stay (LICU), the service instituted a dedicated program enrolling patients requiring more than 2 weeks of ICU treatment.
OBJECTIVES. The study aimed at investigating the demographic, nutritional and metabolic aspects of their stay, including in the factors associated with Hypoglycemia (<4.1mmol/l) or Hyperglycemia (>10mmol/l) during the different phases of their ICU stay
METHODS. Retrospective analysis of 150 consecutive patients admitted to the ICU long-stayer program. Data extracted from the PDMS: age, SAPSII, weight, NRS-2002 score, daily energy, protein, and glucose intakes, blood glucose (Glu) and lactate, 24hr insulin needs to achieve Glu 6-8 mmol/l, 24hr-insulin, length of stay (LICU), and outcome. Data median [IQR 25-75], univariate analysis.
RESULTS. Cohort characteristics were: age 62 years [52-71], NRS 5 [3-7], SAPSII score 51[39-66]. LICU was 28 days [22-42] with mortality 18.7%: NRS was significantly higher in those dying (p=0.007). The nutrition intakes were extremely variable during the first week with multiple interruptions, stabilizing thereafter at values below the protocol recommendation. Median protein intakes and energy balances from D1-D7 were 0.92g/kg [0.79-1.15] and -380kcal/d [-1170/19] respectively, and from D8-D30 were 0.97g/kg [0.82-1.11], and -7 kcal [-259/78] respectively. During D1-D5, blood glucose was correlated 24hr-insulin (r2 =0.41, p< 0.001), but only weakly with glucose intake, and not with C-Reactive-Protein, without difference in septic and non-septic patients. Early HyperGlu was associated with higher severity (p=0.040) and lactate (p<0.001), but not with Glu intake, and resulted in higher Insulin (p<0.001) needs; late HyperGlu was observed in younger (p=0.013), heavier patients(p< 0.001), and resulted in higher insulin(p<0.001)needs. Early HypoGlu was observed in younger(p=0.013) and leaner patients(p<0.001), and late HypoGlu, in younger patients (p=0.003) with low Glu intake (p<0.001).
CONCLUSION. Long-stayer patients were characterized by a higher NRS-score, highest in those dying. Variability of nutritional intakes compared to the protocol was a striking characteristic. Energy and protein intakes were especially variable during the first week, and below the ICU recommendation. Factors associated with Hypo- and HyperGlu differed over time. Early HyperGlu was associated with higher severity. Late HypoGlu was associated with low Glu intake. Leaner younger patients were at highest risk of HypoGlu, while modestly overweight elder patients were most exposed to HyperGlu. Blood glucose had no clear association with glucose intake nor with inflammatory status.

Role of the chest wall in airway closure and expiratory flow limitation in patients with acute respiratory distress syndrome
N. Terzi[1], LM. Galerneau[1], M. Mezidi[2], H. Yonis[2], L. Baboi[2], B. Louis[3], C. Schwebel[1], C. Guérin[1]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000048

INTRODUCTION. When flow does not go up after increasing expiratory driving pressure during tidal breathing expiratory flow limitation (EFL) occurs heralding airway closure (AC). We were wondering whether chest wall can contribute to small airways closure and hence to either EFL or AC occurrence in acute respiratory distress syndrome (ARDS) patients.
OBJECTIVES. To investigate the role of chest wall elastance (EcW) relative to lung elastance (EL) as a mechanism by which airways would close in ARDS patients. Our hypothesis was that the lower the EcW/EL ratio the higher the likelihood of EFL and AC.
METHODS. Moderate to severe ARDS patients intubated, sedated and paralyzed were prospectively included in two centers. Mechanical ventilation was delivered in volume-controlled mode (Evita XL or V500 ICU ventilators, Draeger) with tidal volume 6 ml/kg predicted body weight at positive end expiratory pressure 5 cmH2O in semi-

recumbent position. Airway (Paw) and esophageal (Pes) pressures and flow were continuously recorded during 2 minutes by a data logger (Biopac 150). Then, end-expiratory and end-inspiratory occlusions were performed for 5 seconds each, then respiratory system was slowly inflated at constant flow from the ventilator. Finally, patient was allowed to breathe out freely to atmosphere by using a three-way stop lock by-passing expiratory valve. AC and airway opening pressure (AOP) were determined according to Chen et al. (1) from the pressure-volume curve. EFL was assessed by the atmospheric method (2). Dynamic elastances of chest wall (Edyn,cW) and lung (Edyn,L) were obtained from least square linear regression method over 10 consecutive breaths. Static elastances (Est,cW and Est,L) were determined by classic formulas and also by taking into account AOP (Est,cW_aop and Est,L_aop, respectively). The performance of EcW/EL ratio to predict EFL and AC was assessed by area under receiver operating characteristic (AUCROC) curve.

RESULTS. Among 21 included ARDS patients EFL was observed in 7 (33%) and AC in 15 (71%). Median AOP was 7.8 (95%CI 7.6-11.7) cmH2O. The AUCROCs for EcW/EL ratios to detect EFL and AC are shown in table 1. Edyn,cw/Edyn,L ratio has the best performance to detect EFL(Edyn,cw/Edyn,L≤0.16 100% sensitivity and 85% specificity). Correction for AOP worsened the performance of Est,cW/Est,L ratio. AC was poorly predicted but prediction was improved with AOP correction. AOP values had an AUCROC of 1 (0.84-1) (P<0.0001) to predict EFL at the threshold of 8.3 cmH2O.

Table 1. Area under ROC curve (95% confidence intervals) for EcW/EL ratio for EFL and AC prediction

CONCLUSION. Low Edyn,cW/Edyn,L ratio and AOP predicted EFL occurrence. However, EFL and AC are two distinct phenomena in ARDS patients and should be assessed together to identify specific ARDS subphenotypes in terms of small airway contribution in ARDS.

INTRODUCTION. Oxygen therapy is part of the invasive mechanical ventilation strategy in the intensive care unit (ICU). Hyperoxaemia may however increase mortality.

OBJECTIVES. To assess degrees of hyperoxaemia, adjustments of fraction of inspired oxygen (FiO_2) in response to hyperoxaemia, and associations between hyperoxaemia and mortality in invasively mechanically ventilated ICU patients.

METHODS. We conducted a retrospective study of all invasively mechanically ventilated patients in 5 ICUs admitted from January 2011 to June 2016, retrieving all oxygen tension (PaO_2) and FiO_2 data. Time between arterial blood gas (ABG) samplings, proportions of hyperoxaemia (PaO_2 > 16 kPa), FiO_2 adjustments upon hyperoxaemia, and associations between mechanically ventilated exposure-time-divided area-under-the-curve (AUC) PaO_2 and ICU mortality was assessed. Primary ICU admissions were included in the mortality analyses, which used a multi-state illness-death model with transition intensities estimated by Cox proportional hazards models. The exposure-time-divided AUC measure represents the average PaO_2 level during invasive mechanical ventilation. Permission to use data without patient consent was obtained from the Danish Patient Safety Authority.

RESULTS. The study included 4,998 patients and 177,769 ABGs. Median time between ABGs was 3 hours (inter-quartile range: 2-4 hours), PaO_2 was 11.3 kPa (9.8-13.6 kPa), and FiO_2 was 0.40 (0.35-0.50). Hyperoxaemia was present in 11.9% of the ABGs. In 15.4% of the hyperoxaemic ABGs with $FiO_2 \geq 0.50$, the subsequent ABG remained hyperoxaemic with uncorrected FiO_2, whereas this was the case in 64.6% of hyperoxaemic ABGs with $FiO_2 < 0.40$. Exposure-time-divided AUC PaO_2 > 16.0 kPa was associated with increased ICU mortality (Table 1). This association was accentuated when censoring at the first PaO_2 < 8 kPa to diminish the impact of hypoxaemia (adjusted HR: 1.90 (95% CI: 1.27-2.86)).

CONCLUSION. ABG samplings were frequent and hyperoxaemia was common in invasively mechanically ventilated ICU patients. While FiO_2 in general was adjusted upon hyperoxaemia, several patients remained hyperoxaemic, especially at FiO_2 < 0.40. This may not be optimal as hyperoxaemia was associated with increased ICU mortality in the cohort.

Positive end-expiratory pressure affects the position and contractile efficiency of the human diaphragm: MRI and functional analysis

INTRODUCTION. Mechanical ventilation with positive end-expiratory pressure (PEEP) limits alveolar collapse, thereby improving oxygenation. However, PEEP-induced increase of end-expiratory lung volume may flatten the diaphragm dome. Experimentally, we showed that PEEP induced caudal diaphragm displacement, leading to an acute reduction in diaphragm fiber length [1]. As the muscle is forced to act at this shorter length, PEEP might impair diaphragm function.
OBJECTIVES. To test the hypothesis that PEEP acutely induces a caudal displacement and reduction in contractile efficiency of the human diaphragm.
METHODS. 18 healthy subjects participated. Non-invasive ventilation (NIV) was used to apply PEEP at 2, 5, 10 and 15 cmH2O, for 15 min. per level. For the first part, two nasogastric catheters were inserted to measure diaphragmatic pressure (Pdi) and diaphragm electromyography (EMGdi). Neuromechanical efficiency (NME) was defined as Pdi/EMGdi during tidal breathing with PEEP. Second, a MRI scan was made to measure diaphragm position at each PEEP level.
RESULTS.*Preliminary results:* Fig.1 shows a MRI scan of the diaphragm at end-expiration. A gradual PEEP-induced caudal displacement of the diaphragm dome was found for all subjects (mean±SD 20.2±9.5 mm after increasing PEEP from 2 to 15 cmH2O, p<0.001). In 9 of the subjects, NME could be obtained at all PEEP levels and decreased gradually with higher PEEP. Median NME reduction was 20% (p= 0.31), 27% (p<0.05) and 41% (p<0.05) after increasing PEEP from 2 to 5, 10 and 15 cmH2O, respectively.
CONCLUSION. In healthy subjects, acute application of PEEP results in caudal diaphragm displacement and reduction in diaphragm contractile efficiency. If similar effects occur in the critically ill, acute *reduction* in PEEP (i.e. during a spontaneous breathing trial) may result in an overstretched diaphragm and consequently impair diaphragm performance.

EtCO2 doesn't always predict paCO2 during mechanical ventilation and negative paCO2-EtCO2 gradient can result because of the development of a new hyperinflated compartment in the lung

INTRODUCTION. End-tidal carbon dioxide pressure is used routinely as an indicator of arterial partial pressure of carbon dioxide, giving an estimation of adequate ventilation. Normally paCO2-etCO2 gradient is positive, representing normal ventilation-perfusion mismatch. This can vary during mechanical ventilation.
METHODS. 42 healthy piglets, 24,2±2 Kg, were mechanically ventilated for 48 hours in prone position with a similar mechanical power, delivered by primarily increasing tidal volume (TV), respiratory rate (RR) or PEEP. The ventilation was set as follow:
1) High TV group (14 pigs): TV 803±122 ml/min, RR 11±4,5, PEEP 5,3± 0,8 cmH2O, mechanical power 20,8±7,9 J/min
2) High RR group (14 pigs): TV 299±61 ml/min, RR 40±1, PEEP 8,3±1,5 cmH2O, mechanical power 22,2±8,5 J/min
3) High PEEP group (14 pigs): TV 319±21 ml/min, RR 16,3±5,5, PEEP 24±1,1 cmH2O, mechanical power 21,3±8,5 J/min.
RESULTS. We observed after the set of our ventilatory strategy an inversion of the paCO2 and etCO2 values with a negative gradient for the entire experiment and in all groups of animals (EtCO2 30±18 paCO2 29±17 p=0,29)(fig1). The degree of hyperinflation was computed as PEEP volume plus FRC and the median value (511,5 ml) was taken as cut off above which the hyperinflation group was defined. Hyperinflation significantly affected the inversion of EtCO2 and paCO2: in fact the hyperinflation group (EtCO2 38±19,9 paCO2 37± 18 pCO2mixed 43±19) compared to the hypoinflation group (EtCO2 22±9, paCO2 21±10,6 and pCO2mixed 26,38±11,12) was significantly different (p < 0,0001)(fig 2).
CONCLUSION. A possible reason for the inverse relationship between etCO2 and paCO2 is indeed the development of hyperinflation and for this reason of areas of the lungs open but without ventilation. These areas will have longer time constants, behaving like a new compartment or reservoir of CO2 for the expired air. This will make the etCO2 more similar to the mixed venous pCO2, having more time to reach equilibrium, while paCO2 will increase less the etCO2. The overall phenomenon is the result of an impaired ventilation/perfusion mismatch.

Cytomix Preactivated UC-MSCs as a Treatment of Acute Lung Injury in a New Model of Rodent Staphylococcus Aureus–Induced Pulmonary Acute Respiratory Distress Syndrome

E. Rezoagli, D. O'toole, EJ. Murphy, JG. Laffey
Anaesthesia, National University of Ireland, Galway, Galway, Ireland

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001604

INTRODUCTION. Models of gram negative bacteria induced acute respiratory distress syndrome (ARDS) have been well established in rats. The therapeutic role of mesenchymal stromal/stem cells (MSCs) looks promising in such a model (1). Contrarily, no information is available on the role of MSCs in the treatment of pulmonary ARDS induced by gram positive bacteria. *Staphylococcus Aureus* is a clinically relevant gram positive bacteria, which is associated with >40% health care pneumonia cases and with mortality rates of >50% (2).
OBJECTIVES. Objectives of our investigation were: 1. to establish a model of gram positive bacterial pneumonia using a clinically relevant strain of *S. Aureus* from a human isolate (Newman) (3); 2. To evaluate the potential therapeutic role of naïve and preactivated umbilical cord (UC) MSCs freshly harvested from culture in the treatment of acute lung injury in a new model of Rodent *S. Aureus*–induced ARDS.
METHODS. Adult male Sprague Dawley rats underwent intratracheal instillation of *S. Aureus* Newman to induce pulmonary ARDS. Animals were randomized, within 2 hours post infection, to intravenous administration of: (1) vehicle (phosphate buffered saline (PBS)); (2) 1x10^7/kg fresh UC-MSCs; and (3) 1x10^7/kg fresh UC-MSCs preactivated for 24 hours with cytomix (TNF-α; IL-1β; and IFN- γ [50 ng/mL each]). Comparisons among the groups were tested for differences in bacterial load and white blood cell count in the bronchoalveolar lavage (BAL), and arterial oxygenation after 48 hours.
RESULTS. Endotracheal instillation of *S. Aureus* Newman induced a model of moderate ARDS in rats. Fresh naïve UC-MSCs did not treat the lung injury at 48 hour post infection. In contrast, the preactivation of fresh UC-MSCs with cytomix for 24 hours allowed to significantly increase the pulmonary bacterial clearance – as shown by the lower bacterial load in the BAL (**Figure 1A**), to reduce the lung cell infiltrates – as shown by the lower white blood cell count in the BAL (**Figure 1B**), and to improve oxygenation with an average PaO2/FiO2 ratio above 300 at an FiO2 of 1.0 (data not shown).
Data are expressed as mean (SEM). n=6-8 per group. p-UC-MSCs=preactivated UC-MSCs.
CONCLUSION. Fresh preactivated UC-MSCs therapy decreased the severity of *S. Aureus* induced ARDS by the reduction of bacterial load and white blood cell infiltrates into the lungs, and by the increase of arterial oxygenation. The use of preactivated UC-MSCs could represent a potential clinically relevant treatment of acute lung injury in patients with gram positive induced ARDS.

INTRODUCTION. In observational studies, higher body mass index (BMI) has been associated with increased incidence and mortality of bloodstream infection (BSI) and sepsis in the general population (1,2), but with reduced mortality among patients with BSI or sepsis (3). However, traditional observational studies are subject to bias and confounding (4). Mendelian randomization studies utilizes the fact that genotypes are randomly assigned at conception, which make these studies less susceptible to reverse causation and confounding (5).
OBJECTIVES. To evaluate the causal association of BMI with risk and mortality of BSI in the general population, and with mortality among patients with BSI.
METHODS. Non-linear Mendelian randomization study with a 23-year prospective follow-up between 1995 and 2017 using a population-based cohort in Norway (The HUNT Study). Of 93,865 invited subjects, 65,236 (70%) participated, and 55,908 (60%) had complete data on genotype and anthropometric measures. Genetically-predicted BMI was calculated based on 939 single nucleotide polymorphisms identified in an independent genome-wide association study. To account for selection bias, inverse-probability weighting was used in the sub-analysis restricted to patients with BSI.
RESULTS. The mean age at enrollment was 48.3 years, 26,324 (47.1%) were men, and mean BMI was 26.3 kg/m2. During median 21 years

follow-up, 2,547 (4.6%) subjects experienced a BSI and 451 (0.8%) died from BSI. Compared with a genetically-predicted BMI of 25 kg/m2, a genetically-predicted BMI of 30 kg/m2was associated with a hazard ratio (95% confidence interval) for BSI incidence of 1.78 (1.40 – 2.27) and for BSI mortality of 2.56 (1.31 – 4.99) in the general population, and for mortality of 2.34 (1.11 – 4.94) in the sub-analysis of patients with BSI.

CONCLUSION. Supportive of a causal relationship, we found that genetically-predicted BMI was associated with BSI incidence and mortality, even within the normal BMI range. Our findings contradict the "obesity paradox" where previous traditional epidemiological studies have found increasing BMI to be protective in terms of mortality for patients with BSI or sepsis.

INTRODUCTION. Targeting normal macro hemodynamics in septic shock (SS) does not ensure adequate tissue perfusion. Thus, assessing biological markers of tissue hypoxia may help to titrate therapeutics. The lactate/pyruvate ratio (L/P) and the venoarterial CO2 gap / arteriovenous O2 content difference (PcvaCO2/CavO2) have been proposed as markers of anaerobic metabolism and as a surrogate of the respiratory quotient, respectively.

OBJECTIVES. We attempted to determine if L/P ratio and PcvaCO2/CavO2 correlates adequately as tissue hypoxia markers and if they may predict lactate outcome in SS patients.

METHODS. Data from an ongoing prospective clinical randomized control trial performed in 2 ICUs were analyzed. Patients were divided into 2 groups: Lactate improvers (LI), defined as a decrease ≥10% at 6 hours or normalization (<2.0 mmol/L), and no-LI (decrease <10%). L/P ratio and PcvaCO2/CavO2 samples were collected and compared at time 0 (basal), 2 and 6 h.

RESULTS. Twenty-seven septic shock patients have been studied until now. Basal demographic and hemodynamic characteristics are described in Table 1. No clinical differences were observed. No correlation was found between L/P and PcvaCO2/CavO2 (r=0,11 p=0,34) (figure 1). L/P ratio did not discriminate between LI and no LI, whereas PcvaCO2/CavO2 did as a whole (1.63±0.31 vs 2.26±0.5; p=0,024) and by 2 and 6h (1.26 vs. 2.07; p=0.006 and 1.79 vs 2.84; p=0.006, respectively). No other perfusion parameter showed a significant difference. These and other perfusion parameters are shown in Fig 2.

CONCLUSION. PcvaCO2/CavO2 was accurate to identify lactate improvers and thus might be a reliable surrogate of tissue hypoxia, whereas L/P did not. L/P and PcvaCO2/CavO2 values did not correlate in septic shock patients and might represent different biological mechanisms.

INTRODUCTION. CAP is the most important cause of infectious death worldwide. A major hallmark of CAP physiopathology is the high systemic proinflammatory state that generates in part, when pathogens induce mechanisms of host necrotic cell death, exacerbating inflammation. It is well known that CAP patients experiencing uncontrolled systemic inflammation, have worse clinical outcomes. However, the underlying mechanisms of these proinflammatory reactions are not well understood. NETosis, a recently described pro-inflammatory pathway of neutrophil death and the driver of NET formation, has been shown to be important in patients with pulmonary diseases such as bronchiectasis or COPD, and directly associated with lung inflammation and damage. However, the role of serum NETs has not been investigated as the cause of the proinflammatory state and mortality observed in patients with CAP. Therefore, this study attempted to bridge this knowledge gap.
OBJECTIVES. To determine the role of circulating neutrophil extracellular traps (NETs) in the systemic proinflammatory state and mortality observed in patients admitted with community-acquired pneumonia (CAP).
METHODS. Here, we report a multicenter cohort study designed to better understand the role of baseline circulating NETs in the systemic inflammation and mortality of CAP patients. Thirty-seven CAP patients and twenty-five controls (patients with stroke and healthy individuals) were prospectively enrolled in 2 university hospitals in Spain. Baseline serum cfDNA was quantified using the Quant-iT PicoGreen® dsDNA Kit. To detect NETs in human serum samples we used a modification of the MPPO-DNA ELISA method. Interleukins were tested by ELISA. Descriptive statistics and logistical regressions were used to assess the results.
RESULTS. We show that patients with CAP developed a systemic proinflammatory profile characterized by increased serum concentrations of IL-6 and IL-10 (1,025pcg/mL, 172.5pcg/mL respectively). Patients diagnosed with CAP had higher levels of free-DNA in serum (Median [IQR]; 0.273 [0.216, 0.391] Vs 0.480 [0.357, 0.720], p=<0.001) and NETs (Median [IQR]; 32 [25, 36] Vs 76 [47, 125], p=<0.001). A linear regression among free-DNA and NETs was confirmed with a r2=0.5788. The relation among IL-6 (r2=0.11), IL-10 (r2=0.09) and NETs was not significant. Regarding ICU mortality, 7 (19%) CAP patients died and had lower levels of circulating NETs compared with patients who survive (Median [IQR]; 34.00 [24.00, 70.00] Vs 50.75 [32.25, 94.50], p=0.12).
CONCLUSION. Our results provide a mechanistic link to the proinflammatory state of patients with CAP. Serum concentration of NETs associated to up-regulation of NETosis and IL-6/IL-10. However, serum NETs are not associated with mortality due to CAP. Finally, there is no relation among interleukin levels and NETs concentration. Other pro-inflammatory cell death pathways should be investigated to better understand inflammation and mortality in CAP patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001187

INTRODUCTION. Hypocholesterolaemia and catecholamine hyporesponsiveness are hallmarks of sepsis, with a greater degree of abnormality associated with worse prognosis [1,2]. Cholesterol is a crucial component of the cell plasma membrane, regulating membrane permeability and responsiveness to hormones though expression and activity of G-protein coupled receptors such as the β-adrenergic receptors. We have previously shown in our rat model of sepsis that membrane cholesterol levels fall in heart and liver, with the extent correlating with mortality.
OBJECTIVES. To determine whether restoration of membrane cholesterol concentration levels in a rat model of sepsis would rescue adrenergic signalling and improve catecholamine responsiveness.
METHODS. Awake, instrumented male Wistar rats (300±50g) received an i.p. injection of faecal slurry with i.v. fluid resuscitation commenced from 2h. Sham operated rats were treated identically but did not receive slurry. At 6 h post-induction of sepsis, the intervention group received an i.v. infusion of cholesterol containing liposomes (10 mg cholesterol/300g bw) over 15 hours. Catecholamine responsiveness was then tested by consecutively administering dobutamine (10 μg/kg/min for 10 min, and norepinephrine (0.5 μg/kg/min for 10 min) with a 30 min washout period in between. BP (invasive), HR and SV (by echocardiography) were measured before and after each drug was administered. Results are presented as mean ± SE, analysed using Student's t test and considered statistically significant when $p < 0.05$.
RESULTS. Animals treated with cholesterol-containing liposomes demonstrated a more pronounced cardiac response after dobutamine (DB) administration, with a significant increase in stroke volume over untreated septic animals (Table 1). No improvement was seen in the blood pressure response to norepinephrine (NE).
CONCLUSION. Administration of cholesterol-containing liposomes improved myocardial responsiveness to dobutamine, but not the pressor response to norepinephrine

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000615

INTRODUCTION. Ventilator associated pneumonia (VAP) is common in critically ill patients and associated with high morbidity and mortality, especially when caused by antibiotic resistant bacteria. Recently, phage therapy has emerged as a promising non-antibiotic based treatment of antibiotic resistant bacterial infections. However, proof-of-concept experimental and clinical studies are missing before its wider use in clinical medicine. In our previous study, we have shown, that intravenous phage therapy was as effective as antibiotics (teicoplanin) in improving outcome of rats with VAP caused by methicillin-resistant *S. aureus* (MRSA).
OBJECTIVES. The goal of our current study was to evaluate the efficacy of inhalative administration of phage cocktails (aerophage) for the treatment of lethal MRSA VAP in a rat model.
METHODS. Four hours after intubation and protective ventilation, rats were inoculated via the endotracheal tube with 1 x 1010 CFU (LD100) of the MRSA clinical isolate AW7. Two hours after bacterial challenge, rats were randomised and received either inhalative (n=10), intravenous (n=10) or combination of both (n=11) administration of a cocktail of four phages (1 x 1010 plaque forming units/ml of 2003, 2002, 3A and K). Therapy was repeated after 12 and 24 hours and then once daily for four days in a blinded manner. The primary outcome was survival at day four. Secondary outcomes were bacterial and phage densities in the lungs and spleen.
RESULTS. Application of the multiphage cocktail using a combination of inhalative (aerophage) and intravenous (IV) route significantly improved survival compared to IV or aerophage monotherapies in this lethal pneumonia model (91 % vs. 50 % and 50%, respectively, p< 0.04, log-rank test). Mortality correlated with high bacterial load within the lungs and spleens. Animals that succumbed to infection had over 19,000-times more MRSA in the lung when compared to those that survived until 96 hours (8.8 x 108 CFU/g vs. 4.6 x 104 CFU/g, respectively, p < 0.0001, t test). Similarly, spleen in dying animals had over 150-times more MRSA when compared to those that survived until 96 hours (4.1 x 104 CFU/g vs. 2.6 x 102 CFU/g, respectively, p < 0.0001, t test). Despite improved survival for rats treated with the combination of aerophage and IV, the treatment groups did not differ in the bacterial burden in the lung or the spleen (p=0.20, two-way ANOVA). High phage loads were detected in the lungs of all treatment groups. In contrast to IV administered phages, inhalative phages did not readily accumulate in the spleen.
CONCLUSION. The combination of aerosol and intravenous phage therapy significantly improved outcome compared to inhalative or intravenous phage therapy alone.

INTRODUCTION. Early rapid loss of skeletal muscle is common in critical illness and is associated with negative outcomes[1-4]. Continuous feeding, routine in most intensive care units (ICUs), suppresses myofibrillar protein synthesis[5], whereas intermittent feeding may augment it[6]. We report safety data from a study comparing muscle mass after intermittent versus continuous enteral feeding during early ICU care.
METHODS. Adults (mechanically ventilated ≥48hours, on ICU ≥7days, with multi-organ failure) recruited within 24 hours of admission to one of 8 UK ICUs were randomised to receive four-hourly intermittent feed (intervention) or continuous (control) enteral feed for 10 days (NCT02358512). We recorded events associated with significant morbidity or death (Adverse Events, AEs; Serious Adverse Events, SAEs), including pulmonary aspiration; gastric intolerance (vomiting, diarrhoea [Bristol Stool Score ≥5], need for prokinetics use, gastric residual volume (GRV)>300mls); adverse blood glucose levels (>10.1mmol/l hyperglycaemia, <3.9mmol/l hypoglycaemia); Coefficient of Glucose Variation [CGV]). Daily insulin use was also documented. Data are reported descriptively and analysed by two sample t-tests or Mann-Whitney U-tests as appropriate.
RESULTS. Participants (mean [95% Confidence Intervals] age: 57.7 [54.7-60.6] years; 67% male) received intermittent (n=62) or continuous (n=59) enteral feed. No cases of pulmonary aspiration were reported. Groups did not differ in proportion of days in which prokinetics were used, GRVs were >300ml, or in which diarrhoea, vomiting, hypoglycaemia or hyperglycaemia occurred. Daily insulin use was also similar. Glucose variation was greater in those intermittently fed (p<0.001, Table 1).
Ten SAEs and AEs were reported (3, Continuous vs. 7, Intermittent): two of latter AEs were probably/possibly considered to be intervention-related (both due to abnormal glucose levels). One patient transferred from intermittent to continuous feed (consultant decision).
CONCLUSION. Intermittent enteral feeding in early critical illness is safe and associated with similar levels of gastric intolerance, but greater glucose variation than continuous feeding; however, daily insulin use was similar between patient groups.

Associations between anesthesia type and transfer to higher level of care in patients with rapid response team activation within 24 hours after undergoing anesthesia

C. Wu[1], A. Gallo De Moraes[2], Y. Dong[3], RD. Frank[4], JB. Jensen[5]
[1]Anesthesiology, West China Hospital, Sichuan University, Chengdu, China; [2]Pulmonary and critical care medicine, Mayo Clinic, Rochester, United States of America; [3]Anesthesiology and perioperative medicine, Mayo Clinic, Rochester, United States of America; [4]Biomedical statistics and informatics, Mayo Clinic, Rochester, United States of America; [5]Anesthesiology and critical care medicine, Mayo Clinic, Rochester, United States of America

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001457

INTRODUCTION. Rapid response teams (RRT) provide critical care services for deteriorating patients outside of intensive care units to stabilize them, and if necessary, facilitate transfer to a higher level of care within the hospital [1]. There is a paucity of literature looking into characteristics of RRT activations in the post-operative period. There is no data looking into the correlation of RRT activations and outcomes and the types of anesthesia used for adult patients.
OBJECTIVES. Our objective was to explore if specific anesthesia types had any impact in the disposition of patients who required RRT activation during the first 24 hours postoperative period.
METHODS. Patients with RRT activations that occurred within 24 hours after receiving anesthesia at Mayo Clinic in Rochester from July 1, 2012 to November 1, 2017 were included. Only the first RRT activation was included in those patients who had multiple RRT activations. Anesthesia types were extracted from established Operation Room DataMart and divided into 6 groups: general anesthesia (GA), regional block (RB), local anesthesia (LA), sedation (SE), monitored anesthesia care (MAC) and combined anesthesia with general anesthesia and regional block (CO).
RESULTS. A total of 2,046 (54% men) unique patients aged >=18 years (median 65 years) with RRT activations within 24 hours after procedures were identified and their anesthesia types were: 825 (40 %) GAs, 91 (4 %) RBs, 165 (8 %) LAs, 445 (22%) SEs, 329 (16 %) MACs and 191 (9 %) COs. 62% of those patients were ASA 3 or higher. The median time to the RRT calls after anesthesia was 8 hours (interquartile range: 4, 16). The most common reason for RRT activations in each group was due to cardiovascular issue, accounting 61% for 2046 RRT activations and including bradycardia (5%), tachycardia (24%), hypotension (30%), hypertension (6%), chest pain (6%) and other symptoms (1%). 897 patients (44%) were transferred to a higher level of care unit immediately after RRT activations. Multivariable logistic regression analysis revealed the following factors to be associated with increased transfers to higher levels of care: anesthesia type (p=0.004), the procedure type (p<0.001), preoperative history of hypertension (p<0.001), intraoperative use of vasoactive drugs (p=0.02). Compared with the GA group, patients who underwent LA (OR=2.39; p<0.05) and SE (OR=1.83; p<0.01) had significant more transfers to a higher level of care.
CONCLUSION. Patients who had RRT activations during the first 24 hours after local anesthesia or sedation required transferring to the higher level of care more often, when compared to general anesthesia. We hypothesize that this occurs because the above patients who underwent local anesthesia or sedation had a higher ASA status and more serious disease so that they might not be able to undergo the complicated procedures, and the anesthesia type might not be a direct factor. Maintaining vigilance in non-GA patients is critical to ensuring postoperative safety in these patients.

The correlation between length of ward stay prior to icu admission and mortality

A. Taylor[1], D. Leith[2], T. Samuels[2], P. Morgan[2]
[1]Critical care, East Surrey Hospital, Redhill, United Kingdom; [2]Critical care, East Surrey Hospital, Redhill , United Kingdom

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000128

INTRODUCTION. Correlation between mortality and the length of hospital stay (LOS) prior to ICU admission is relatively understudied. Some studies have previously shown that admission to ICU from the ward vs from ED, and LOS prior to ICU admissions, is associated with higher mortality[1-4]. This study aimed to determine if LOS prior to admission to the ICU significantly affects mortality rate in emergency admissions in an undifferentiated patient population at a district general hospital. We looked for correlation between LOS and likelihood of requiring invasive ventilation and renal replacement therapy (RRT).
METHODS. This study is a retrospective analysis of 13,270 patients from the WardWatcher Database at the ICU at East Surrey Hospital. Analysis included all unplanned ICU admissions (n=8,623). Patient data on LOS prior to ICU admission was compared against hospital and unit mortality, and requirement for invasive ventilation and RRT. The mean APACHE II score and the absolute number of patients admitted with respect to LOS prior to ICU admission was also recorded. We used regression analysis and bootstrapping to assess for significant correlations, producing an R-square value for mortality, the need for invasive ventilation and RRT.
RESULTS.
Both the hospital mortality and the ICU mortality increased as LOS on the ward prior to ITU admission increased (fi.g1). Using bootstrapping (1000 samples), we estimated the R-squared value and 95% confidence interval for mortality in the groups with 14 and 28 day

stays on the ward as 0.94 [0.88 - 0.97] and 0.26 [0.01 - 0.66] respectively. There was also a weak positive correlation between the mean APACHE II score (days 0-14) and LOS prior to ICU admission (R= 0.4634). However, there was almost no correlation between LOS prior to admission and the need for ventilation/RRT (fig.4).

CONCLUSION. In conclusion, this study found no correlation between duration of stay in hospital prior to ICU admission, and requirement for invasive ventilation and RRT. Interestingly, however, there was a strong positive correlation between length of ward stay and hospital and unit mortality up to 14 days. A similar correlation, albeit not as strong, was seen with APACHE II scores and LOS prior to ICU admission. Patients admitted to ICU from the ward have been previously shown to have higher illness severity scores compared to those admitted from ED[4]. More work looking into ward patients' antecedent events prior to ICU referral is needed to establish whether there are predictors of a requirement for critical care that could prompt earlier referral, and whether earlier critical care input actually improves outcomes in this cohort.

Predictive performance of SAPS 3, SOFA, ISS and New ISS in trauma patients admitted to a specialized trauma ICU

RML. Roepke, RM. Guazzelli, RDD. Oliveira, E. Bassi, EM. Utiyama, LMS. Malbouisson

Trauma and emergency surgery intensive care unit, Hospital das Clínicas Faculdade de Medicina USP, São Paulo, Brazil

Correspondence: R. Roepke

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000331

INTRODUCTION. Several specific predictive models were developed to predict outcomes in victims of trauma. Among the most widely used are those based on anatomical injury patterns, derived from the Abbreviated Injury Scale (AIS): the Injury Severity Score (ISS) and its later modification New Injury Severity Score (New ISS). However, it's not known whether these scores perform better than general critical care scores for trauma patients admitted to the intensive care unit (ICU).

OBJECTIVES. To compare the predictive ability for hospital mortality of a general critical care score (SAPS 3), an organ dysfunction score (SOFA) and anatomical injury based scores (ISS and New ISS).

METHODS. Retrospective cohort study of patients admitted to a specialized ICU from a tertiary university hospital in São Paulo, Brazil between March, 2012 and January, 2016. Admission data were prospectively collected in the ICU clinical database. We retrieved SAPS 3 and SOFA within 24 hours of ICU admission from the database. Both ISS and New ISS were retrospectively calculated based on the analysis of whole-body CT results and medical records by three independent and trained evaluators. We compared the different models overall accuracy with area under the receiving operator characteristic (AUROC) curves using the DeLong method.

RESULTS.

The study cohort included 1110 victims of trauma admitted to the ICU. Males were 84.1% of the patients and mean age was 40 (±18) years. Main injury mechanism was blunt trauma (89.1%). Traumatic brain injury was present in 733 patients (66%). Whole-body CT scan

was performed in 689 patients (62%). At the time of ICU admission, 861 patients (77.6%) were on mechanical ventilation and 549 (49.5%) on vasoactive drugs. Hospital mortality was 26.7% (296 patients), ICU length of stay (LOS) was 7 [4,15] days and hospital LOS was 15 [7,33] days. Mean SAPS 3 was 48.6 (±16.5) and mean SOFA was 6.4 ± 4.2. Mean ISS was 30 (±12) and New ISS 41 (±15). In a complete case analysis, 918 patients were included. AUROCs (95% CI) were as follows: SAPS 3 = 0.79 (0.76; 0.82); SOFA = 0.78 (0.75; 0.81); ISS = 0.60 (0.56; 0.64); 0.67 (0.63; 0.71). In pairwise comparisons, SAPS 3 and SOFA did not differ (p = 0.53), while both outperformed the anatomical scores (p <0.001); New ISS was a better predictor than ISS (p <0.001).

CONCLUSION. Critical care predictive scores outperform anatomical based injury scores in predicting hospital mortality in trauma patients admitted to the intensive care unit.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000606

INTRODUCTION. At present, there are so many ICUS implement restrictive visiting system at home and abroad, which could reduce ICU acquired infection by limiting visiting time, number of visitors and other ways. The concentrated visiting method enables family members and patients to have certain communication and contact, and that maybe alleviates the anxiety of family members and patients [1-2]. One study found that the restricting relative visits is the main cause of patients' pain [3], and another study also found that ICU patients who lack visitation have a more than threefold increased risk of delirium[4], but unrestricted relative visitation may increase infection, affect medical treatment work, and increase job burnout of ICU medical staff, etc. [2,5]. However, at present, there is no relevant guidance or consensus on the visiting of relatives of ICU patients at home and abroad [1,2], which visiting mode is more beneficial to ICU patients, and there is no clear concept on the visiting time and number of the two visiting modes.

OBJECTIVES. To compare the effects of un-restrictive visiting policy(UVP) and restrictive visiting policy(RVP) on ICU patients' delirium and ICU acquired infection, to explore the best visiting policy in ICU.

METHODS. Randomized controlled trails (RCTs) and quasi-experiment about UVP and RVP in ICU were retrieved in CBM, CNKI, Wanfang Data, PubMed, Cochrane Library and Web of Science from their foundation to Decmber 31 2018, and other sources as supplement was also retrieved. Data were extracted after strict evaluation of literature quality by two researchers, and Meta-analysis was conducted on literatures that met the inclusion criteria.

RESULTS. A total of 18 studies and 4647 patients were included in this study. There are 8 RCT studies and 10 quasi-experimental studies. The included studies were divided into subgroups according to study design and length of visitation. The results of the forest plot showed that UVP can not only effectively decrease the incidence of ICU patients delirium [RR = 0.19, 95% CI (0.10, 0.18), P < 0.00001), reduce the ICU patients anxiety score [RR = 1.60, 95% CI (1.67, 1.54), P = < 0.00001] and depression score [RR = 1.63, 95% CI (2.76, 0.49), P = 0.005), as well as effectively improve the family members' satisfaction [RR=3.56, 95%CI(2.32,5.48),P=<0.00001]. Meanwhile, the UVP did not increase the incidence of ICU acquired infection [RR=0.82, 95%CI(0.53,1.36),P= 0.31], ICU mortality [RR=0.61, 95%CI (0.21,1.79), P=0.37], and length of ICU stay [RR=-0.40, 95%CI(-1.29, 0.50),P=0.39]. In addition, without considering the study design, we found that the UVP may reduce the incidence of ICU acquired infection [OR=0.65, 95%CI (0.51,0.816), P= 0.002], and the longer the visit, the lower the incidence of ICU acquired infection [OR=0.75, 95%CI (0.61,0.91), P=0.004].

CONCLUSION. The UVP does not increase the incidence of ICU acquired infection , the length of ICU stay and the ICU mortality. On the other hand, the UVP can effectively decrease the incidence of ICU patients' delirium, reduce the ICU patients' anxiety score and depression score and improve the ICU patients family' satisfaction.

INTRODUCTION. The epidemiology of traumatic brain injury (TBI) is rapidly changing, with an increasing number of old and fragile patients. The aim of this study is to describe the characteristics of elderly TBI and the effect of age on patients' outcome.
METHODS. The CENTER-TBI (clinicaltrials.gov registration NCT02210221) is a prospective observational longitudinal cohort study including patients with TBI from centers across Europe. Data were extracted from the CENTER-TBI database v1.1 with Neurobot v2.6. Inclusion criteria were:

- diagnosis of TBI, with indication for Computed Tomography (CT),
- presentation to study center within 24 hours of injury.
- ICU stay >72h.

We excluded patients discharged alive from the ICU in < 72 hrs. Patients aged ≥65 were classified as elderly.
RESULTS. A total of 4509 patients were included in the CENTER-TBI study, 2138 were admitted in the ICU and we focused on the 1488 fulfilling the inclusion criteria. Overall, mean age was 48.3 years (sd = 20.37) and 395 patients (26.5%) were considered elderly. Elderly patients presented significant differences (p<0.001) with respect to not elderly both in the admission characteristics and in the discharge status:

- higher incidental fall rate (59% vs 32.9%), mainly at home (43.3% vs 17.3%)
- higher morbidities, as cardiovascular history (70% vs 13.4%), or pulmonary disease (13.8% vs 8.6%)
- higher use of anticoagulants (20.6% vs 1.3%) and antiplatelet (27.6 % vs 3.9%)
- higher Glasgow Coma Score at admission (GCS higher than 13: 24.8% vs 15.5%)
- higher non-evacuated mass lesion (Marshal score 6 in 54.3% vs 31.1%)
- more frequent subdural hemorrhage (73.3% vs 51.8%)
- less Intracranial pressure monitoring (ICP 46.7% vs 63.9%)
- less days in ICU (8 days vs 12 days, in median)
- higher mortality in ICU (32.7% vs 13.2%) and at 6 months (52.7% vs 18.6%)
- more unfavorable status (GOSE ≤4: 79.2 % vs 46.2%) but similar severe disability (lower or upper) at 6 months (26.5% vs 27.6% p= 0.728)

No statistically significant differences according to age were shown in pre-hospital hypotension (14.7% vs 17.3%, p=0.285), hypoxia (13.2% vs 17.7%, p=0.052) and also in the discharge location (in both cases, general ward was the most common 50.7% vs 48.8%, p=0.599).
CONCLUSION. Elderly patients have more comorbidities, different mechanism of injury, more severe CT scan findings, and have a higher mortality when compared to the younger population.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000588

INTRODUCTION. Acute kidney injury (AKI) is frequent in polytrauma patients and it is associated with increased mortality, hospital stay, and morbidity. However, the real prevalence and impact on the outcome of AKI in isolated traumatic brain injury (TBI) are unclear. Our aims were

1. to assess the incidence and timing of AKI in a large cohort of prospectively enrolled TBI,
2. to assess in-hospital factors related to AKI development;
3. to assess the association between AKI at different stages and patients' outcome.

METHODS. The CENTER-TBI is a prospective observational longitudinal cohort study including patients with TBI from centers across Europe. Data were extracted from the CENTER-TBI database v1.1 with Neurobot v2.6. Inclusion criteria for our study were ICU length of stay >72 h and > two creatinine values or at least one urine output (UO) available measures during the ICU stay.
AKI was defined by applying the RIFLE criteria.
RESULTS. 4509 patients were included in the CENTER-TBI study, of which 2138 were admitted to the ICU. 1317 fulfilled the inclusion criteria. Patients were grouped in three categories: normal renal function (N), risk or injury (R/I) and failure (F). The median age in the 3 groups was similar (around 50 y/o). The majority of AKI occurred within the first 10 days from admission, with a median of 2 days (IQR: 1-4 days) for the R/I category, and a median of 4 days (IQR: 1-6 days) for the F group. Patients with history of cardiovascular (CV) disease had a higher occurrence of both R/I and F (F= 45%, R/I = 31% vs N= 25.5%, p = 0.003). During the ICU stay, patients in both the R/I and in the F group suffered more from: episodes of neuroworsening (F= 45%, R/I= 43% vs N= 30%, p < 0.001), raised ICP (F= 34%, R/I= 39% vs N= 27%, p=0.003), respiratory failure (F= 40%, R/I= 44% vs N= 29%, p < 0.001)and pulmonary edema (F= 2%, R/I= 6% vs N= 1%, p < 0.001). Unsurprisingly, patients in the F group underwent more renal replacement therapy (F= 27% vs R/I= 3.5%, N= 2%, p < 0.001).

Median length of stay in ICU for R/I (14 days, IQR 7.5–28.5) and F (15 days, IQR 8 –26) is longer than that of N patients (11 days, IQR 6–19.5). Patients in the R/I and in the F groups showed higher ICU mortality (F 25.5%, R/I 27% vs N 9%, $p < 0.001$) as well as higher 6-month mortality (F 40%, R/I 28% vs N 17.5%, $p < 0.001$) and higher incidence of 6-month unfavorable outcome (GOSE≤4 in F 62%, R/I 66% vs N 47.5%, $p < 0.001$).

CONCLUSION. The development of AKI seems to be an early phenomenon, associated with the presence of previous CV history. It is associated with increase LOS, ICU mortality and 6-month unfavorable outcome.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000838

INTRODUCTION. In patients with Traumatic Brain Injury (TBI), impaired cerebrovascular autoregulation (CAR), decreases the ability of the brain to tolerate the burden of elevated ICP [1]. This burden is defined as the combination of the intensity and duration of events of elevated ICP. The association with the 6-month Glasgow Outcome Score (GOS) can be visualized with the color-coded plots proposed by Güiza [1]. In these plots, impaired CAR shifted the transition curve, which divides good ad poor neurological outcome, towards lower ICP values. This methodology can be applied to other neuro-monitored patients. The proposed study aimed to investigate whether CAR status plays a role in determining the ability of the brain to sustain elevated dose of ICP after subarachnoid hemorrhage (SAH).

METHODS. Retrospective analysis of ICP and mean arterial blood pressure (MABP) time series of 98 patients with severe-grade SAH, prospectively collected in two large European centres, (Innsbruck University Hospital (Austria); San Gerardo University Hospital, Monza (Italy)). The methodology proposed by Güiza [1] was used to visualize the association of the dose of ICP with outcome, for active and passive CAR.

RESULTS. The transition curves resulting from the evaluation of ICP dose events during passive and active CAR presented a negligible difference with the "all-events" curve, Fig 1. This may be due to the low prevalence of prolonged elevated ICP, the median [IQR] percentage of ICP monitoring time above 20mmHg was equal to 6.2 % [0.4 - 6.5], where CAR status may have a stronger impact on outcomes.

CONCLUSION. No difference in the association between the ICP dose burden and outcome could be demonstrated for active and passive CAR. In absence of prolonged intracranial hypertension other factors, apart from CAR status, may have a more important role in determining the outcomes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000934

INTRODUCTION. Estimation of patients' neurological prognosis after cardiac arrest is challenging and reliable prediction of the outcome can usually be made only after few days. Lack of slow waves in electroencephalogram (EEG) has been associated with hypoxic ischemic encephalopathy [1]. Quantification of slow wave activity offers a potential tool for early prediction of neurological outcome in comatose cardiac arrest survivors.

OBJECTIVES. To investigate the association between continuously measured frontal slow wave activity and neurological outcome at six months after cardiac arrest.

METHODS. In this study (NCT03485781), data from 66 comatose cardiac arrest survivors treated in the intensive care units (ICUs) of Helsinki University Central Hospital and Oulu University Hospital was used. EEG was recorded from the ICU admission until 48 h from return of spontaneous circulation (ROSC) using self-adhesive disposable forehead electrode and wireless measurement device. The slow wave activity was determined by calculating the low-frequency (< 1 Hz) power of EEG. The low-frequency activity at different time points after ROSC was statistically compared between patients with good and poor neurological outcome using Wilcoxon rank sum test. The outcome was defined by evaluating the patients' neurological recovery at six months using Cerebral Performance Category (1-2 = good outcome; 3-5 = poor outcome).

RESULTS. The patients with poor outcome (N = 26) had less frontal slow wave activity in the early phase of ICU admission compared to the patients with good outcome (N = 40). The median low-frequency power at 6-15 h after ROSC in patients with poor outcome was 48.4 ± 9.7 % (mean ± std) compared to the median low-frequency power in patients with good outcome. The difference between groups was statistically significant until approximately 15 h from ROSC.
CONCLUSION. Frontal EEG slow wave activity may be a suitable objective measure for the early prediction of neurological outcome in comatose cardiac arrest survivors.

Intracranial pressure and cerebral oxygenation at different levels of PaCO2 in critically ill patients with acute cerebral aneurysm rupture and high risk of cerebral vasospasm

A. Solodov[1], ED. Mekhia Mekhia[1], S. Petrikov[1], V. Krylov[2]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001454

INTRODUCTION. To prevent of secondary ischemic brain damage in critically ill patients with acute cerebral aneurysm rupture, a level of PaCO2 should be adjusted to achieve the best cerebral oxygenation with stable intracranial pressure (ICP). Presently the maximum safety level of hypocapnia has not been determined.
OBJECTIVES. To determine intracranial pressure and cerebral oxygenation in different levels of PaCO2 in patients with acute cerebral aneurysm rupture and high risk of cerebral vasospasm.
METHODS. We analyzed the acid-base and gas composition of arterial blood, intracranial pressure, mean arterial blood pressure (ABPmean) and cerebral perfusion pressure (CPP), jugular bulb oxygenation (SvjO2) at different levels of PaCO2 in 30 critically ill patients with acute cerebral aneurysm rupture and high risk of cerebral vasospasm (Fisher III-IV, Hunt-Hess III-IV). In this patients were recorded - 84 cases a decrease PaCO2 ≤ 30 mm Hg. and less (group 1), in 50 cases - PaCO2 30.1-33 mm Hg (group 2), in 36 cases - PaCO2 33.1-36 mm Hg (group 3), in 57 cases - PaCO2 ≥ 36.1 mm Hg (group 4).
RESULTS. Different levels of PaCO2 were due to different minute ventilations (MV) (Table 1). The medians of SvjO2 at different PaCO2 levels were within normal limits, but the severe hypocapnia (≤ 30.1 mmHg) was accompanied by episodes of a decrease SvjO2 ˂ 60%. The back side of the PaCO2 selection for prevention of cerebral blood flow disturbance is the increase of ICP during the elimination of hypocapnia. We identified highest ICP levels with an increase PaCO2 ≥ 33.1 mm Hg and no negative changes in cerebral oxygenation, despite a decrease in CPP. The minimum levels of cerebral perfusion pressure were noted in group 3 (Table 1).
CONCLUSION. Moderate hyperventilation with a decrease PaCO2 to 33.1 mm Hg. can be a safe method for the ICP correction in critically ill patients with acute cerebral aneurysm rupture and high risk of cerebral vasospasm. PaCO2 ˂ 30.1 mm Hg increased risk of cerebral desaturation and cerebral metabolism disorders.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000528

INTRODUCTION. Objectives: To analyze the relationship between serum inflammatory cytokines in adult patients in the first hours of severe trauma, and hospital mortality.
METHODS. Prospective cohort study. Consecutive adult patients with trauma admitted to a teaching hospital - reference in trauma (traffic accidents or violence) care. In all patients the serum cytokines were collected within the first 6 hours of trauma. Descriptive statistics and univariate analysis were performed.
RESULTS. It were studied 40 patients (mean age 33.8y, 77.5% male, APACHE 21.0); 77.5% traffic accidents, 15% violence, 7.5%

falls/ work accidents, 32.5% had AKI (7% needed dyalisis), 15% ARDS. Mean ICU and hospital LOT of 11.8 and 25.2 days, respectively. Hospital mortality of 15%. Higher serum cytokines IL-1, IL-6 and TNF where inversely related to hospital mortality (table 1 and figure 1).
Figure 1
CONCLUSION. In adult patients with severe trauma (most of them with brain trauma), the serum level of inflammatory cytokines (mainly IL-1, IL-6 and TNF-α) in the first 6 hours of trauma is inversely related to hospital mortality.

Epidemiological patterns for early onset and late onset bacteremia after trauma

TY. Kim, L. Jeong Woo, L. Hak-Jae, H. Suk-Kyung
Dept of surgery, division of critical care and acute care surgery, Asan Medical Center, Seoul, Republic of Korea
Correspondence: T.Y. Kim
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001724

INTRODUCTION. Bacteremia is a major nosocomial infection problem in view of its high mortality.
The aim of this study was to identify risk factors and to describe epidemiological patterns for early onset (EOB) and late onset (LOB) bacteremia after trauma
METHODS. All trauma patients admitted to our surgical intensive care unit (SICU) and general ward (GW) from January 2011 to December 2015 were retrospectively enrolled. The following information was collected for each patient and recorded in a computer database: demography, severity of trauma according to the Injury Severity Score (ISS) and each abbreviated injury score (AIS), severity of coma according to the Glasgow Coma Scale (GCS), presence of shock and transfusion. Early onset bacteremia was defined as EOB when onset occurred within 7 days after trauma, and late onset bacteremia was defined as LOB when appearing after 7 days from trauma.
RESULTS. Thirty-seven patients developed bacteremia during their hospital stay: 9 (24.3%) EOB, 28 (75.6%) LOB, and 4 (10.8%) patients developed both of them. Sixty-eight events of bacteremia happened to these patients: 10 (14.7%) EOB and 58 (85.3%) LOB. Gram-positive cocci were isolated more frequently than Gram-negative bacilli in both groups. Gram-positive cocci were more frequently isolated in EOB than in LOB: otherwise, there was no statistical significance (80% versus 67.2%, $P = 0.702$). Central line associated blood stream infection (CLABSI) and surgical site infection (SSI) were the most common identified source for LOB. The risk of EOB was significantly increased by the presence of pelvic and liver injury on arrival in emergency department (ED), transfusion within the first 24 hours after trauma. Presence of liver and pancreas injury, gastrointestinal tract perforation and shock represented risk factors for LOB. LOB had a different pattern and their risk was significantly increased by ISS ($P = 0.002$) and abdominal injury score ($P = 0.003$).
CONCLUSION. Presence of pelvic and liver injury on arrival in ED and transfusion within the first 24 hours after trauma appear a significant risk factor for EOB. Scoring with the ISS and intra-abdominal injury at admission to ED appears a useful tool for identifying trauma patients at increased risk of LOB.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001435

INTRODUCTION. The burned patient is one of the most complex cases and Intensivist can face, with a high mortality rate and multiples connotations on the hemodynamics of the patient. Those with Inhalation Injury have a worst prognosis, typically associated with respiratory complications. However, the possible effects of inhalation in the cardiac conduction and therefore in the development of critical arrhythmias have been less studied.
OBJECTIVES. To Study the possible association of toxic gas inhalation with the development of critical arrhythmias in burned patients with Inhalation Injury.
METHODS. Retrospective observational study performed in the Critical Burn Unit (January 2017 to February 2019) including 16 patients over 18 years old with a high suspicion or confirmed Inhalation Injury. Mean and standard deviation were used for normal quantitative variables and median and interquartile range in the opposite case. Qualitative variables were presented by absolute and relative frequencies.
RESULTS. We studied 152 patients admitted in our Critical Burn Unit of the La Paz Hospital in Madrid Spain from January 2017 until February 2019. 16 patients (10.5%) with high suspicion or compatible criteria with Inhalation Injury, with initial carboxyhemoglobin over 4% at admission. Mean age was 59 (± 17.1), Median burned TBSA was 17% (RI 6-36%), Median APACHE II was 13 (RI 10-19), Median ABSI score was 7 (RI 5-9). The initial Carboxyhemoglobin at the burn site was not registered in the majority of the patients, so we couldn't study it's correlation with the evolution of the patients. 65% of the patients received treatment with 5grs of hydroxocobalamin before

Hospital Admission. The median initial levels of Carboxyhemoglobin at admission in the ICU was 13 (RI 5-22), mean Lactate at admission was 4.2. 31% of patients had corrected QT interval prolongation. Troponin I was measured only in 8 patients, 75% had elevated levels in the first 24hours. Mortality was 25% (4 patients), 2 patients developed Ventricular tachycardia followed by cardiac arrest.
CONCLUSION. There might be correlation between toxic gas mediated Inhalation Injury and electrocardiographic disorders as suggested by the prolongation of the Corrected QT interval, which represents a good indicator of myocardial repolarization, elevation of Troponin I levels and the development of cardiac arrhythmias. Further studies must be performed.

Pre-empting In-Hospital Cardiac Arrests

A. Doolan, J. Clarke, S. Clarke, C. Broe, M. Power, G. Curley
Anaesthesia and critical care, Beaumont Hospital, Dublin, Ireland
Correspondence: A. Doolan
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000161

INTRODUCTION. There continues to be a significant mortality burden associated with cardiac arrests. The percentage discharged home remains low. (5 to 27%) [1,2] A failure to recognise clinical antecedents and involve intensivists has been found in previous studies. [2, 3]
OBJECTIVES. 1. Identify the frequency and outcomes of in-hospital cardiac arrests.
2. Asses were the cardiac arrests preceded by clinical antecedents in the 24 hours before arrest and were they recognised and acted upon
METHODS. An audit was performed of all in-hospital cardiorespiratory arrests in 2017. Cardiac arrests in ED, endoscopy, theatre and ITU were excluded. In the 24 hours before arrest, all clinical antecedents to suggest deterioration were noted.
RESULTS. 37 of the 23,398 inpatients had cardiorespiratory arrests. The median age-adjusted Charlson's comorbidity index (CCI) was 6. The median age was 72. (IQR 81-63) In the 24 hours before arrest, the 4 most common symptoms and signs were dyspnoea, tachypnoea, agitation and arrhythmias. 42% of patients had an EWS of 7 or higher. 45% had RR >/= 22. 42% had HR >/=100. 32% had SBP </= 90mmHg. 33% had 02 saturations </= 92%. **In the previous 24 hours, 32% of patients did not have a registrar or consultant review. (Table 1.)** Only 11% had an ICU review. Only 22% had ABGs performed. 67% of arrests occurred after hours. **(Table 2.)** 65% had ROSC and 30% were discharged home.
CONCLUSION. Patients who proceed to cardiorespiratory arrest during their admission have a high pre-existing morbidity burden and one third are expected to die within the year. The rates discharged home after cardiorespiratory arrest remain low. Similar to previous studies, failure to recognise clinical antecedents and involve senior doctors and intensivists still occurs. A critical care outreach team is being introduced to help address this concern.

The clinical application of Neurone Specific Enolase to prognosticate neurological recovery in cardiac arrests patients

C. Maher[1], J. Worthy[2], R. Grey[2], O. Boyd[2]
[1]Brighton & Sussex Medical School, Falmer, United Kingdom; [2]Intensive caure unit, Brighton & Sussex University Hospitals Nhs Trust, Brighton, United Kingdom

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000407

INTRODUCTION. Hypoxic-ischaemic brain injury (HIBI) is a common complication following out of hospital cardiac arrest (OOHCA), and is the cause of death in 68% of patients surviving to ICU admission(1). Prediction of neurological outcome is a multimodal approach, with no singular method giving 0% false positive rate(FPR)(2). Neurone specific enolase (NSE) is a biomarker that positively correlates with poor neurological outcome, with European Resuscitation Council (ERC) guidelines having an NSE cut off of 33μg/L for poor neurological outcome(2). Controversially, recent studies have shown higher thresholds. With new techniques such as targeted temperature management (TTM), previous work gives little indication of the utility of NSE in clinical practice. This study looked retrospectively at the use of NSE in a single centre and describes the predictive value for NSE in prognostication for HIBI post OOHCA.
OBJECTIVES. The Primary outcome was to find an NSE threshold value with 0% FPR for poor neurological outcome at ICU discharge (GCS <7/15, or death due to neurological causes).
METHODS. A retrospective study was carried out on all adults with OOHCA admitted to the Royal County Sussex Hospital ICU between

April 2017-November 2018. NSE levels, TTM, brain imaging, comorbidities, survival and GCS at ICU discharge were recorded. NSE was measured using Chemiluminescent-immunoassay. NSE data was not used for clinical decision making by the ICU team.
RESULTS. 89 patients were admitted with an OOHCA, 59 patients had an NSE measured. NSE was sampled 48-72 hours post arrest. 61% had poor neurological outcome, median NSE was significantly higher in this group than those with good neurological outcome (103µg/L vs 20µg/L, p= 0.001). ROC analysis showed AUC of 0.901, sensitivity 77.8%, specificity 100%, and Yougen's Statistic showed an NSE cut off value of 64.5µg/L. A significant negative correlation was found between NSE and discharge GCS.
CONCLUSION. Our results show that NSE can reliably and safely be used to prognosticate for HIBI in clinical practice after an OOHCA, an NSE over 64.5µg/L indicates poor neurological outcome with 0% FPR. Furthermore we suggest that ERC guidelines need updating.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000713

INTRODUCTION. EWS allows detection of patients at clinical risk of deterioration in order to establish an early and adequate response.
OBJECTIVES. To implement a system for early detection of patients at clinical risk in conventional ward based on the NEWS-2 score, using the SBAR tool as a communication system.
METHODS. A unicentric and descriptive pilot study. Period: Weekends (Friday 4 pm to Monday 8 am) and bank holidays from 13th December 2018 to 14th January 2019. Inclusion criteria: Patients allocated in a medical ward (pilot ward) that deteriorate their condition during the period of study. Exclusion criteria: Palliative patients with indication of no reanimation orders. The score used NEWS-2 (Figure 2). Response protocol to alerts is shown in figure 1.
RESULTS. 20 patients included: 4 with NEWS-2 ≥ 7; 2 patients with NEWS-2 = 5-6 and 14 paties with NEWS-2 ≤ 4. 3 patients recorded a determination of 3 points in at least one parameter. NEWS-2 score was correctly performed in 100% of cases.9 patients met the alert criteria. 78% of the cases being high risk (NEWS ≥ 7 and/or value 3 in any individual parameter).Medical team activation was adequate in 67% of cases; in the other 33%, despite register a score of 3 points in only one parameter, the alert protocol was not activated.The time until medical evaluation was adequate in 67% of the casesA single determination of 3 points in one variable was more common in respiratory system variables: 67% of the cases of arterial oxygen saturation and in 45% of the cases the respiratory rate.No patient required admission to ICU, and clinical deterioration was solved with measures implemented in the ward. We indicated no reanimation orders In 2 patients (both with NEWS2 ≥7) after evaluation. These 2 patients died despite treatment implemented.
CONCLUSION. Our EWS system could be a very useful tool to detect patients at risk of deterioration in a high percentage.Protocol deviations were related to no medical team activation and delayed response times.Measures to improve training in the ward teams could improve these results.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000736

INTRODUCTION. ECG is simply method accesible in prehospital care and is commonly used in management of OHCA. Previous studies was focused mainly on ST elevation. Value of ECG after OHCA could be influenced by haemodynamic instability, acido-basis changes and hyposaturation after resuscitation.
METHODS. Observation retrospective study from prospective OHCA registry of Cardiac Arrest Center (CAC). It was described different pathologies and its frequency immediately after ROSC and after Hospital Admission and their relation to coronarography findings and finaly diagnosis.
RESULTS. It was included 146 patients after OHCA with Restitution of Spontaneous Circulation (ROSC). Their ECG was provided after OHCA and than after Admission to Hospital. ST elevation was presented by 52% of patients after ROSC and STEMI diagnosis was confirmed by 65,8% of patients (senzitivity 66%, specificity 96% for STEMI). ACS was confirmed by 68,4% of this patients and signifficant Coronary Artery Disease (CAD) by 91,7% and percutaneous coronary intervention (PCI) by 73,3% (patients underwent coronarography).
ST elevation were presented by 36% of patients after Admission, diagnosis of STEMI confirmed by 75,5% (senzitivity 75%, specificity 89% for STEMI), ACS was confirmed by 75,5%, significant CAD by by 93,2% and PCI was provided by 77,3% of patients. Between ROSC and Admision ECG is significant difference in STE elevation incidence (p=0,009) and QRS latitude (p=0,003). We observe no significant diferences between both groups in incidence of ACS, of significant CAD, PCI and systolic blood pressure. Time between both curves was median 60 min,(IQR 25-75) 45-90 min.
Left bundle branch block (LBBB) was presetend by 9,6% of patients after ROSC and 11,6% after Admission and has low sensitivity and specificity for STEMI and ACS. Incidence of STEMI is 7,14% after ROSC and 11,8% after Admisssion. ACS is present by 21,4% after ROSC and 17,6% after Admission, significant CAD by 62,5% and 75%.
ST depression are by 24,8% of patients after ROSC and 27,8% after Admisssion, sensitivity and specificity for ACS is low (ACS by 36,1% after ROSC and 45,7% after Admission, significant CAD by 79,2% after ROSC and 80,6% after Admission and PCI was provided by 52,4% and 51,6%). Normal ECG has low incidency after ROSC (5,5% after ROSC and 6,85% after Admisssion). ACS was confirmed by 50% of patients after ROSC and 0% after Admission. (sensitivity for ACS exclusion 100%, secificity 56% after Admisssion). Significant CAD was by 100% after ROSC (if coronarography was provided) and 12,5% after Admission. PCI was provided by 100% and 20%.
CONCLUSION. ST elevation has for STEMI diagnosis no significant higher sensitivity, if they remain after Admisssion and both ST elevation groups have high incidency of significant CAD and PCI. ST elevation after ROSC has high specificity for STEMI. Normal ECG after ROSC has are not well for ACS exclusion and normal ECG after Admission is very high sensitive for ACS exclusion. LBBB and ST depression has low sensitivity and specificity for ACS and CAD.

CPR related trauma from autopsy reports, their incidency and seriousness

J. Karasek[1], B. Blankova[2], T. Bartes[3], D. Nahalka[3], J. Seiner[1], M. Strycek[1], R. Polasek[1], T. Adamek[2], J. Hladik[4], P. Ostadal[5]
[1]Cardiology, Hospital Liberec, Liberec, Czech Republic; [2]Forensic medicine, Hospital Liberec, Liberec, Czech Republic; [3]3. medical faculty, Charles University, Prague, Czech Republic; [4]Forensic medicine, Faculty Hospital Kralovske Vinohrady, Prague, Czech Republic; [5]Cardiology, Na Homolce Hospital, Prague, Czech Republic
Correspondence: J. Karasek
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000739

INTRODUCTION. CPR related injuries were not properly observed since were established new guidlines for resuscitation (CPR) 2015 with stronger recomandation for bystader and topless CPR. Data were not objectivised by any scale in effort to establish seriousness of injury.
OBJECTIVES. To describe incidency and seriousness of injuries related to CPR and compare it by gender, bystander CPR, out vs. in-hospital CPR and try identify factors for seriousness of injury.
METHODS. Multicentric study, retrospective analysis of autopsy reports of patients after CPR, cardiac arrests caused by trauma were excluded. We describe damage of particular organs and we objectivised the most serious injury with Abbreviated injury scale (AIS)and summary of all injuries with New injury severity score (NISS).
RESULTS. We have enroled 701 autopsy reports , traumatic cardiac arrests were excluded. We have analyzed 628 autopsies: 80,4% men, age median 67 years, out of hospital cardiac arrests 89,2%, bystander CPR 56,8% and cardiac ethiology 78,2%. Ribs injury were founded by 94,6%, injury of lung by 9,9%, sternal injury by 62,4%, liver by 2,5% and spleen by 1,8%. Mechanical CPR was provided by 11,5%. Median of the most serious injury was 3 (serious by Abbreviated injury scale) and median of summry of injuries was 13 by NISS-low risk of fatal injury. By out of hospital cardiac arrest was hifgher incidency of pleural injury and thorax vessles injuries without influence on total seriousness of injury compared to hospital cardiac arrests. Bystanders provided CPR had similar incidency and seriousness of injury like CPR provided only by professional emergency stuff, also by mechanical chest deviced CPR we have observed no differences comapred to manually. Women are significant older (p=0,0001), frequency of their injuries are similar to men, but seriousness of their injuries by NISS is significant higher (p= 0,01). Patients with life threatening injury (AIS 4 and more) has similar baseline profil to their without injury (AIS 0), exept of significant higher cardiac etiology of cardiac arrest by AIS 4+.
CONCLUSION. Incidency of CPR related injuries from autopsy reports is very high, but life threatening injuries create only 3%. The highest incidency have injuries of thoreax sceleton, especially ribs. There is no difereneces if patients were resuscitated by bystander or by mechanical chest devices compared to those by professional stuff or manually. Women has similar frequency of injuries like men, but significant more serious by NISS

Cardiac Manifestations of Pheochromocytoma: A review of the literature

A. Kastoris, F. Georgiou, C. Timiliotou-Matsendidou
Intensive care unit, Limassol General Hospital, Kato Polemidia, Cyprus
Correspondence: A. Kastoris
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000769

INTRODUCTION. Pheochromocytoma represents a rare tumour that originates in chromaffin tissue, producing distant effects by secretion of catecholamines. Usual clinical manifestations include headaches, palpitations, hyperhidrosis and hypertension. Cardiac manifestations of the disease are rare and throughout the literature sporadic cases of phaechromocytoma mimicking acute coronary or Takotsubo syndrome have been reported. Acute cardiac manifestations in these patients, may be dramatic and even life threatening.
OBJECTIVES. A review of the literature regarding cardiac manifestations in patients with pheochromocytoma mimicking acute coronary syndrome, cardiogenic shock or Takotsubo syndrome. In the review of the literature we included a case reported in our ICU.
METHODS. A review of the literature was conducted using the key words 'pheochromocytoma' and 'cardiac manifestations', 'acute coronary syndrome', 'Takotsubo syndrome', 'pulmonary oedema' in PubMed, Scopus, and Google Scholar databases. Published case reports and series written in English were included. Abstracts were not included in the review. Data was extracted regarding the presentation of symptoms such as pulmonary oedema, Takotsubo syndrome, ECG changes consistent with acute coronary syndrome, elevated cardiac enzymes and cardiogenic shock in patients with pheochromocytoma. The second part of the study includes a case reported in the ICU of our hospital of a 45-year-old patient, with cardiogenic shock due to pheochromocytoma.

RESULTS. A total of 91 studies were included in the review of the literature, 2 case series and 89 case reports, with a total of 128 patients. The mean age of the patients was 46 years of age with ages ranging between 17 and 89 years of age with 1 case report not reporting the age. Seventy nine of the 128 patients were female (62%). Forty nine of the 128 patients (38%) presented symptoms of pulmonary oedema, 38 of the 128 patients (30%) Takotsubo syndrome, 38 of the 128 patients (30%) cardiogenic shock, 101 of the 128 patients (80%) ECG changes consistent with ACS, and 45 of the 128 patients (35%) presented cardiac enzyme elevations. Only 5 of the 128 (4%) patients presented all the above symptoms. A 45-year-old patient admitted in our ICU with chest pain, emesis, and nausea, and a history of smoking, presented all the above symptoms of pulmonary oedema, cardiogenic shock, Takotsubo syndrome, ECG changes consistent with acute coronary syndrome and cardiac enzyme elevation. After percutaneous coronary angioplasty and exclusion of acute coronary syndrome, abdominal CT revealed pheochromocytoma.
CONCLUSION. It is rare for pheochromocytoma to present all cardiac manifestations of pulmonary oedema, cardiogenic shock, Takotsubo syndrome, ECG changes consistent with ACS, and elevated cardiac markers. Although reviews of the literature exist regarding the presentation of Takotsubo Syndrome in pheochromocytoma, no other review has presented all possible cardiac manifestations of pheochromocytoma. Every clinician should be aware of the possible presence of pheochromocytoma especially in middle aged, female patients, with negative angiography results, however rare the occurrence.

Severe acute liver failure: Epidemiology and prognosis

D. Arias-Verdú, G. Seller-Pérez, J. Barrueco-Francioni, C. Aragón-González, M. Lebrón-Gallardo, A. Muñoz-López, G. Quesada-García, M. Herrera-Gutiérrez
Intensive care, Regional Hospital of Malaga, Málaga, Spain
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001143

INTRODUCTION. .
OBJECTIVES. To analyse the epidemiology and prognosis of acute liver failure in patients admitted to the intensive care unit (ICU).
METHODS. Third level ICU covering the provinces of Malaga and Almeria (2,350,000 inhabitants) for liver transplantation. This retrospective cohort study comprised all patients admitted to our unit with acute liver failure between 2010-2016, excluding acute-over-chronic failure and subacute decompensated failure after a first admission. All patients or their relatives signed the consent form for use of their data. The results are described as mean (standard deviation), median (quartiles) or %. Given the low number of patients we applied non-parametric tests and no multivariate analysis could be performed.
RESULTS. There were 27 cases, 66.7% women, with an average age of 34.1±13.1 years. The failure was hyperacute in 33% of cases, acute in 37% and subacute in 29.6%. The cause was related to use of medicines in 22.2%, toxic in 14.8%, virus in 7.4%, pregnancy in 7.4%, Wilson in 3.7%, other in 29.6% and cryptogenic in 14.4%. Biopsy was performed before the OLT in 29.6% and in the extracted organ in 51.9%. The results confirmed the suspected diagnosis in 15.4%, did not agree with the initial diagnosis in 22.2%, and suggested the diagnosis although not definitively in 57.7%. Hepatic clearance was used in 96.3% of the cases and 66.7% received a transplant during their admission to the ICU.
The ICU stay was 10 (4-16) days and the hospital stay was 25 (18-35). ICU mortality was 18.5% (5 cases) and hospital mortality 22.2%. None of the variables analysed was related to mortality but the low number of cases detracts from this analysis. However, mortality for transplanted patients was 11.1% vs. 33.3% in non-transplanted patients (ns).
CONCLUSION. : Severe liver failure is a condition with a low incidence but nevertheless a very high mortality, especially among patients who do not receive a transplant, which can reach one third of cases. These results emphasize the convenience of treating these patients in reference centres with the possibility of carrying out an emergency transplant. The aetiology of the liver failure is still difficult to determine in many cases and biopsy does not prove conclusive in a high percentage of cases.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001574

INTRODUCTION. The effects of reaching nutritional caloric goals and negative fluid balance on outcomes have not been clearly demonstrated in critically ill patients. Electronic recording systems (ERS) are widely used and may help to answer this question.
OBJECTIVES. Our hypothesis was that achieving the nutritional caloric goals along with a negative fluid balance would have a positive effect on survival.
METHODS. In our two centered retrospective study, data were reviewed from the ERS (Metavision) between 2015 and 2018. 2814 critically ill patients ≥ 18 years of age and who had been hospitalized ≥ 72 hours were included. Predicted body weight on admission day and data on fluid balance, duration of mechanical ventilation, length of ICU and hospital stay and mortality were recorded. Patients target calorie were calculated from the average of Harris-Benedict and Schofield formula. Last day NUTRIC scores were also noted. Caloric balance on third day was recorded as positive if the target value was achieved and as negative if not. Fluid balance was recorded as positive if balance was ≥ 500 and negative if < 500 according to the total balance on third day; hence, balance-negative, balance-positive, calorie-negative, and calorie-positive groups were formed.
RESULTS. There were no differences in demographic data between the groups.
Calorie-positive and negative-groups did not differ significantly in terms of mortality.
CONCLUSION. Caloric intake and fluid balance on the first three days does not appear to have an impact on mortality.

Table 1 (abstract 001574). See text for description

Groups and Mortality	
	Mortality (%) (number)
Calorie + Balance -	39.2 (249/636)
Calorie - Balance +	34.1 (307/901)
Calorie - Balance -	36.2 (199/550)
Calorie + Balance +	38.5 (276/717)

Managing critically ill cirrhotic patients admitted in the ICU. The burden of ACLF

E. Marques Mendes, R. Corga Da Silva, P. Moura, J. Caldeiro, S. Oliveira, A. Bal
Departamento de medicina crítica, Unidade Local de Saude do Alto Minho, Viana do Castelo, Portugal

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001599

Correspondence: E. Marques Mendes

INTRODUCTION. It is a common known fact, that cirrhotic patients have worse prognosis, with high mortality associated with their decompensations. Admitting these cases in the intensive care unit (ICU) has been longed discussed, weighting the cost-effectiveness, and the adequacy of resources. Until the canonic study, medical community didn't understand which patients would progress worse, and for what reasons. The definition of the Acute on Chronic Liver Failure (AoCLF) as an individual syndrome, its diagnostic CLIF SOFA and the prognostic CLIF-C ACLF scores where an important improvement. Still, to this day, there is no predicting wich AoCLF will die irrespective of medical intervention, and witch will benefit from monitoring, early identification and early organ support. Studies also suggest that AoCLF development and evolution is independent of the identification of a precipitating event. In our study, we decided to evaluate every cirrhotic patient admitted to the ICU, evaluating if the decompensating event was identified, and the mortality rate (comparing it with the prognostic mortality rate calculated).

OBJECTIVES. To prospectively assess and characterize all cirrhotic patients admitted in the Intensive Care Unit of a secondary hospital and evaluate decompensation factors and mortality rates.

METHODS. All cirrhotic patients over 18 years, were prospectively enrolled between 01/01/2017 to 31/03/2019. For each patient, grade of ACLF and specific ICU prognostic scores were collected at the time of ICU admission. All cirrhotic patients over 18 years, were prospectively enrolled between 01/01/2017 to 31/03/2019. For each patient, grade of ACLF and specific ICU prognostic scores were collected at the time of ICU admission.

RESULTS. A total of 32 cirrhotic patients were admitted in intensive care unit, of which 71.9%(n=23) were male and the median age was 55.38 (±8.85) years. The majority (53.1%; n=17) of these patients died during ICU hospitalization. One-year mortality rate was 33% (n=5). Mean APACHE score was 26.8 and SAPSII score was 59.8. The CHILD score at admission was elevated, and 68.8%(n=22) had a C stage. Mean CLIF-SOFA was 11.4. A total of 81.3% had criteria of AoCLF, with 7.7% grade 1, 30.8% grade 2 and 61.5% grade 3 criteria. Mean CLIF-C-SOFA was 54.1. In only 2 patients (6.3%) there was no trigger identified. The trigger factor mostly identified was infection (56.3%; n=18), particularly spontaneous bacterial peritonitis and nosocomial pneumonia.

CONCLUSION. This is a population of adult patients, with high severity scores, that were predicted to have high risk of short-term mortality. Their survival is dependent of diagnosis, intensive monitoring and early organ support, with the difficult decision of admitting and treating them. The mortality rate observed proves that this syndrome, even in CHILD C score patients, doesn't necessarily mean short term fatality, since the mortality observed was not as high as it would be expected. 46.9% of patients survived the ICU stay, even though the majority of patients (61.5%) where grade 3 AoCLF (with correspondent 31.3% ICU survival).

INTRODUCTION. Drowning is a common cause of accidental deaths. Complication rate and mortality of patients requiring intensive care support are high. The aim of our study was to reveal the clinical course and treatment efficiencies of a limited number of patients in the intensive care unit due to the drowning.

METHODS. Patients who were admitted to the intensive care unit for >24 hours and who met the inclusioncriterias between January 2010 and August 2018 were examined retrospectively.

RESULTS. Thirteen of the 103 patients needed intensive care who admitted emergency service. Five (38.4%) of the patients died. Steroids were used in 6 patients (46.2%) but no statistically significant difference was found in terms of mortality (p=0.592). The presence of diffuse cerebral edema 5(38.5%) was associated with a statistically higher mortality rate compared to 6 (46.2%) patients with normal findings (p=0.003). Mechanical ventilator supports were provided with SIMV mode in 9(69.2%) patients and APRV mode was used in 4 (31.8%) patients. According to our clinical observations, the radiological improvement was observed in patients with APRV mode (Table 1).

CONCLUSION. The effect of steroid and prophylactic antibiotherapy on mortality was not determined. APRV can provide the recruitment of consolidated lung areas and prevent the decruitment of alveoli. These effects should be kept as a mode of choice in cases of severe alveolar and interstitial edema in drowning cases. Mechanical ventilation strategies, the degree of metabolic acidosis at admission and the neurological status of the patient may be considered as variable clinical parameters that may affect patient outcome.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001123

INTRODUCTION. Aneurysmal subarachnoid hemorrhage (SAH) is a worldwide health burden with fatality as permanent disability.To know risk mortality factors is important,with particular regard to the identification of potentially avoidable factors, in order to reduce SAH mortality.

OBJECTIVES. To assess the mortality risk factors in patients with subarachnoid hemorrhage (SAH), admitted in a neurotraumatic ICU

METHODS. Prospectively collected data of patients admitted from October, 2013 to December 2017 to a 10-bed Neurotraumatic ICU. We analyzed: main diagnosis at admission; demographic data including sex and race; neurological data (clinical examination, pupils reactivity and size, and Glasgow Coma Score: GCS; localization and aneurysm size; presence of intracranial hematoma (ICH); presence and volume of intraventricular bleeding; days to develop vasoespam; development of DCI; Fisher scale, Modified Fisher scale, Hunt and Hess scale, Word Federation of Neurosurgeons (WFNS) scale; presence of vasoespasm in doppler or arteriography; delayed of admission in ICU; treatment of the aneurysm; complications, including infections; Glasgow Outcome Scale (GOS) at ICU discharge and 6 months after ICU discharge and several other risk factors. In order to identify factors that maintain independent association with mortality, a multivariate logistic regression analysis were performed. It was considered significant if $p \leq .05$.

RESULTS. Among 83 SHA admitted patients, 18 (36.44%) out of 64 patients died. In a univariate analysis, age, APACHE II, SOFA and GCS at ICU admission, GCS at site and at emergency room, to be oriented and alert, isochoric pupils, posterior cerebral artery aneurysm, decompressive craniectomy, dead after treatment, hidrocephalus, mechanical ventilation > 7 days, ICH, frontal ICH, internal carotid artery aneurysm ICH, rebleeding within 72 hours, McCabe, GOS at ICU discharge and 6 months after ICU discharge, Fisher scale, Hunt and Hess scale and WFNS scale were statistically significant. Among the patients who died versus survivals, ICU stay was not significantly different (Table 1a y 1b). The independent risk factors associated with mortality were: isochoric pupils OR (95% CI): 0.118 (0.022 ; 0.644), frontal ICH OR (95% CI): 7.121 (1.577 ; 32.159), GCS at ICU admission OR (95% CI): 0.824 (0.719 ; 0.944) (Table 2).

From the logistic model also summarized inTable 2, a prediction score was obtained (require further validation) (Figure 1):*SHA mortality Score=-2.143 X Isochoric pupils + 1.963 X Frontal ICH-0.194 X GCS at ICU admission*

CONCLUSION. In SHA admitted to a neurotraumatic ICU, risk factors that were independently associated with mortality were: isochoric pupils , frontal ICH and GCS at ICU admission. A mortality prediction score was estimated.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001430

INTRODUCTION. External ventricular drainage (EVD) is frequently used in different groups of patients in neurocritical care. EVD related infection (ERI) is a common complication in these patients, and it can worsen their condition.
OBJECTIVES. Our aim in this study is to analyze which factors are associated with the development of ERI and its effects in the prognosis of these patients.
METHODS. A retrospective, observational study including fifty one patients with EVD was performed during 2017 and 2018. Data collected were analyzed using SPSS Statistics v.24.
RESULTS. Fifty one patients (51% men) with a mean age of fifty eight (58 ± 13 years) and a APACHE II mean score of thirteen (13 ± 6). Seventeen patients were diagnosed of ERI (34%) The mean length of stay was 50 +- 25 days in those with infection and 25 +- 14 p< 0,05 (IC 95% 8-41) in those without it. Total days with EVD were 15 +- 10 in patients without ERI and 28 +- 14 days in patients without ERI (IC 95% 4-20), with significant association (p=0,03). 23.5% were tunnel EVD and were placed in the operating room (OR) (ERI in 50%) and the rest (78.5%) were intraventricular catheters placed bedside in the ICU (ERI in 28,2%), without significant association. Regarding the relationship between infection and the number of handlings (opening for treat Intracranial hypertension (IH) or to provide antibiotics). In 29.4% of patients we used antibiotic through the EVD and in this group we diagnosed ERI in 100% of patients. Mortality was 35,5% in the group diagnosed with ERI and 29.4% in the other group, with no significant association between the two groups.
CONCLUSION. ERI is a common complication in patients with EVD. In our study this was associated with more days needing a EVD and increased length of hospital stay. However mortality was not different between groups. Despite no significant differences, it seems that tunnel EVD and handling of these drainage system are associated with a higher infection rate. Further studies with larger sample size are necessary to identify risk factors that have impact in the prevalence and development of EVD related infections.

INTRODUCTION. External ventricular drainage (EVD) is frequently used in different groups of patients in neurocritical care. EVD related infection (ERI) is a common complication in these patients.
OBJECTIVES. In this study, we try to determine the prevalence of external ventricular drainage related infections in our ICU, just as the demographic characteristics of the patients.
METHODS. A retrospective and observstional study in which we included 51 patients during 2017 and 2018 with a EVD insertion as a part of the neurological monitoring and treatment in different neurocritical conditions. Data collected was analyze using SPSS Statistics v.24.
RESULTS. 51 patients were included in the study, 49% were women and 51% were men. The mean age was fifty eight (58 ± 13 years) and the APACHE II mean score was thirteen (13 ± 6). Patients were admitted in the ICU with different conditions. 28 patients (54.9%) had a subarachnoid hemorrhage (SAH), 14 had an hemorrhagic stroke (27,5%), 1 had ischemic stroke (2%), 7 patients (13,7%) had traumatic brain injury (TBI) and 1 had acute hydrocephalus (2%). 23.5% were tunnel EVD and were placed in the operating room (OR) (ERI in 50%) and the rest (78.5%) were intraventricular catheters placed bedside in the ICU (ERI in 28,2%). ERI confirmed with microbiological studies was diagnosed in 24% of patients en in 10% ERI was highly suspected regarding clinical and laboratory data, but without microbiological confirmation. We identified gram positive cocci (GPC) in 70.6% patients with ERI (Staphilococcus epidermidis in 10 patients and Enterococcus faecalis in 2) followed by gram negative bacteria (GNB) in 11.8% (acnetobacter Pitt and pantoea aglomerans). Empiric antibiotic was used in most of cases (94.4% of patients diagnosed with ERI). Mortality was 35,5% in the group diagnosed with ERI and 29.4% in the other group, with no significant association between the two groups
CONCLUSION. External ventricular drainage (EVD) is frequently used in different groups of patients in neurocritical care and its been proved as an useful monitoring tool. However ERI is a common complication in these patients, and can worsen their condition. In this study we had analyze the characteristics of our patients during two years. We believe that ERI rate is high in our ICU comparing with the existing publications. Further studies are necessary to identify the cause or the risk factors of this high rate of these infections.

INTRODUCTION. Increasing bloodstream after angioreconstructive surgery is usually called as cerebral reperperfusion syndrome. It can

manifested by headache, seizures, neurologic symptoms and in severe cases with cortical edema.
OBJECTIVES. Hyrperfusion injury after carotid artery stenting (CAS) may engage disruption of the blood-brain barrier (BBB) by sharp rise of cerebral blood fluid. Recent studies have shown that extravasation of gadolinium visible on magnetic-resonance imaging (MRI) in the subarachnoid space are a marker for early BBB damage.
METHODS. We collected all clinical data of 3 patients with severe and uncommon complications associated with cerebral hyperperfusion syndrome (CPS) after stenting of the left internal carotid artery. Each patient was performed MRI head near after CAS and repeat MRI with gadolinium on a next day, lumbal puncture was made also.
RESULTS. All patients have had aphasia, meningeal syndrome and temperature rising. They were initially with mild aphasia after the CAS and then developed severe aphasia and meningeal syndrome, with a normal blood pressure. MRI head did not show any acute changes. Ultrasound ICA showed non-occluded stent. Their body temperature increased to 39.2℃. Repeat MRI head performed 20 hours post-CAS showed cortical edema of left hemisphere in all patients and leptomeningeal gadolinium-enhanced MRI has been in 2 patients. Cerebrospinal fluid (CSF) revealed a white blood cell count of 96x10^6/L in 2 patients and 1856x10^6/L in 1 patient, that was 90% neutrophils, increase proteins of 1.5g/L and normal glucose. Bacterial culture was negative. These cases with clearly inflammatory CSF and the development of meningeal syndrome in the absence of infection were regarded as aseptic meningitis. MRI with intravenous gadolinium was repeated 48 hours after operating and it shown no increase MR-signal from the subarachnoid space. We repeated the lumbar puncture on the 3st day after surgery to the patient in whose CSF there were 185610^6/L cells and the number of cells in the CFS decreased from 1856 to 4310^6/L. 2 days after CAS their neurologic symptoms were mild and in 3 days it was resolved, patients were discharged home.
CONCLUSION. Thus, our presented clinical observations are very rare complications of the hyperfusion syndrome after CAS. Despite a lot of publications on the reperfusion syndrome, observatios of aseptic meningitis after carotid artery stenting are few; in the worldwide literature we have met one clinical case. These clinical manifestations require further research and develop conception of pathogenesis.

INTRODUCTION. Patients with cardiovascular diseases requiring surgical treatment, especially those that compromise the ascending aorta and crust, often require extracorporeal circulation (ECC), aortic clamping and hypothermia. Such procedures are related to poor perfusion. One of the main concerns of the intensive care team is to avoid secondary neurological damage after a long time of blood hypoflow, which can lead to cerebral edema and seizures. The most common parameters for neurological monitoring would be intracranial pressure and electroencephalogram and cerebral oximetry, however, for non-neurological patients, this information is uncommon and impedes optimal management.
OBJECTIVES. Our objective was to evaluate the cerebral compliance and the neurological condition of ICU patients in the immediate postoperative period of cardiovascular surgery using a new noninvasive intracranial pressure device (NIICP).
METHODS. This new method of noninvasive ICP monitoring consists of a strain gauge attached to a mechanical device that touches the surface of the scalp in the frontoparietal region laterally to the sagittal suture. The device can detect small changes in skull size resulting from changes in ICP, without the need for surgical procedures.
RESULTS. Twenty-two patients were included in this study; 20 required CPB. The mean ECC time was 123 minutes. Of those who required ECC, 8 presented alterations in the ICP curves with low cerebral compliance (P2 / P1 ratio> 1.0) evaluated by the morphological analysis of the curve and 9 were submitted to cerebral hypoflow, 4 of which presented cerebral complacency . Volume optimization and neuroprotection measures, such as MAP between 90 and 100 mmHg, temperature control, target pCO2 between 35 and 40 mmHg, sodium between 140 and 150 meq / dL, glycemic control between 140 and 180 mg / dL, and analgesic with RASS target -3 to -5 were initiated based on this NIICP information for the management of these cases. Among those patients with altered PICNI curves, 7 were discharged from ICU with good clinical condition and Glasgow Coma Scale of 15.
CONCLUSION. The cerebral monitoring of cardiovascular postoperative patients is important to prevent complications and may be a useful tool for acute neuroprotective treatment in the ICU.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001572

INTRODUCTION. Cervical spine injury often occurs after major trauma, impairing motor and sensory impairment and causing complete or incomplete paraplegia or quadriplegia.
Characterization of the patient according to their comorbidities and the presence of complications during hospitalization in relation to the prognosis. Follow-up after hospital discharge with retrospective evaluation of the patient, their evolution as well as their current health status.
METHODS. Statistical analysis were performed with SPSS (version 24). Descriptive statistics were presented as means (M) and standard deviations (SD) for symmetrical continuous variables and medians (Mdn) and percentiles P25 and P75 for skewed continuous variables.
Chi-square tests or Fisher exact tests were used to associate prognostic with independent variables. The association of hospital length of stay (days) and the prognosis, as favorable or unfavorable, with the independent variables, was performed with Mann-Whitney test. Statistical significance was considered for $p<.05$ and marginal significance for $p<.10$.
Telephone interviews were carried out in 20 of the 24 patients and a questionnaire was applied.
RESULTS. A total of 24 patients, mostly males (23; 87.5%), aged from 19 to 89 years old (M=48.88; SD=19.08) with spinal-cord injury (SCI) were enrolled during 2017 and 2019. Cervical was the most frequent lesion (13; 54.2%). Surgical fixation was performed in 19 (79.2%) patients; 4 (16.7%) patients had non invasive ventilation and 11 (45.8%) tracheostomy. TCE was present in 14 (58.3%) patients, infection in 14 (58.3%) and other complications in 19 (79.2%).

Infection was associated with unfavorable prognostic (p=.005); 73.3% of the unfavorable prognostics had infection against 33.3% of the favorable prognostics. Noninvasive ventilation was associated with hospital length of stay (p=.068) (Mdn=20.5; P25=19.0, P75=25.5). Tracheostomized patients were hospitalized during longer periods (Mdn=21.0; P25=15.0, P75=27.0) (p=.006). The follow-up performed in 20 of the 24 patients involved in the study, 37.5% did not present any memory of hospitalization. Post-discharge clinical progression is positive in about 90% of patients.

CONCLUSION. The presence of traumatic brain injury is associated with a worse prognosis. Surgical fixation did not show statistically significant values (p=. 367).

There is association between infection and unfavorable prognosis (p= .006), with significant statistical value. Complications during hospitalization presented slight variations in prognosis, as well as duration of hospitalization.

Tracheostomy showed a statistically significant relationship (p = .006) with duration of hospitalization, but no relation to prognosis (p = .341). These results may have been affected by the size of the sample, by polytrauma or hospitalization complications in ICU.

Altered Airway Ward Round Review: How are we doing three years on?

J. Longo[1], A. Chan-Dominy[2]
[1]Rehabilitation & therapies, Royal Brompton Hospital, London, United Kingdom; [2]Intensive care, Royal Brompton Hospital, London, United Kingdom
Correspondence: J. Longo
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000515

INTRODUCTION. Tracheostomy insertion is known to be associated with significant morbidity and mortality (Cipriano et al., 2015). An Altered Airway Ward Round (AAWR) was introduced to the Brompton Hospital in 2015 as per the NCEPOD (2014) report 'On the Right Trach' in tracheostomy care recommendations. An initial audit in 2015 highlighted that the presence of the ward round had a positive impact on patient safety 3 months post introduction.

OBJECTIVES. The aim of this study was to assess for ongoing improvement in safety, and to measure the number and types of adverse incidents in altered airway patients since the initial audit of the AAWR.

METHODS. A retrospective review was carried out of all adult inpatients with altered airways (tracheostomy, laryngectomy, airway stent) for the period of January 2017-September 2018 inclusive using electronically recorded AAWRs, tracheostomy insertion data and all reported incidents. These incidents were collected and analyzed in terms of categories. A 3 month segment of this data (from January-March 2018) was also directly compared to the initial audit performed January-March 2015.

RESULTS. A total of 319 patients were seen during the AAWRs from January 2017-September 2018. 45 incidents were identified (45/319; 13%); Lack of insertion form (n=17; 48%), missing or incorrect equipment (n=4; 9%), emergency airway plan related (n=22; 38%), other (n=2; 4%).

A direct comparison of a 3 month snapshot is reported below in the table:

CONCLUSION. Three years on from the commencement of an AAWR, we have seen a considerable reduction in reported clinical incidents (down from 30% to 13%), reflecting the ongoing efficacy of a dedicated ward round.

Table 1 (abstract 000515). See text for description

Incident type	Jan-Mar 2015 (n=64)	Jan -Mar 2018 (n=81)
Total recorded incidences	19 (30%)	6 (8%)
Lack of insertion form/data	N/A	4 (5%)
Equipment missing/incorrect	8 (12.5%)	1 (1%)
Bedside emergency airway plan/details	11 (17%)	1 (1%)

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000519

INTRODUCTION. The prognostic value of oxygenation indexes for mortality prediction in ARDS is limited. Increased dead space fraction (VD/VT) determined during its first week is a predictor of survival independent from oxygenation.

Estimated methods for impaired ventilation such as the estimated dead space fraction calculation and the ventilatory ratio (VR) are feasible to do at the bedside and correlate well with direct dead space fraction measurements.

OBJECTIVES. The primary objective was the predictive accuracy of the estimated dead space fraction and ventilatory ratio on mortality at 30 days after ARDS diagnosis measured by area under the receiver operating characteristics curve (AUROCC), net reclassification improvement and integrated discrimination index on top of a model with other predictors of outcome and calibration

METHODS. Secondary analysis of 940 patients with ARDS from the "Molecular Diagnosis and Risk Stratification of Sepsis" (MARS) project in mixed ICUs of two teaching hospitals. Different formulas were used to calculate dead space fraction: 1) Unadjusted Harris-Benedict (VD/VTHB); 2) Penn State (VD/VTPS); and 3) Direct estimate (VD/VTdirect). VR was calculated as per the following formula: VEmeasured X PaCO2measured/VEpredicted x PaCO2predicted. where VEpredicted is 100 ml/kg/min on the basis of predicted body weight and PaCO2predicted is 37.5 mm Hg.

RESULTS. VD/VT estimations and VR were significantly higher among non-survivors for all estimating equations at both days 1 and 2. VD/VTdirect and VR were statistically independent predictors of death at 30 days on day 2. The addition of each one of the predictors improved the predictive accuracy of the baseline model on day 2.

CONCLUSION. Estimated methods for impaired ventilation were associated with mortality in the early course of ARDS patients and added predictive value to indexes of oxygenation and respiratory system mechanics. These indexes offer clinicians information about ventilatory efficiency at the bedside and may provide useful prognostic information. Measurement of the dead-space fraction could help clinical investigators to identify the patients who may benefit most from a particular therapeutic intervention.

The multi-disciplinary collaboration team to improve the outcome of patients with respiratory failure

CM. Chen
{street_address}, Tainan, Taiwan
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000534

INTRODUCTION. Early extubation for the critically ill patients on mechanical ventilation (MV) due to acute respiratory failure (ARF) is the primary treatment aim in intensive care unit (ICU). Overt sedation of ICU patients is associated with extended MV, increased ICU length of stay (LOS) and long-term cognitive impairment.
OBJECTIVES. By using the different ways of quality control, team resource management (TRM) and also a bundle-care approach with evidence-based medicine, we hope to improve the quality of care in critically ill patients with MV due to ARF.
METHODS. Since 2014, we had established a multi-disciplinary team (physical therapist, nurse, the medical staff and the patient's family) for MV quality improvement in a 19-bed medical ICU at Chi-Mei medical center. We performed early mobilization program (within 72 hours after MV use) with a four-phase rehabilitation protocol, which range from passive movement to active mobilization, and they were named as different Chinese kungfus to help the teams to remember. Although the implementation of this rehabilitation program had shortened the duration of MV from 2014 to 2015, the outbreak of influenza in 2016 with the increased sedation use for patient-ventilator synchrony made the prolonged use of MV. Thus, the performance of early mobilization might not be easily achieved. In order to improve the outcome of patients with MV, we represented the use of an evidence-based, interdisciplinary team approach, patient-centered and integrated protocol, known as ABCDE care bundle (Awake trial, Breathing Trial, Coordination of drugs, Delirium management and Early Mobilization).
RESULTS. Before the quality improvement of care (Jan 1 to March 30, 2014) , the average duration of MV was 6.6 days. After the intervention of early mobilization program, the duration of MV was down to 4.4 days (July 1 to September 30, 2014), 4.1 days (November 1to December 31, 2014) and an average of 4.5 days in the majority of 2015. Unfortunately, MV duration raised up to 8.8 days (Dec 1, 2015 to March 31, 2016). After the performance of ABCDE bundle, the average duration of MV was gradual reduced to 4.8 days (September 1to December 31, 2016) and 4.5 days (April 1 to August 31, 2017). Also the percentage of delirium assessment increased from 0% to 100% after ABCDE bundle. The ICU LOS (from 2014 to 2017) decreased gradually each year, as 10.0, 7.5, 7.3 and 6.8 days separately.The hospital cost and delirium rate were also decreased respectively.
CONCLUSION. To improve the outcomes of ARF patients with MV, we have performed different way of quality control, TRM and ABCDE Bundle Care. They could effectively decrease the duration of MV, ICU LOS and hospital cost. Moreover, we hope to share, expand and promote this effective strategy, ABCDE bundle care to all hospitals in Taiwan in order to achieve a favorable quality of care in MV patients.

Transdiaphragmatic Inspiratory Pressure and Ultrasound Study of Diaphragm for Mechanical Ventilation Weaning Prediction

AA. Menis[1], V. Tsolaki[2], E. Zakynthinos[1], D. Makris[1]
[1]Department of intensive care medicine, University of Thessaly, Medical School, Larissa, Greece; [2]Department of intensive care medicine, University Hospital of Larissa, Larisa, Greece
Correspondence: A.A. Menis
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000537

INTRODUCTION. Difficult weaning causes a prolongation of the patient's hospitalization and of his dependence from mechanical ventilation (MV).
OBJECTIVES. The main objective of this study was to identify whether indices of diaphragmatic function obtained by diaphragmatic pressure measurement or ultrasound imaging could predict successful weaning from MV.
METHODS. The study took place in the Intensive Care Unit of a tertiary Greek hospital. Patients who fulfilled criteria for weaning from MV were included in the study and underwent a spontaneous breathing trial (SBT). Successful weaning was defined when a patient remained 48 hours without mechanical ventilation following a successful SBT. Esophageal and gastric pressures were measured with esophageal balloon-tipped-catheters. Diaphragmatic movement was assessed by ultrasound using a Linear 3-11 MHz head. The ultrasound probe was placed in the mid axillary line perpendicular to the zone of apposition between the 8th-10th intercostal spaces.
RESULTS. Twenty-five patients were evaluated. Peak esophageal inspiratory pressure, peak transdiaphragmatic inspiratory pressure, Peak Inspiratory (Tdpi) and End Expiratory (Tdee) diaphragmatic thickness, Diaphragmatic Thickening Fraction (Tfdi), Diaphragmatic Thickness (Tdth) and Excursion (Tdex) during SBT were significantly different ($p<0.05$) between those who succeeded and those who failed weaning. The receiver operating characteristics curves to identify those who succeeded weaning were: for Esophageal inspiratory pressure 0.872 ($p<0,01$)(C.I.95% 0.733-1), for Transdiaphragmatic inspiratory pressure 0.792 ($p<0.05$) (C.I. 95% 0.616-0.907), for Tdpi 0.868 ($p<0.01$) (C.I. 95% 0.682-1) for Tdee 0.819 ($p<0.01$) (C.I. 95% 0.644 – 0.995), for Tfdi 0.764 ($p<0,05$) (C.I. 95% 0.571 – 0.957), for Tdth 0.837 ($p<0.01$) (C.I.95% 0.653-1) and finally for the Tdex 0.893 ($p<0.01$) (C.I. 95% 0.722-1) having a sensitivity of 93.8% and specificity of 85.7%.
CONCLUSION. Ultrasound imaging may be useful in identifying patients who are ready for weaning from MV and might be useful in reducing MV duration.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000542

INTRODUCTION. Maximal Inspiratory Pressure trial (MIP) is used as a predictive index for weaning from mechanical ventilation (MV). Resistive Breathing (RB) follows the same physiological rationale as MIP without fully obstructing the airway.
OBJECTIVES. The main objective of this study was to identify whether indices of diaphragmatic function obtained by diaphragmatic imaging or relevant pressures during MIP or RB may be useful in predicting successful weaning from MV.
METHODS. The study took place in the Intensive Care Unit of a tertiary Greek hospital. Patients who fulfilled criteria for weaning from MV were included in the study and underwent a spontaneous breathing trial (SBT), with an airway of reduced diameter (RB) and a MIP trial. Successful weaning was defined when a patient remained 48 hours without mechanical ventilation following a successful SBT. Esophageal and gastric pressures were measured with esophageal balloon-tipped-catheters. Diaphragmatic movement was assessed by US using a Linear 3-11 MHz head. The US probe was placed in the mid axillary line perpendicular to the zone of apposition between the 8th-10th intercostal spaces.
RESULTS. 16 out of 25 (64%) patients succeeded and 9 (36%) failed weaning. Esophageal inspiratory pressure, Diaphragmatic Thicknening (Tdth) and Excursion (Tdex) during RB and Peak Inspiratory (Tdpi) and End Expiratory diaphragmatic thickness (Tdee) during MIP were significantly different ($p<0.05$) between those who succeeded and those who failed. The receiver operating characteristics curves to identify successful weaning were: for Esophageal pressure during RB 0.748 ($p<0.05$) (C.I. 95% 0.550-0.946), for Tdth-RB 0.759 ($p<0.05$) (C.I. 95% 0.540-0.979), for Tdex–RB 0.875 ($p<0.01$) (C.I. 95% 0.716-1) with a sensitivity (sn) of 93% and specificity (sp) of 75%, for Tdpi-MIP 0.850 ($p<0.05$) (C.I. 0.575-1) and Tdee-MIP 0.857 ($p< 0.05$) (C.I. 95% 0.638-1) both having a sn of 100% and sp of 80%.
CONCLUSION. Ultrasound imaging during RB and MIP might be useful in predicting patients who are ready for weaning from MV.

Severe cardiovascular collapse following endotracheal intubation and its association with prolonged ICU length of stay and ICU mortality

A. elsharkawy, S. Al-Awady, T. Helmy
Critical care medicine, Alexandria Faculty of Medicine, Alexandria, Egypt
Correspondence: A. elsharkawy
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000543

INTRODUCTION. Cardiovascular collapse (CVC) is a serious complication of endotracheal intubation (ETI). From a physiological point of view, it could be attributed to the changes that occur in venous return, intrathoracic pressure, PaCO2 and catecholamine level. Many studies have evaluated risk factors for postintubation hypotension. However, there is no universally agreed definition of postintubation cardiovascular collapse. In this study, we considered severe (CVC) as systolic blood pressure ≤65 mmHg recorded at least once and/or ≤90 mmHg for ≥30 minutes or the requirement of vasopressors and/or inotropes.
OBJECTIVES. The aim of this study is to assess the incidence and potential risk factor for severe CVC after ETI and its impact on ICU length of stay and mortality.
METHODS. This is a prospective cohort study that was conducted on 300 patients. Subjects were classified into two categories: those who were haemodynamically stable after intubation and those who collapsed. Different variables were documented in both groups and they were compared with the incidence of postintubation CVC. ICU length of stay and 28-day mortality were assessed in both groups.
RESULTS. 26.3% of subjects have developed CVC after ETI. Factors that were associated with increased incidence of CVC include: old age, heart failure, CKD, COPD, higher heart rate before and during intubation and propofol usage for intubation. The mean value for ICU length of stay for collapsed patients was 15.08 ± 8.51 days whereas it was 10.97 ± 9.60 days for non-collapsed patients ($P < 0.001$). 67.2% of collapsed patients have died within 28 days of intubation while only 27.1% of non-collapsed patients have died within the same period ($P < 0.001$).
CONCLUSION. Postintubation CVC is associated with poorer outcomes as regards ICU length of stay and ICU mortality. There are potential risk factors that need further evaluation to predict and/or decrease the incidence of CVC after ETI.

Predictors of early readmission in patients with home mechanical ventilation

EY. Kim[1], HJ. SUH[1], GJ. Seo[1], SB. Hong[2], Y. Koh[2], CM. Lim[2], JW. Huh[2]
[1]Respiratory care services, Asan Medical Center, Seoul, Republic of Korea; [2]Department of pulmonary and critical care medicine, Asan Medical Center, Seoul, Republic of Korea
Correspondence: E.Y. Kim
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000562

INTRODUCTION. With advanced respiratory care, the number of critically ill patients receiving home mechanical ventilation (HMV) therapy has increased. Readmission due to disease progression and medical emergencies in these fragile patients is also increasing.
OBJECTIVES. The purpose of this study was to investigate the factors affecting early readmission of patients who received HMV for the first time.
METHODS. This is a retrospective study of adult patients who were admitted to Asan Medical Center from March 2014 to February 2018. The inclusion criterion was readmission of patients within a year of initiating HMV. We compared the clinical characteristics of the patients at the time of discharge between those who had readmission within 30 days (early readmission group) and those who had readmission within a year from the 31st day (late readmission group). Additionally, we investigated the clinical outcomes at the time of readmission.
RESULTS. In total, 78 patients had unplanned readmission within a year from discharge, and 27 (34.6%) had early readmission. Among the causes of readmission, aspiration event was significantly higher in the early readmission group than in the late readmission group (29.6% vs 7.8%; $p = 0.011$). Among the underlying diseases, neoplasm (55.6% vs 21.6%; $p = 0.002$) and sequelae of acute respiratory failure (63.0% vs 33.3%; $p = 0.012$) were significantly higher in the early readmission group. In contrast, chronic respiratory failure was higher in the late readmission group (44.4% vs 74.5%, $p = 0.008$). Among the types of HMV, use of the tracheostomy tube was more common with early readmission than non-invasive mask ventilation (66.7% vs 19.6%; $p <0.001$), and all-day support was also more common with early readmission (44.4% vs 17.6%; $p = 0.011$). In a multivariate logistic regression analysis, neoplasm and tube-feeding methods, such as nasogastric and gastrostomy tubes, had a correlation with early readmission.
CONCLUSION. Underlying diseases and feeding methods were significantly associated with unplanned early readmission. The medical staff should educate the patients, such as on aspiration prevention, for home mechanical ventilation.

The use of high flow nasal cannula oxygen (HFNC 02) and its impact on patient outcomes in a tertiary hospital in Singapore

R. Gokhale[1], KGF. Jean[2], CMJ. Ni[3], A. Leylane[3], C. Siau[4]
[1]Intensive care, Changi General Hospital, Singapore, Singapore; [2]Respiratory therapy, Changi General, Singapore, Singapore; [3]Respiratory therapy, Changi General Hospital, Singapore, Singapore; [4]Respiratory and critical care medicine, Changi General Hospital, Singapore, Singapore
Correspondence: R. Gokhale
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000564

INTRODUCTION. High flow nasal cannula oxygen (HFNC 02) was introduced in December 2017. Changi General hospital is a 1000 bedded hospital which caters to the population in the east of Singapore.We have an 18 bedded Medical Intennsive Care Unit and we recieve around 1000 admissions over a year
OBJECTIVES. To identify indications for the use of HFNC 02 in our hospital and to look at the impact on need for Invasive Mechanical ventilation (IMV) and ICU mortality in these patients.
METHODS. All patients who required HFNC 02 from February to November 2018 were included and data was collected with regards to their diagnosis, indication for HFNC O2, PF ratio, length of time on HFNC 02, final outcome on discharge from critical care.
RESULTS. 60 patients received HFNC 02 during the stated time period. The mean age was 63.5 years, and there were 43 males. The main diagnoses were Community acquired and hospital acquired pneumonia. 47 patients received therapy for Type 1 Respiratory failure, 9 patients were post extubation, 2 for Type 2 respiratory failure and 2 received therapy as palliation.
The mean Pf ratio was 130.5 .The average length of time spent on HFNC 02 was 42 hours. At the end of HFNC 02 therapy, 35 patients were weaned off to face mask oxygen (58.3 %), 2 palliative patients died and 23 patients (38.3%) needed intubation. The most common reason for intubation was rapidly progressive respiratory failure. Of the 23 patients 8 patients died in critical care. Overall mortality at discharge from critical care was 16% including the 2 palliated patients.
CONCLUSION. Despite having a cohort of patients with moderate to severe hypoxia, a majority of patients (58.3%) avoided IMV and the average length of therapy was under 2 days. The ability to identify the right patients, who will benefit from HFNC 02 and avoid IMV, continues to pose the biggest challenge. Rapidly progressive respiratory failure was the main reason for the need for IMV.

The use of airway pressure release ventilation for severe respiratory failure; a retrospective review of the clinical effectiveness and patient safety in an adult critical care unit in the south east of England

S. Bahlool, G. Millen
Critical care, William Harvey Hospital, Willesborough, United Kingdom
Correspondence: S. Bahlool
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000569

INTRODUCTION. Airway pressure release ventilation (APRV) has been recently gaining more popularity in many adult critical care units in the south east of England. Although it is now widely used in the region as part of the management of severe respiratory failure, it failed to find its way into the national guidelines for the management of ARDS (1). I guess the paucity of clinical trials plus some conflicting results from already published studies could be the reason (2, 3). Since the publication of Guidelines for the Provision of Intensive Care Services (GPICS) by the Faculty of Intensive Care Medicine and the Intensive Care Society in April 2015(4), all critical care units were encouraged to develop a pathway for refractory hypoxaemia. At the William Harvey Hospital in south east of England, we introduced our local pathway for severe respiratory failure that includes APRV as one option.
OBJECTIVES. One year following the introduction of the APRV into the local practice, we decided to retrospectively review all the patient who had received APRV from two points of view; clinical effectiveness and safety profile. Effectiveness was measured by the improvement in oxygenation whilst safety was judged by the incidence of serious adverse events like barotrauma.
METHODS. We retrospectively reviewed all patients admitted to our critical care unit over a period of a year and had received APRV for at least six hours or more. Data collection was anonymous and only non-identifiable information was used. There were no patients with head injury in our audit. Data collected for each patient included: age, sex, ventilation days and total Intensive care days. Physiological data collected for each patient were the worst daily value for PO2, PCO2, peak airway pressure and the P/F ratio. We also recorded the incidence of barotrauma and patients' final outcome.
RESULTS. Seventy six patients received APRV over the period of the review. The average patients' age was 55 (16 – 85) years with male to female ratio of 1.5. The average length for mechanical ventilation was 6 (2 – 38) days and the length of total ITU stay before final destination was 8 (2- 28) days. The average P/F ratio significantly improved over the first three days following the application of APRV. This coincided well with a reduction in the peak airway pressure and no significant hypercapnoea. Pneumothorax occurred in only three patients (incidence of 4%); all those patients had a chest drain sited promptly and two of them were eventually transferred to a tertiary centre. One patient developed Pneumo-mediastinum and was managed conservatively.Regarding the final outcome, 59 (77%) patients were weaned successfully from mechanical ventilation, 14 (18%) patients died and 4 (5%) patients retrieved by a tertiary centre (three of which received ECMO).
CONCLUSION. The results showed that application of APRV was associated with dramatic improvement in oxygenation over a very short period of time. There was no significant hypercapnoea associated with the application of APRV and the incidence of barotrauma was 4% which is less than described in the literature for such cohort of patients(5). Although our patients sample is small, this review showed that APRV is very effective tool in the management of severe respiratory failure with no evidence of increased harm to our local patients.

ADVOS removes CO2 and corrects acidosis: Mechanism of action following a H+ and HCO3- gradient (physiological approach) or pCO2 and SID variations (quantitative approach)

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000576

INTRODUCTION. Acid-base balance is a complex continuous process regulated by several organs, including the lung, the kidney and the liver. The ADVOS therapy is based on albumin dialysis and can support all three organs by, among others, removing CO2, counterbalancing electrolyte disturbances and correcting acidosis. This is achieved with a recirculating dialysate formed by mixing an acidic and an alkaline concentrate at a modifiable ratio to reach a desired pH.
OBJECTIVES. In this work we explain the mechanism of ADVOS to achieve CO2 removal and acidosis correction in an ex vivo blood model with a carbonate-free dialysate using the classical (i.e. Henderson-Hasselbalch) and modern (i.e. Stewart) approach for acid-base balance.
METHODS. Briefly, 5 liters of swine blood were dialyzed with the ADVOS system using a high pH carbonate-free dialysate. For experimental purposes a pH of 10.0 was set. Combinations of blood flows (QB = 100, 200 or 400 ml/min) and concentrate flows (QC = 160 or 320 ml/min) were tested for 1 hour each. A pH-probe controlled blood pH continuously. CO2 was supplied to reach a constant blood pH of 7.35-7.45. Blood gas analysis were performed every 15 minutes in the inlet and the outlet of the dialyzer.
RESULTS. With a Qc of 160 ml/min a maximum continuous CO2 supply of 114 ml/min was achieved with QB of 400 ml/min. Blood pH was maintained between 7.35-7.45, while pCO2 and HCO3- were elevated. With a QC of 320 ml/min, HCO3- levels were lower. Moreover, every blood gas value remains physiological with a 70 ml/min CO2 supply and a QB of 400 ml/min.
The acid-base balance can be explained through the physiological Henderson-Hasselbalch or the quantitative Stewart approach, which use the relationship between pCO2 and HCO3-, or variations in pCO2, strong ion difference (SID) and total weak acids, respectively. Anyhow for ADVOS, the recirculation of the dialysate, to adjust pH to a desired level, is determinant.
According to dialyzer inlet and outlet values in Table 1, first, the high pH carbonate-free dialysate induces a concentration gradient between blood and dialysate for H+ and HCO3-, which triggers CO2 removal and pH increase. Second, a reduction in pCO2 and SID occurs, which can predict the increased pH level [1].
CONCLUSION. ADVOS therapy can remove CO2 and correct acid-base balance using a high pH dialysate. The mechanism of action can be explained through a H+ and HCO3- gradient and by pCO2 and SID variations.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000583

INTRODUCTION. The PaO2/fraction of inspired oxygen (FIO2) (P/F) ratio is correlated with the ratio of the pulse oximetry saturation (SpO2)/FIO2 (S/F) in intubated hypoxic patients. Whether this correlation exists in acute hypoxic respiratory failure (AHRF) patients treated by nasal high flow (NHF) remains to be determined.
OBJECTIVES. To describe the correlation between P/F and S/F values in patients with AHRF supported by NHF.
METHODS. Measurements of P/F and S/F of the patients enrolled in the ROX index studies (1, 2) were compared to assess the relationship between them (derivation cohort). SpO2 values ≥98% were excluded from the analysis. Scatterplot of S/F and P/F ratios were used to determine the linear correlation. Generalized estimating equations were used to estimate the best regression line. S/F threshold values correlating with P/F ratios of 200 and 100 were determined. The area under receiver operator characteristic (AUROC) curves was calculated to assess the diagnostic ability to discriminate between patients with P/F ratio ≤200 and ≤100. Patients from the FLORALI trial (3) and 3 other physiologic studies (4-6) were used as validation cohort.
RESULTS. Using the 638 measurements of the derivation cohort, the relationship between S/F and P/F was described by the equation S/F= 45 + P/F * 0.78, R2=0.68; p<0.0001) (Figure 1). A S/F of 201 corresponds to a P/F of 200, and a S/F of 123 to a P/F of 100. S/F ratios demonstrated high diagnostic accuracy to discriminate between patients with P/F ≤100 and ≤200 (AUROC 0.91 [0.88-0.95] and 0.86 [0.77-0.94], respectively). Sensbility, specificity and positive and negative predictive values are presented in Table 1. Similar results were observed in the validation cohort (280 measurements).
CONCLUSION. S/F ratio correlates with P/F ratio in AHRF treated with NHF. S/F values of 201 and 123 correlate with P/F of 200 and 100, respectively. S/F thresholds could be a non-invasive but accurate measure to stratify severity of hypoxic patients treated with NHF.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000591

INTRODUCTION. High dose Steroids for ARDS have not shown survival value, and possible harm beyond 14d (1,2). However, dosing, timing and variation in study design influence published outcomes (3). Extended lower doses (1-2mg/kg/d) may improve hospital outcomes (4). High dose immunosuppression (IS) benefits some patients(pts) with severe ILD on mechanical ventilation (MV)(5). Furthermore, steroids in severe pneumonia can improve survival (6). Thus, high dose steroids continue to be given in ARDS when, clinicopathoradiographic features suggest a potentially steroid responsive behavior pattern, or as a last resort, if faced with an inability to wean off MV. The outcomes from this strategy are unclear.
OBJECTIVES. We reviewed outcomes of pts with ARDS treated with immunosuppression.
METHODS. A retrospective case matched study from a single tertiary respiratory critical care unit(2009-17), identified sequential pts who received intravenous Methylprednisolone (MePred), +/- Rituximab, +/- cyclophosphamide, for ARDS. ARDS pts, (AECC/Berlin criteria - 10% of all ARDS patients), 81 given IS, were case matched with 81 pts without IS (by P/F ratio, gender, age, SOFA-all in 34 cases). Outcomes of survival (30d, 6mo, 12mo), Covariates such as SOFA score, MV days, length of stay (LOS), presence of infection, antibiotic usage were analysed. Cox multiple comparisons regression identified prognosticators.
RESULTS. 162 pts (81 ARDS-IS and 81 ARDS). Mean age 51y±4.9 and 44y±12.9. Male 48(59%) and 45(56%). For ARDS-IS 70(86%) had MePred and 6(7%) received MePred+cyclophosphamide. Percentage of pts given IS at <7d 34(42%), 7-14d 24(30%), >14d 23(28%). Veno-venous ECMO in 49(60%) ARDS-IS and 62(77%) ARDS pts. Mean SOFA scores 10.8±3.71 and 13.5±3.47. Neuromuscular blockade in 65(80%) and 68(84%). Mean mechanical ventilator days were 34 and 16 days($p<0.05$). Mean length of stay 40 and 19 days($p<0.05$). Mean total antibiotic (AB) days 97(±101) and 61(±20); AB/day 2.42 and 3.25 ($p>0.05$). AB days pre and post ARDS-IS were 34(±34) and 63(±88.5). In ARDS-IS, respiratory was the highest positive microbiology site. There was a 1.5x increase in positive respiratory and 2x urine/line infection post IS, but not causing worse outcome. Fungal infections were the most frequently encountered organism followed by gramve. Overall, survival was 29% v 71.4% for ARDS-IS v ARDS ($p<0.0001$). Survival at 30d, 6mo and 1 yr was 75, 48 and 46% for ARDS-IS, and 79, 75 and 74% for ARDS. Overall mortality by timing of IS was 70% 24/34(<7d), 58% 14/24(7-14d), 65% 15/23 (>14d). Immunosuppression, diabetes, age, length of stay were univariately associated with a worse outcome. Hazards ratio (HR) for death in ARDS given IS was 2.73 ($p<0.0001$). Only age (HR 1.03, $p=0.002$), length of stay (HR 0.47, $p=0.0001$) and diabetes (HR 2.34, $p=0.021$) were independently associated with mortality.
CONCLUSION. After high dose IS, post discharge survival for ARDS-IS was significantly worse than case matched ARDS pts. Age, length of stay and diabetes were independent factor for increasing risk of death. No survival difference based on early or late timing of IS. High dose IS is associated with significantly worse post discharge survival. Investigation of causes of post 30d deaths and predictors of steroid responsiveness in ARDS is necessary.

Active humidification system used in mechanical ventilation not associated to infectious respiratory complications

R. Muñoz-Bermúdez[1], L. Picazo,[1], X. Durán[2], F. ÁLvarez-Lerma[1], MP. Gracia[1], JR. Masclans[1]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000592

INTRODUCTION. The importance of gases administered during invasive mechanical ventilation (IMV) reaching the patient in adequate conditions of heat and humidity through the respirator's circuits is indisputable. Controversy remains about which is the most appropriate humidification system and its influence on the incidence of mechanical ventilation-related respiratory infection.
OBJECTIVES. To evaluate differences in the rate of incidence of pneumonia and tracheobronchitis associated with mechanical ventilation (VAP and AVT respectively) with a hygroscopic heat-moisture exchanger with antibacterial filter versus active humidification with heating of inspiratory and expiratory tubulars.
METHODS. Retrospective descriptive study in a polyvalent ICU. Included were all patients undergoing IMV for more than 48 hours during 2014, when passive humidification was used (EdithFlex of the brand AirlifeTM®), and 2016, when active humidifiers (Fisher & Paykel MR850®) were used. In both groups, identical measures were established to prevent VAP (Pneumonia Zero project). European Centre for Disease Prevention and Control (ECDC) diagnostic criteria were used to define VAP. Centers for Disease Control (CDC) diagnostic criteria were used to define TAV. Any NAV developing in ≤7 days from the beginning of the IMV was considered early NAV. Incidence rates of VAP and TAV were estimated for 1000 days of IMV in both groups. Late and early VAP were determined as well. Statistically significant differences between both groups were assessed between by Poisson regression. Clinical Research Ethics Committee authorization was obtained.
RESULTS. 287 patients were included (116 ventilated with passive humidification and 171 ventilated with active humidification). The mean age of the sample was 62.3 ± 16.2 years, 61.2% males, average APACHE II of 23.5 ± 9.5 points and ICU mortality of 31.1%. Demographic characteristics were not significantly different between both groups. The incidence density of VAP for 1000 days of IMV was 5.68 for the passive humidification group and 5.80 for the active humidification group (p= NS). The incidence density of TAV was 3.41 and 3.26 cases per 1000

days of IMV with passive and active humidification, respectively (p=NS). The duration of IMV was identified as a risk factor for NAV. The incidence density of early VAP per 1000 days of IMV was 3.03 with passive humidification and 2.53 with active humidification (p=NS).
CONCLUSION. In our study, active humidification in patients with IMV for more than 48 hours was not associated with an increase of infectious complications.

000601

The effect of driving pressures during the initial 24 hours of ventilation on 28-day crude mortality rate

A. Rochester, N. Clayden, M. Alice, T. Samuels
Intensive care unit, East Surrey Hospital, Redhill, United Kingdom
Correspondence: A. Rochester
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000601

INTRODUCTION. It is well documented that lung-protective ventilation strategies are associated with favourable outcomes in patients with ARDS.[1-3] In 2015, Amato et al. showed that increased driving pressure (ΔP) was associated with increased 60-day mortality in patients with ARDS, especially during the first 24 hours of ventilation.[4]
OBJECTIVES. To ascertain if there was any association with a median ΔP greater than or equal to 14 cmH2O during the initial 24 hours of ventilation and 28-day crude mortality rate.
METHODS. Data were collected at regular intervals during a one-month period. ΔP (cm H2O) was calculated as the difference between the peak pressure and positive end-expiratory pressure. Data were further divided into a survivor and deceased group according to the 28-day crude mortality rate. Patients ventilated via APRV or NIV were excluded from the study, as were patients with incomplete data. Statistical analysis was carried out using R version 3.5.3 (R Foundation).
RESULTS. 32 patients met inclusion criteria. Overall, 22 patients survived and 10 patients were deceased at 28 days. The mean ages (SD) for the survivor and deceased groups were 60.8(18.3) years and 68.5 (16.1) years respectively (Fig A, p=0.20). During the first 24 hours of intubation, 90% (9 patients) of the deceased group and 68% (15 patients) of the survivor group had a median ΔP ≥ 14cmH20 (Fig B, p=0.30).
CONCLUSION. On Day 1 of intubation 71.8% of our patients had a median ΔP ≥ 14cmH2O, yet, when data from the initial 24 hours were split into two groups (ΔP < 14cmH2O or ≥ 14cmH2O), a Fisher's exact test showed no significant association with outcome at 28 days (p=0.20; Fig. B). Amato et al. evidenced that 60-day mortality risk was significantly increased by both age and median ΔP when compared to multiple variables.[4] Our data demonstrated neither variable proved significant on crude mortality at 28 days. Nonetheless, our data set is small and looked at all-cause intubation, not just patients with ARDS, as in the Amato study. In fact, patients ventilated using APRV (often used for those with severe ARDS) were excluded from this study, which may have removed a key patient population from the mortality analysis. However, Schmidt et al. found no association with day 1 ΔP and mortality (ICU and at 6-months) in patients without ARDS, suggesting it is the severity of respiratory compromise which has the greatest impact on mortality, not ΔP, which may, therefore, reflect the degree of morbidity rather than mortality.[5] Further investigation is therefore required in a larger patient cohort throughout the full ventilation period to compare ΔP in patients with and without ARDS if an association between mortality and ΔP is to be proven.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000608

INTRODUCTION. Lung transplant (LT) has improved survival (although average is only 5.8 years) [1], whereas the number of LTs has been progressively increasing. Consequently, the interest for intensive care specialists, even those not directly involved in LT, has gone beyond the post-operative period, due to the increase of ICU readmissions (ICUr) of LT subjects [2, 3], also occurring in centres without a LT programme. Acute respiratory failure (ARF) and sepsis have been described as the most frequent conditions determining ICUr in LT recipients [4–9]. However, factors influencing the ICUr of this unique subgroup of immunocompromised patients after the post-operative period have been reported by few, mainly retrospective and single-centre studies. Thus, it is of paramount importance to have an updated snapshot of this emerging condition.
OBJECTIVES. We aimed to assess the main causes of ICUr in lung transplant adults and identify potential predictors of ICU-mortality.
METHODS. This 5-centre prospective cohort study enrolled all LT adults readmitted to ICU after post-transplantation ICU discharge (2012-2016). Patients were followed until hospital discharge or death. Primary end-point was to identify independent predictors of ICU-mortality (by multivariate logistic regression analysis).
RESULTS. We followed 153 patients (with 174 ICUr), readmitted a median of 6 months [6-25] (33, 21.6% within 1 month) post-

LT. Thirty-five (22.9%) had chronic allograft dysfunction (CLAD). ARF (110, 71.9%) was the main condition requiring ICUr. Pneumonia (56, 36.6%) was the main cause (50 admitted due to ARF and 6 for shock), with *P. aeruginosa* (50% MDR) being the predominant pathogen. Graft rejection (6, 5% acute) caused 12 (11%) admissions. The ICU and hospital mortality were 55 (35.9%) and 69 (45.1%) subjects, respectively. CLAD (adjusted-OR: 3 and 3.5) and pneumonia at ICUr (aOR: 3 and 2.4) were identified as independent predictors of ICU and hospital mortality ($p<0.05$).

CONCLUSION. Acute respiratory failure was the main condition requiring ICU readmission in lung trasnplant recipients and it was associated with high mortality. Pneumonia was the main cause and an independent predictor of death.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000611

INTRODUCTION. Respiratory muscle weakness leads to prolonged mechanical ventilation, difficulty in machine withdrawal, tracheal intubation again and tracheotomy caused by respiratory weakness, increased mortality and reduced the quality of life of survivors[1-3]. There are some studies found that withdrawal time accounts for about 40% of patients' mechanical ventilation time [4]. If withdrawal is delayed, significant weakness of respiratory muscles means that 5%-15% patients cannot successfully withdraw[5]. Inspiratory Muscle Training (IMT) has been shown to improve the respiratory muscle strength in patients with chronic obstructive pulmonary disease (COPD) [6], chronic heart failure[7]and asthma [8]. The IMT also could improve patients' mobility and the quality of life [9-10]. However, there is a major controversy whether the threshold inspiratory muscle training(TIMT) could promote weaning mechanical ventilation, and benefical to the respiratory muscle recovery and clinical outcomes.

OBJECTIVES. To study whether the Threshold Inspiratory Muscle Training(TIMT) can improve respiratory muscle strength and clinical results for machinery ventilates patients.

METHODS. To retrieve the related randomized controlled studies by following databases: the Cochrane Library, PubMed, Embase, Web Of Science, The Chinese Biomedical Literature Database, Wan Fang Database, China National Knowledge Infrastructure (CNKI) and VIP Database, retrieval ends on July 1, 2018. Two researchers strictly evaluated literature quality and extracted information, and then meta-analysis the including literatures which met the inclusion criteria.

RESULTS. There are 1 Chinese and 14 English literatures including the study. The total sample size was 657.TIMP can effectively improve the maximal inspiratory pressure(MIP) [*RR*=6.64, 95%*CI*(5.10, 8.17), *P*] and respiratory muscle strength [*RR*=7.64, 95%*CI* (2.99,12.29)], reduce weaning time [RR=-2.24,95%CI (-4.33,-0.15), shorten mechanical ventilation time[*RR*=-1.04, 95%*CI* (-1.66,-0.42), *P*=0.001], P=0.04],the ICU length of stay [*RR*=-2.95, 95%*CI* (-5.38,-0.52), *P*=0.02], and reduce the rate of weaning failure [*RR*=0.57, 95%*CI*(0.36,0.89),*P*], in mechanical ventilation patients compared with conventional treatment. However, TIMP compared with traditional treatment, there was no statistically significant difference in improving the maximum expiratory pressure(MEP) [*RR*=1.22, 95%*CI* (-6.55,9.00), *P*=0.76], reducing the rate of reintubation/tracheotomy [*RR*=0.99, 95%*CI* (0.56,1.73), *P*=0.96] and mortality [*RR*=1.05, 95%*CI* (0.53,2.06) in mechanical ventilation patients.

CONCLUSION. The TIMP can significantly improve the mechanical ventilation patients' MIP and respiratory muscle strength, shorten the weaning time, the mechanical ventilation time and the ICU length of stay, reduce the incidence of weaning failure.

INTRODUCTION. The clinical practice and the weaning of patients from the ventilator is a highly time dynamic process. The ventilation parameters must be permanently adjusted individually, as the patient can unexpectedly become exhausted at any time. However, a target-oriented weaning therapy can only be realized as soon as all technical dead space (DS) increasing influences are identified. On the ICU, commonly used devices influencing the dead space volume are either an HME (35ml) or anesthetic conserving devices (ACD, AnaConDa, Sedana Medical, Danderyd, Sweden) - ACD (50 ml and 100 ml).
OBJECTIVES. The objective was to determine the influence of devices that are widely used in intensive care medicine on ventilation parameters during Controlled Mechanical Ventilation. The elimination of CO2 and the increase in the tidal volume needed to compensate for those devices were our main endpoints. In addition to that, we wanted to quantify the impact of CO2 reflection in anesthetic gas reflection devices.
METHODS. After written informed consent, a total of 34 patients undergoing orthopedic surgery under general anesthesia have been included in our trial. Patients were randomly assigned into two groups (16 to 18 each). Anesthesia was induced as a TIVA and maintained as such for the first phase of measurements. In the second phase, anesthesia has been maintained using sevoflurane as the anesthetic agent. Patients were ventilated with the ICU respirator S1, Hamilton Medical (Bonaduz, Switzerland), which is equipped with a flow-through capnometry. After a baseline measurement without any additional dead space (no-DS), the devices have been installed sequentially and we waited for a steady state in etCO2 for at least 5 minutes until proceeding to the next device. Our study has been designed as a case-control study, randomizing the order in which the two different AnaConDa-devices have been measured.
RESULTS. As both groups were comparable in age, weight, ASA, sex and ventilation parameters the groups have been analyzed together. While maintaining a steady breathing rate and inspiratory pressure, in TIVA phase the etCO2 (mmHg) changed as following: no-DS-1 30.0±0.0, HME 33.9±2.5, ACD50 40.2±5.3 and ACD100 44.2±5.8 (ANOVA: $p<0.001$). Compensating the devices by an increase of inspiratory pressure and maintaining the etCO2 measured in the baseline measurement, the tidal volume (ml) acted as follows: no-DS-1 454.1±94.7, HME 534.1±100.4, ACD50 603.9±101.8 and ACD100 740.2±113.8 (ANOVA: $p<0.001$). After a second baseline measurement with an etCO2 of 30.0±0.0mmHg, in sevoflurane phase, etCO2 for the ACD50 increased to 35.5±2.4mmHg and 37.4±2.6mmHg for the ACD100 (ANOVA: $p<0.001$). For the ACD50 a tidal volume (ml) of 571.3±92.3 was needed and for the ACD100 one of 636.7±119.8 in comparison to a no-DS-2 tidal volume of 446.8±99.9 (ANOVA: $p<0.001$).
CONCLUSION. This study showed, that the usage of devices influencing the dead space volume can drastically change the elimination of CO2. The ventilation parameters have to be altered significantly to level out the increased dead space ventilation. Using an anesthetic gas reflector, the addition of the anesthetic gas sevoflurane reduces CO2 reflection.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000604

INTRODUCTION. Patient selection and optimal timing for coronary angiography (CA) and percutaneous coronary intervention (PCI) following out-of-hospital cardiac arrest (OHCA) have been contentious. PCI is resource-intensive, and whilst large observational studies have concluded that early PCI improves survival in patients with non-ST elevation myocardial infarction, a recent Dutch randomised controlled trial - COACT - demonstrated no survival benefit of immediate over delayed PCI in patients without evidence of STEMI. Our 700-bedded UK DGH has a 24-7 Cardiac Cath Lab service that has routinely investigated OHCA patients with indications pre-ICU admission.
OBJECTIVES. To identify factors affecting hospital mortality in OHCA patients admitted to our ICU; in particular, disease severity, CA pre and post ICU admission, and adoption of 36°C targeted temperature management (TTM) target on 01/01/15.
METHODS. We analysed prospectively collected data from all comatose OHCA patients admitted to our ICU between 01/01/12 and 31/12/17 using Trust electronic databases. Data were statistically analysed using a key driver analysis to identify factors that correlate most with survival.
RESULTS. Of 283 patients identified, summary values [presented as median (range) or percentages] were: age 66 (16-93); APACHE II score 19 (4-44); ICNARC score 28 (9-83); male 70%; presented with VF 61.8%, PEA 24.7%, asystole 8.8%, VT 2.1%, unknown primary arrest rhythm 2.5%; CA pre-ICU 62%; PCI pre-ICU 35%, CA post-ICU 6%; completed 24 hours of TTM 75%; survived to hospital discharge 42%. Of survivors: ICU length-of-stay (LOS) 4.4 (0.5-34) days, hospital LOS 12 (0.5-101). Of non-survivors: ICU LOS 2.5 (0.1-16) days, hospital LOS 3 (0.1-70) days. On univariate analysis, survival was increased by male sex, VF as primary rhythm, completing 24 hours of TTM, CA and PCI before ICU, CA after ICU. On multivariate analysis, drivers for survival were APACHE II score ($p=0.000$), VF as primary rhythm ($p=0.001$), having completed 24 hours TTM ($p=0.004$); undergoing CA after ICU admission (0.01) and ICNARC score ($p=0.03$).
CONCLUSION. Changing TTM target to 36°C did not affect ICU or hospital survival. Neither pre-ICU CA or PCI were found to be significant drivers on multivariate analysis. Strongest independent predictors of survival in our study were APACHE II mortality score and VF rhythm, followed by completing TTM, undergoing CA after ICU admission and ICNARC score, which were all linked by selection criteria. Our results, in keeping with the recent CO-ACT study, demonstrate that performing CA before ICU admission does not improve mortality and we conclude that this should be considered in comatose OHCA patients only on a case-by-case basis.

The Value of Arterial Blood Gas Parameters for Prediction of Mortality in Survivors of In and Out-of-hospital Cardiac Arrest

K. MOHEE[1], M. Protty[2], H. Haboubi[3], S. Pillai[1]
[1]Ed major critical care unit, Morriston Hospital, Morriston, United Kingdom; [2]Systems immunity university research institute, Cardiff University, Cardiff, United Kingdom; [3]Medical school, Swansea University, Swansea, United Kingdom

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000668

INTRODUCTION. Cardiac arrest is one of the leading causes of mortality in Europe, and early prognostication remains challenging. There is a paucity of valid parameters for the prediction of survival after both in hospital (IHCA) and out of hospital cardiac arrest (OHCA). Arterial blood gas (ABG) monitoring evaluates partial pressures of gas and acid-base content.
OBJECTIVES. This study aims to investigate if arterial blood gas parameters correlate with mortality of patients after in and out-of-hospital cardiac arrest following admission to intensive care unit (ICU).

METHODS. This is a single centre retrospective observational review of the database WardWatcher. Cardiac arrest patients who were admitted between January 2007 to July 2018 to a tertiary ICU were included. The patient's survival 30 days after resuscitation defined the study end-point. For the statistical analysis, the mean, standard deviation, Mann Whitney-U test, Chi-square test, and logistic regression analyses were used (level of significance $p < 0.05$).

RESULTS. ABG samples were taken from 1034 patients during the study period. When compared with OHCA cases, patients admitted with IHCA were older 68 vs 62 years, (p<0.0001), had higher GCS score 5.4 vs 4.5, (p<0.0001), higher APACHE II scores 18.9 vs 17.1 (p<0.0001). 30-day mortality was higher in the OHCA cohort but not statistically significant.

In both cohorts (together and independently), lactate ≥ 4.0 mmol/L showed strong and independent correlations with mortality within the first 30 days after admission to ICU [All: OR 2.37 (95% CI 1.77-3.19), IHCA: OR 1.81 (95% CI: 1.19 – 2.76), OHCA: OR 3.26 (95%CI: 2.12-5.07)], whereas a GCS score > 8 showed strong and independent correlations with survival within the first 30 days after admission to ICU [All: OR 0.17 (95% CI:0.11-0.26), IHCA: OR 0.31 (95% CI:0.19-0.52), OHCA: OR 0.06 (95% CI: 0.02-0.13)].

CONCLUSION. Our study results indicate that blood gas parameters correlate with mortality of patients after cardiopulmonary resuscitation. In both IHCA and OOHCA, the most relevant parameter is a lactate ≥ 4.0 mmol/L which was observed to be a strong and independent predictor associated with mortality within the first 30 days after resuscitation. In contrast, having a GCS>8 on admission to ICU is associated with good outcome at 30 days. Despite these findings, it is likely that early prognostication relies on multiple factors beyond individual covariates. Nevertheless, these parameters can form a part of a multimodal approach to assessing the patients' prognosis.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000670

INTRODUCTION. Recent studies have shown temporal variations in the incidence of out of hospital cardiac arrest (OHCA), however, there is a dearth of studies investigating similar variations in in-hospital cardiac arrest (IHCA) especially in the Welsh population.

OBJECTIVES. This study aims at investigating the epidemiology, circadian, weekly and seasonal variations of patients with IHCA and OHCA admitted to a tertiary intensive care unit (ICU) in South Wales.

METHODS. This is a single centre retrospective observational review of Wardwatcher database. All post cardiac arrest patients admitted to a tertiary referral ICU from January 2007 until December 2017 were included. A variety of data including demographics and comorbidieties were collected.

RESULTS. Of the 475 IHCA, 53% were females with mean age of group 68 ± 14.0 years. Conversely, the majority of the 490 OHCA cases were males with 53% with mean age of group 62 ± 16.5 years. From 2007 until 2017, admissions of patients with cardiac arrest increased steadily with an exponential increase within the IHCA group. During that 11-year period, May and June were the months with the lowest number of admissions for both IHCA and OHCA.

The incidence of OHCA admitted to ICU in the studied population was 44.5 patients per year. Admission of patient with OHCA to ICU stayed stable low levels between 22:00 and 4:59 and started to increase at 5:00, with a modal peak: 13:00–14:59. The lowest number of OHCA admitted to ITU occurred from 07:00 to 8:59, the highest from 13:00 to 14:59 (1.2% vs. 8.2%, p < 0.001). The day with the lowest cases of OHCA admitted to ITU was Sunday, the highest Monday (12.7% vs. 16.3%, p = 0.01). Summer was the season of the lowest cases of OHCA admitted to ITU, while winter — the highest (22.4% vs. 29%, p = 0.001).

The incidence of IHCA admitted to ICU in the studied population was 43.2 patients per year. IHCA admitted to ICU increased with age reaching a peak of 95 years. Patients with IHCA admitted to ICU stayed high levels between 07:00 and 1:59 and started to decrease at 02:00, with bi-modal peaks: 00:00–01:59 and 18:00-18:59. The day with the lowest admission of IHCA to ICU was Sunday, the highest Thursday (8.8%% vs. 17.1%, p <0.001). Spring was the season of the lowest number of patients with IHCA admitted to ICU, while winter — the highest (21.7% vs. 27.3%, p = 0.001)

CONCLUSION. This is the first study of a large Welsh subpopulation over an 11-year period, which confirmed that times of admission, weekly variability and seasonal differences exists in both IHCA and OHCA patient who are admitted to ICU.

The effect of veno-arterial extracorporeal membrane oxygenation (VA-ECMO) for patients with out-of-hospital cardiac arrest: A propensity score matched analysis

T. Tsuchida[1], T. Wada[1], S. Gando[2]
[1]Department of acute and critical care medicine, Hokkaido University Graduate School of Medicine, Sapporo, Hokkaido, Japan; [2]Acute and critical care center, Sapporo Higashi Tokushukai Hospital, Sapporo, Hokkaido, Japan
Correspondence: T. Tsuchida
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000719

INTRODUCTION. Some studies both support and refute the use of veno-arterial extracorporeal membrane oxygenation (VA-ECMO) for out-of-hospital cardiac arrest (OHCA) patients, and there is no sufficient evidence on the characteristics of patients who should receive VA-ECMO.

OBJECTIVES. We evaluated the relationship between the use of VA-ECMO, the outcome and some physiological parameters in OHCA patients.

METHODS. We extracted 239 OHCA patients from computer-based medical records from February 2000 to December 2017. The 239 patients were all hospitalized after a return of spontaneous circulation (ROSC) from cardiac arrest of cardiac origin at 16 years of age or older. We divided the patients into two groups: patients who underwent VA-ECMO (n=84) and those did not (n=155) and established propensity score (PS) matched groups with patients matched according to pre-hospital factors (gender, age, time from the detection of cardiac arrest to ROSC, and the initial rhythm at cardiac arrest). We compared the following factors in two groups of 24 PS-matched patients: platelet count, coagulation and fibrinolysis marker and lactate levels, International Society on Thrombosis and Haemostasis (ISTH) DIC score, sequential organ failure assessment (SOFA) score, and acute physiology and chronic health evaluation (APACHE) II score. The outcome was measured by all-cause hospital mortality after 28 days of hospitalization.

Furthermore, a sub-group analysis was performed after dividing patients who received VA-ECMO into two groups according to the outcome.

RESULTS. The VA-ECMO group had more severe coagulo-fibrinolytic changes and organ dysfunction than the non-VA-ECMO group. In addition, the VA-ECMO group showed poorer outcomes. A subgroup analysis showed that the patients in the VA-ECMO group with a poor outcome had significantly higher ISTH DIC scores and lower PT% on day 2, while these parameters were not significantly different on day 1.

CONCLUSION. This study showed no beneficial effect of VA-ECMO on the OHCA patients. Furthermore, among the patients who received VA-ECMO, poor outcomes were observed in patients whose ISTH DIC scores and PT% showed deterioration.

INTRODUCTION. Mechanisms by which neutrophils contribute to post-resuscitative brain damage are unknown. In recent years, neutrophil extracellular traps (NETs) have emerged as a central player in inflammation, thrombogenesis and cardiovascular disease. NETs are chromatin fibers consisting of histones, cell free DNA (cfDNA) and granular proteins and are released within minutes (1) to hours (2) following activation by various stimuli including ischemia and reperfusion (3). While NETs have primarily been recognized as mediators of antimicrobial host defense, they may exert detrimental inflammatory and procoagulant effects causing endothelial damage, platelet activation, microvessel occlusions and ultimately tissue malperfusion (4). In particular neutrophil histones and DNA are considered cytotoxic and procoagulant components of NETs (5) and have been implicated in organ damage in various medical conditions (6). Despite this, the role of NETs in cardiac arrest has not yet been investigated. Pro-inflammatory and pro-thrombotic properties, however, render them possible mediators of neutrophil-borne brain injury after successful resuscitation.
OBJECTIVES. We hypothesized that the formation of NETs in the early phase after successful resuscitation may be associated with neurologic impairment in cardiac arrest survivors.
METHODS. This prospective cohort study included adult patients with out-of-hospital cardiac arrest of cardiac etiology who received targeted temperature management. Plasma levels of specific (citrullinated histone H3, H3Cit) and putative (cell free DNA and nucleosomes) biomarkers of NET formation were assessed at 0 and 12 hours after admission and categorized into quintiles prior to analysis. The primary outcome variable of interest was the effect of H3Cit levels at 12 hours on 30-day neurologic function, assessed by logistic regression. Results are given as odds ratio (95% confidence interval).
RESULTS. Between January 2014 and January 2017 62 patients (79% male, median age: 57 years) were enrolled at the Emergency Department at the Medical University of Vienna. In total, 52% of patients (n=32) had a poor 30-day neurologic function. The odds of neurologic impairment linearly increased with 12-hour levels of H3Cit (1.6, 1.1-2.3; p=0.029) and were highest in patients in the fifth quintile of the histone level distribution (9, 1.3-63; p=0.027). The effect remained unchanged after bivariate adjustment for covariables.
CONCLUSION. Increased plasma levels of H3Cit 12 hours after successful resuscitation are associated with poor 30-day neurologic recovery in adult out-of-hospital cardiac arrest survivors with cardiac etiology.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000738

INTRODUCTION. Resuscitation (CPR) with mechanical chest devices are not recomanded for routine CPR according to randomised trials. One of possible explanation could be CPR related trauma caused with mechanical chest devices. Current data are based on subanalysis from randomised trial, but autopsies are limitated by law and autopsy results are not objectivised.
OBJECTIVES. To compare injuries after CPR in autopsy results by manually resuscitated and mechanical (LUCAS 2, AutoPulse, CORpulse) resucitated patients and establish possible proportion of CPR related injuries on death without respect to cause of cardiac arrest.
METHODS. Retrospective multicentric study based on autopsy reports by patients died after CPR, patients with traumatic cause of cardiac arrest were excluded. Patients were devided in two groups: mechanical and manually CPR. For objective evaluation of injury seriousness we used Abbreviated injury scale scoring for the most serious injury and New Injury Scale Score for summary of all injuries.
RESULTS. We have enroled 704 patients, after trauma exclusion we have analyzed 630 autopsies. Manually CPR were provided by 559 patients and mechanical by 64 (11,4%) patients. Both groups are no diferent in age, gender, bystander CPR and cardiac etiology of Arrest. Mechanical CRP was significantly longer (p=0,0005). Both groups have no diferences in incidency of injuries of thoracic vessels, lungs, heart, pericard, pleura, stomach, liver and spleen. We have observed injuries by 80% of manual and 87,5% of mechanical CPR (p=0,18). The most frequent was thorax sceleton injury 85,5% vs. 87,5%. Median of the most seriuos injury was 3 (serious by Abbreviated injury scale scoring) without statistical difference, median of summary of injuries (New Injury Severity Score) was 13 in both groups (low probability of fatal injury). If we analysed CPR by LUCAS 2 compared to manual, results are similar, only pericard injuries are higher with LUCAS 2.
CONCLUSION. Incidency a seriousness of CPR related injuries according to autopsy reports are no diferent in comapring of manually and mechanical CPR. Mechanical CPR is significant longer a LUCAS 2 leads to significant more pericard injuries without influence to total seriousness of injury

Post Resuscitation Care: Are Intensive Care Units Adhering To Resuscitation Council (UK) Guidelines?

S. Chaudhry, K. Ooi, M. Ranganathan
Anaesthetics, Warwick Hospital, Warwick, United Kingdom
Correspondence: K. Ooi
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000758

INTRODUCTION. The pathophysiology of the 'post cardiac arrest syndrome' is complex and often requires multiorgan support, which is best managed on the intensive care unit. Good quality post-resuscitation care can greatly influence overall outcome, particularly neurological recovery. The Resuscitation Council (UK) published guidelines for post-resuscitation care in 2015, in line with those set

by the European Resuscitation Council. There are key interventions that should be followed to optimise outcomes and to facilitate accurate prognostication of patients after cardiac arrest.

OBJECTIVES. To determine whether intensive care units in England and Wales are following the Resuscitation Council UK Guidelines for post-resuscitation care.

METHODS. An online survey (generated using SurveyMonkey) was disseminated via e-mail to all Critical Care Network Leads in England and Wales. A reminder was sent two weeks later. The survey was also advertised in the Faculty of Intensive Care Medicine website and Twitter account.

RESULTS. We received 49 responses from across England and Wales. 95% of respondents were aware of the post-resuscitation care guidelines, but only 56% had an established protocol on their ICU. Most physiological targets used correlated with guidelines; however, 49% of respondents used a different target temperature to that recommended in the guideline. With regards to prognostication, the majority (72%) waited 72 hours post-ROSC. Many ICUs have access to EEG (89%) and CT/MRI (78%); however, only 21% of institutions can measure neuronal specific enolase (NSE) levels.

CONCLUSION. Despite clear guidance from the Resuscitation Council, there is heterogeneity in the management of the post-cardiac arrest patient. In particular, access to prognostication facilities varies greatly; EEG is not universally available and NSE level measurement is not possible in most centres. The guideline may therefore not be fit for purpose at all institutions and may require revision. At present, we recommend that each institution establishes their own post-resuscitation protocol, tailored to the facilities available locally. This will ultimately improve the quality of care provided to survivors of cardiac arrest.

INTRODUCTION. The International Liaison Committee on Resuscitation guidelines recommend target temperature management between 32° C and 36° C for patients after out-of-hospital cardiac arrest, but did not indicate patient-specific temperatures. The association of serum lactate concentration and neurological outcome in out-of-hospital cardiac arrest patient has been reported.

OBJECTIVES. The study aim was to investigate the benefit of mild therapeutic hypothermia (32ºC–34ºC) in patients with various degrees of hyperlactatemia compared to normothermia (35ºC or 36ºC) .

METHODS. This study was a post hoc analysis of the Japanese Association for Acute Medicine out-of-hospital cardiac arrest registry between June 2014 and December 2015. Patients with complete targeted temperature management and lactate data were eligible. Patients were stratified to mild (< 7 mmol/l), moderate (< 12 mmol/l), or severe (≥ 12 mmol/l) hyperlactatemia group based on lactate concentration after return of spontaneous circulation. They were subdivided into mild therapeutic hypothermia or normothermia groups. The primary endpoint was an adjusted predicted probability of 30-day favorable neurological outcome, defined as a cerebral performance category score of 1 or 2.

RESULTS. Of 435 patients, 139 had mild, 182 had moderate, and 114 had severe hyperlactatemia. One hundred-eight (78%) with mild, 128 with moderate (70%), and 83 with severe hyperlactatemia (73%) received mild therapeutic hypothermia. The adjusted predicted probability of a 30-day favorable neurological outcome following severe hyperlactatemia was significantly greater with mild therapeutic hypothermia (27.8%, 95% confidence interval: 22.6%–33.1%) than normothermia (15.3%, 95% CI: 6.7%–23.9%; p = 0.015). The differences in outcomes in those with mild and moderate hyperlactatemia were not significant.

CONCLUSION. Mild therapeutic hypothermia independently predicted a greater probability of a favorable 30-day neurological outcome in patients with severe hyperlactatemia compared with normothermia.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000833

INTRODUCTION. Optic nerve sheath diameter (ONSD) is considered as one of the prognostic factors in cardiac arrest (CA) survivors because of a parameter reflecting intracranial pressure (ICP) indirectly. We aimed to investigate the correlation between ONSD measured by magnetic resonance imaging (MRI) and ICP in CA survivors who underwent target temperature management (TTM).

METHODS. In this retrospective cohort study conducted in 2018, ONSD and cerebrospinal fluid (CSF) pressure were measured before (Day 0 group) and after (Day 3 group) TTM. ICP and ONSD were respectively measured with CSF pressure and an axis perpendicular to the optic nerve 3 mm behind the eyeball in MRI. Increased ICP was defined as an opening pressure over 20 mmHg. The primary outcome was the correlation between ONSD and ICP.

RESULTS. A total of 37 patients who underwent ONSD measurement, with simultaneous lumbar drainage catheter placement, were enrolled in this study. The median and interquartile range [IQR] of ICP was significantly higher in the Day 3 group than in the Day 0 group (14.9 mmHg [12.4-19.1] versus 10.5 mmHg [8.4-11.9], P < 0.001). However, ONSD showed no difference between both groups (5.21 mm [4.80-5.58] versus 5.20 mm [4.79-5.70], P = 0.939). Ten cases (26.3%) were found to have an increased ICP. Day 3 showed higher incidence of increased ICP than in the Day 0 group (8% versus 19%, p=0.178). The median and interquartile range of ONSD in the group with increased ICP (6.17 mm [5.11-6.45]) was significantly higher than those without increased ICP (5.19 mm [4.80-5.59]) (P = 0.015). The group with increased ICP showed a statistically significant strong linear correlation with ONSD (r = 0.89, P < 0.001) compared to the other (r = 0.14, P = 0.347). ONSD > 5.99 mm indicated a sensitivity of 60.0% and a specificity of 98.0% for identifying increased ICP.

CONCLUSION. ONSD strongly correlated with ICP, in the case of increased ICP. Therefore, ONSD measurement at an early stage, without increased ICP from return of spontaneous circulation, may not be useful for predicting neurological outcomes in CA survivors, due to poor correlation with ICP. Prospective studies should be conducted to confirm these results.

MEWS vs CART Scores for Prediction of Cardiopulmonary Arrest At the Philippine Heart Center

AD. Tan, M. Dolor-Torres, C. Permejo
Department of adult cardiology, Philippine Heart Center, Quezon City, Philippines
Correspondence: A.D. Tan
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000845

INTRODUCTION. Several clinical scores have been developed to facilitate a well-timed transfer to the intensive care unit (ICU) that could potentially prevent a cardiac arrest (CA). The Modified Early Warning Score (MEWS) is the most studied of these scores and is utilized in many countries to activate rapid response teams. The newer Cardiac Arrest Risk Triage (CART) score was shown to have greater accuracy than the MEWS. However, validation studies are lacking. Several clinical scores have been developed to facilitate a well-timed transfer to the intensive care unit (ICU) that could potentially prevent a cardiac arrest (CA). The Modified Early Warning Score (MEWS) is the most studied of these scores and is utilized in many countries to activate rapid response teams. The newer Cardiac Arrest Risk Triage (CART) score was shown to have greater accuracy than the MEWS. However, validation studies are lacking.
OBJECTIVES. The aim of this study was to validate the CART score and MEWS for predicting cardiac arrest and ICU transfers among patients admitted at the Philippine Heart Center. To our knowledge, no study has validated similar CA predictor scores in our country.
METHODS. This is a case-control study including 82 adult patients (36 cases, 46 controls) admitted at the Philippine Heart Center. Cases included patients who had CA at the wards (18 cases) and those who were transferred to the ICU for any reason (18 cases). Personal profiles and demographic data were collected. Differences in factors were determined between cases and controls. Vital signs and "alert-verbal-pain-unresponsive" (AVPU) scales from 48 hours prior and up to the time of recruitment (CA or ICU transfer for cases) were noted. The MEWS and CART scores for each time point were computed and compared using measures of validity.
RESULTS. There was no significant difference between the case and control groups in terms of age, sex, height, weight, diagnosis, disease classification, and prior ICU admissions. A CART score of 12 was found to have a higher accuracy than a MEWS of 4 across all time points prior to CA or ICU transfer. The highest accuracy of the CART score (cut off $\geq$ 12) was 74.39%, noted 8 hours prior to an event. This had a corresponding specificity of 80.43% and sensitivity of 66.67%. At this hour, the MEWS (cut off $\geq$ 4) had a lower accuracy of 68.29% with a higher specificity of 97.83% but a lower sensitivity of 30.56%. However, area under the curve analysis revealed that the differences in scores between the CART and MEWS were not statistically significant. Among CA patients detected by both tools, the CART was able to detect CA earlier at a median of 30 hours prior versus 24 hours prior for the MEWS.
CONCLUSION. The accuracy of the CART score is comparable to the MEWS which is currently the internationally recognized tool for detecting CA at the wards. In our opinion, the CART is simpler than the MEWS as: 1) it has fewer variables, and 2) it does not contain a factor requiring a higher level of proficiency (such as the AVPU scale of the MEWS). Thus, we recommend the use of the CART score.

INTRODUCTION. Brain injury remains the leading cause of death in comatose patients resuscitated from out of hospital cardiac arrest (OHCA). Markers measuring global cerebral ischemia, and reflecting the metabolic variations after resuscitation are needed for a more individualized care. The lactate-pyruvate (LP) ratio is an important indicator of compromised cerebral oxidative metabolism. The study aims to investigate whether the LP ratio obtained by microdialysis (MD) of the cerebral venous outflow reflects brain injury after OHCA.
METHODS. A feasibility study designed to determine the yield of bedside monitoring of cerebral energy metabolism after OHCA utilizing intravenous MD. 15 unconscious patients were admitted to the intensive care unit following OHCA with presumed cardiac cause. MD catheters were inserted into the jugular bulb and radial artery (reference). The primary end-point was a difference in time-weighted

mean MD parameters and LP ratio measured in venous and arterial blood.
RESULTS. The median time from OHCA to MD analysis was 369 min (IQR 255-444) and patients underwent a median of 76 h (IQR 65-82) of monitoring. The LP ratio of cerebral venous blood increased (LP ratio > 25) after OHCA indicating compromised cerebral oxidative metabolism during the first 20 hours. The difference between time-weighted mean of lactate, pyruvate and glycerol (in intervals of 12 hours) of the jugular venous and the arterial blood was significant during post-resuscitation care ($p < 0.02$) when using mixed effects models. In patients with unfavorable outcome (87 %), cerebral venous lactate remained high with mean and peak venous lactate level > 2.2 and 5.5, respectively.
CONCLUSION. Isolated neurochemical changes indicating brain injury were found after OHCA and consecutive resuscitation. Jugular bulb MD may provide a reliable global estimate of cerebral metabolic state and can be implemented as a new diagnostic tool for ICU patients after OHCA, with implications for early prognosis and treatment.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000927

INTRODUCTION. Despite recent improvements, some patients after out-of-hospital cardiac arrest (OHCA) suffer total loss of brain function, i.e. brain death. Coagulofibrinolyticmarkers and disseminated intravascular coagulation (DIC) score were known to be associated with neurological outcome in patients after OHCA, but the associations between these variables and brain death were not examined.
OBJECTIVES. To evaluate the associations of coagulofibrinolyticmarkers and DIC score with brain death after OHCA.
METHODS. We performed a retrospective analysis using data from the regional UtsteinRegistry and medical records between 2006 and 2012. We enrolled patients who experienced OHCA with successful return of spontaneous circulation and were admitted to Hokkaido University Hospital. Outcome measure was brain death during hospitalization. Logistic regression model was used to evaluate the associations of coagulofibrinolyticmarkers including platelet count, prothrombin time, plasma levels of fibrinogen, fibrin/fibrinogen degradation products, and calculated DIC score on admission with brain death. Classification and Regression Tree (CART) analysis was used to identify specific thresholds of significant variables.
RESULTS. The overall rate of DIC (defined by DIC score >= 5) and brain death were 13.0% (n = 41/315) and 9.5% (n = 30/315), respectively. Compared with non-brain death group, brain death group gained significant lower level of fibrinogen on admission (1.97 vs. 2.45 g/L, p=0.005), but there were no differences about other variables. CART analysis identified fibrinogen level of 2.26 g/L as an optimal threshold. In multivariable logistic regression analysis, fibrinogen level =< 2.26 g/L was associated with increased risk of brain death (adjusted odds ratio 2.87, 95%CI 1.16-7.08, p=0.02).
CONCLUSION. Decreased fibrinogen level at admission was an independent prognostic factor for brain death after OHCA.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000938

INTRODUCTION. Hypoxic-ischemic brain injury (HIBI) is the main cause of death or disability in patients resuscitated from cardiac arrest (CA). Extracorporeal membrane oxygenation (ECMO) is used to treat refractory CA or post-CA shock. However, the potential benefit of this resource-intensive treatment should be balanced against the risk of futility. Automated pupillometry (AP) recently shown to accurately predict HIBI outcome within 24h from CA and may therefore be useful in this setting.
OBJECTIVES. To assess the accuracy of early AP for outcome prediction in CA patients undergoing ECMO.
METHODS.*Post hoc* analysis of an international multicenter prognostication study. The primary study endpoint was the accuracy of a neurological pupil index (NPI) ≤ 2 to predict 3-month poor neurological outcome defined as severe disability, unresponsive wakefulness or death (Cerebral Performance Category [CPC] 3-5).
RESULTS. On a total of 456 included patients, 66 (14%) were treated with ECMO during resuscitation or immediately after the return of spontaneous circulation. Unfavorable outcome was observed in 43 (65%) patients. On admission, 15 (23%) patients had NPI of ≤ 2; 13/15 had CPC 3-5. The two patients with favorable outcome had a continuous EEG background and recovered a normal NPI (> 3.5) within 24 hours. Sensitivity, specificity, and positive predictive value of NPI ≤ 2 on admission for unfavorable outcome was 91%, 30%, and 87%, respectively. On day 1 and 3, NPI ≤ 2 was observed in 11/66 (17%) and 4/42 (10%), respectively; all of them had unfavorable outcome.
CONCLUSION. NPI measured with AP in CA patients undergoing ECMO immediately after hospital admission was a sensitive but not specific predictor of poor neurological outcome. Altered pupillary response should not be used as a tool for deciding on ECMO treatment in this phase.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001092

INTRODUCTION. Hyperlactatemia(1) and hyperglycemia(2) are frequently observed as part of the stress reaction during critical illness. Shorter times to normalization or higher rates of decrease of lactate and glucose have been associated with better outcomes.(3,4) After return to spontaneous circulation (ROSC) after out-of-hospital cardiac arrest (OHCA), blood gas analyses usually demonstrate a marked hyperlactatemia and hyperglycemia. We hypothesize that after ROSC recovery from hyperlactatemia and hyperglycemia can be faster than described for several other critical conditions.
OBJECTIVES. To determine the early kinetics of lactate and glucose in the first 3 hours after ROSC after OHCA in patients presenting with marked hyperlactatemia.

METHODS. We retrospectively analyzed patients that presented between 2006 and 2016 after OHCA in whom initial ROSC was achieved at departure of the ED. Arterial lactate and blood glucose levels were determined by point-of-care blood gas analyzers. We only included patients with an initial lactate immediately after ROSC of ≥8 mmol/L and with ≥2 measurements in the first 3 hours after ROSC. With linear regression we estimated the absolute rate of decrease (mmol/L/h) and relative rate of decrease (% of initial/h) per individual patient. We compared the early kinetics between hospital survivors and hospital non-survivors.
RESULTS. We studied 602 blood samples taken from 152 patients, 82.2% male, with a mean age of 59 years. The mean (±SD) initial lactate and glucose levels were 12.1±3.7 and 18.6±5.2 mmol/L, respectively. The mean relative lactate and glucose decreases were 30% and 14% of initial/h over the first 3 hours. The mean absolute lactate and glucose decrease was 3.6 mmol/L/h and 2.7 mmol/L/h, respectively. Lactate relative kinetics differed between survivors and non-survivors (33%/h vs 27%/h p=0.007). Glucose relative kinetics did not differ significantly between survivors and non-survivors (16 %/h vs 13 %/h p= 0.27).
CONCLUSION. Lactate is rapidly consumed through oxidation and gluconeogenesis early after ROSC. Hospital survivors have relatively higher initial decreases of lactate compared to hospital non-survivors, while there was no difference in the decrease of glucose between the two groups in the first 3 hours after ROSC.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001165

INTRODUCTION. This study aimed to compare the efficacy of endovascular cooling device (ECD) like Thermogard® compared to surface cooling device (SCD) such as Arctic Sun® in outcomes of adult post-cardiac arrest patients treated undergoing targeted temperature management (TTM).
METHODS. We systematically searched MEDLINE, EMBASE, and the Cochrane Library (search date: 14 February 2019) to identify studies on TTM for post cardiac arrest patients. Randomized controlled studies (RCT) and observational studies (OS) comparing in-hospital morality and neurological outcomes between ECD and SCD were selected. We additionally performed subgroup analyses based on confounding factors that could affect patient outcomes. To assess the methodological quality of the included studies, Cochrane Risk of Bias Tool for randomized trials and Risk of Bias Assessment Tool for Non-randomized Studies was used independently by two authors.
RESULTS. A total of 4311 patients from nine studies were finally included. Two RCT and seven OS were included in the meta-analysis. Overall pooled analysis showed no significant difference on in-hospital mortality between ECD and SCD (nine studies; RR, 0.93; 95% CI 0.86–1.00; I2 = 0%). Likewise, there was no statistical difference in RCT (RR, 0.80; 95% CI 0.56–1.14; I2 = 0%) and OS (RR, 0.94; 95% CI 0.86–1.01; I2 = 2%)
In the pooled analysis for neurologic outcome, overall pooled data analysis revealed that neurologic outcome in ECD recipients was better than in SCD recipients (RR, 0.91; 95% CI 0.86–0.96; I2 = 0%), However, ECD showed significantly better neurological outcome compared to SCD only in OS (RR, 0.90; 95% CI 0.85–0.95; I2 = 0%). There was no statistical difference in RCT (RR, 0.95; 95% CI 0.75–1.21; I2 = 0%).
CONCLUSION. This study suggested that ECD could be associated with better neurologic outcomes compared with SCD. However, further studies would be needed to confirm the obvious benefit of ECD in TTM recipients because that most included studies were observational studies.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001460

INTRODUCTION. According to the World Health Organization, trauma is one of the leading causes of death worldwide. Trauma-related injuries are responsible up to 30% of admissions in the Intensive Care Unit (ICU), mainly in young people and it has been recognized as a serious social and economic issue. As expected, traumatic brain injury (TBI) is the main cause of the majority of trauma-related deaths, followed by haemorrhage-induced hypovolemic shock and multiple organ failure syndrome (MODS).
OBJECTIVES. To describe the epidemiology of major trauma and analyse the prognostic factors of ICU-mortality.
METHODS. Prospective, observational and single centre study. All admitted trauma patients and registered in RETRAUCI (National database of trauma in ICU) during 18 months, were consecutively included. Demographic data, severity scores, pre- and intra-hospital care variables and outcomes were recorded. Mann-Whitney U test (continuous variables) and Chi-squared test (categorical variables) were used; Mortality risk factors were evaluated by a multivariable analysis with logistic regression (95% CI) and survival analysis with Cox hazard regression analysis.
RESULTS. Total population comprises 140 patients admitted on ICU due to major trauma. 73.6% (n = 103) were male. The median age was 55 years old (IQR 39-70), and 32.1% were older than 65 years old. The median ISS (Injury Severity Score) was 21 (IQR 13-26); 72.8% (n = 102) had ISS ≥ 16. Blunt trauma was predominant (95%). The most common causes of trauma were traffic accidents (47.1%) followed by falls (37.4%). Alcohol and drug consumption was frequent (40.7% and 63%, respectively of available data). 62.9% required mechanical ventilation (MV), 27.1% developed shock and intracranial hypertension occurred in 25.7%. Only four patients required massive transfusion, and the mean of blood transfusion in the first 24 hours was 3.45 (± 2.5) packed red blood cells. Neurotrauma was frequent (n = 80, 57.1%); among them, 40 patients had severe TBI. 72.5% of these had intracranial pressure catheter (ICPc) monitoring and 30% needed neurosurgery (17.5% of them required decompressive

craniectomy). Overall mortality was 16.4% (n = 23); the mean ICU-length of stay was 13.2 days, and the mean of MV duration was 7 days. The most frequent cause of early mortality (<48 hours) was intracranial hypertension (n=7). The factors independently associated with ICU-mortality were ISS (OR 1.06, CI 1.00-1.12, p=0.034), severe TBI (OR 4.48, CI 1.37-16.61, p=0.014) and shock (4.02, CI 1.21-13.3, p= 0.023). The adjusted survival analysis showed higher ICU-mortality over time in severe TBI patients (HR 2.9, CI 1.18-7.17, p=0.02).
CONCLUSION. The factors associated with ICU-mortality were ISS, severe TBI and shock. It emphasizes the importance of neurotrauma for its frequency as well as its implication as a prognosis in mortality.

INTRODUCTION. Pesticide self-poisoning accounts as a high percentage in suicidal attempts, especially in agricultural countries. Although many of the systemic effects of organophosphate exposure have been extensively studied, endocrine consequences are still unclear.
METHODS. In order to assess the effects of acute organophosphate poisoning we performed a prospective, observational and cross-sectional study on 13 patients admitted in the Intensive Care Department after self-ingestion of pesticides. Patients with documented pre-existing endocrine dysfunction or in treatment with acetylcholinesterase inhibitors were excluded. The final study group included seven patients in whom we determined levels of acetylcholinesterase, cortisol, free triiodothyronine (fT3), free thyroxin (fT4), thyroid-stimulating hormone (TSH) and prolactin on admission and after 24 hours. Results were statistically analyzed using t-test and correlations, setting a standardized significant P value of 0.05.
RESULTS. All patients in the study group survived after adequate treatment was administered. Acetyl-cholinesterase level was significantly lower on admission indicating an acute organophosphate intoxication status (mean difference between determinations 1312 U/L, p = 0.0034). Cortisol level was significantly lower on the second measurement with a mean difference of 25 ng/ml (p = 0.011). Levels of fT3, fT4 and TSH were also significantly lower at 24 hours post-exposure (p=0.001). Increase of fT3 correlated with increase of fT4 on admission with a p = 0.053. Moreover, increase of fT4 on admission was proportional with the increase of cortisol levels (p= 0.04). Prolactin levels registered no statistically significant changes.
CONCLUSION. The present study demonstrates that acute organophosphate poisoning can induce an endocrine dysfunction. High levels of cortisol can be induced by the accumulation of acetylcholine as well as by the direct effects of organophosphate compound. Therefore, normalizing acetyl-cholinesterase levels can solve the adrenal dysfunction. This study identified changes in thyroid hormone levels, suggesting the possibility of a non-thyroidal illness in these patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000090

INTRODUCTION. Antibiotics are overused in elderly patients with acute respiratory tract infection because virus infection is under-evaluated. We aimed to evaluate the effectiveness of combining point-of-care multiplex PCR test (FilmArray Respiratory Panel, BioFire Inc.) and serum procalcitonin (PCT) level for antibiotic stewardship in the emergency department (ED).
OBJECTIVES. To test whether combining procalcitonin test and rapid molecular test for respiratory virus would change physician's antibiotic prescription and patients' outcome
METHODS. We conducted a prospective bi-center cohort study that enrolled elderly (aged ≥ 65 years) patients who presented to the ED with severe acute respiratory illness (SARI) between January 2017 and March 2018. Eligible patients received a rapid molecular test with 17 respiratory viruses and a PCT test. Physicians were recommended to stop or de-escalate antibiotics if a patient had a PCT level < 0.25 ng/mL and a positive test for respiratory viruses. To evaluate the clinical impact, we compared the outcomes of SARI patients between the experimental cohort and a propensity score matched historical cohort. The primary outcome was the proportion of antibiotics discontinuation or de-escalation in the ED. The secondary outcomes included duration of intravenous antibiotics, length of hospital stay, and mortality.
RESULTS. Between January 1, 2017, and March 30, 2018, we enrolled 169 eligible patients, of which 36 (27.9%) were tested positive for virus. Influenza A or B (7.7%) and respiratory syncytial virus (5.3%) were the major two viruses identified. By propensity score matching, we selected 507 SARI patients with similar demographic and comorbidity characteristics in 2016 as the control group. Compared with controls, the experimental group had significantly higher proportion of antibiotics discontinuation or de-escalation in the ED (26.0% vs.16.1%, p = 0.007), neuraminidase inhibitor use in the ED (8.9% vs. 0.6%, p < 0.001), shorter duration of intravenous antibiotics (12.5 ± 12.0 vs. 16.8 ± 13.6, p < 0.001), shorter length of stay (17.0 ± 14.5 vs. 19.7 ± 17. 2, p = 0.042). The 30-day mortality rates were not different in the two groups.
CONCLUSION. Viral infection is under-evaluated in elderly patients with SARI. Combining FilmArray RP and PCT testing may be a useful strategy for antibiotic stewardship in this group of patients.

INTRODUCTION. The randomized, double-blind, multi-center, phase 3, noninferiority ASPECT-NP trial evaluated C/T (at double the currently approved dose) vs MEM for treating ventilated nosocomial pneumonia (NP). As part of randomization, pts were stratified by NP type, i.e., ventilator-associated pneumonia (VAP) vs vHAP, the latter of which is associated with worse prognosis. The expected higher 28-day mortality rate in the vHAP subgroup was only seen in the MEM arm (37.0% in vHAP vs 20.3% in VAP) but not the C/T arm (24.2% in vHAP vs 24.0% in VAP).
OBJECTIVES. To retrospectively explore potential reasons behind the between-treatment mortality difference observed in the vHAP subgroup of ASPECT-NP.
METHODS. Mechanically ventilated pts with NP were randomized 1:1, stratified by NP type (VAP vs vHAP) and age (<65 y vs ≥65 y), to receive 3 g C/T or 1 g MEM, by 1-h IV infusions every 8 h for 8-14 d. Lower respiratory tract (LRT) cultures were obtained from all pts at baseline. Pathogen identification and susceptibility were confirmed at a central laboratory. The primary endpoint was 28-d all-cause mortality in the intent-to-treat (ITT) population, with a 10% noninferiority margin. Pathogens and antibacterial susceptibility are presented for the microbiologic ITT (mITT) population (i.e., pts with ≥1 dose of study drug and with baseline LRT pathogens susceptible to C/T and/or MEM).
RESULTS. 362/362 C/T (27.3%) and 108/364 (29.7%) MEM pts had vHAP. Baseline characteristics and causative pathogens (mostly *Klebsiella pneumoniae, Pseudomonas aeruginosa,* and *Escherichia coli*) in pts with vHAP were generally similar between treatment arms (Table). In the MEM arm of the mITT population (MEM MIC50/90 for gram-negative pathogens: <0.064/8 µg/mL), there were 8 MEM non-susceptible baseline isolates in the 71 mITT pts with vHAP; all Enterobacteriaceae were MEM susceptible (MIC ≤1 µg/mL). In the C/T arm of the mITT population (n=55), the C/T MIC50/90 for gram-negative pathogens was 0.5/128 µg/mL. In the ITT population, 28-day mortality was 24.2% (24/99) with C/T and 37.0% (40/108) with MEM (difference: 12.8%; 95% confidence interval: 0.18, 24.75). As assessed by the investigator, the proportion of vHAP patients who died by Day 28 due to fatal AEs was 9/99 (9.1%) in the C/T arm vs 17/108 (15.7%) in the MEM arm; the proportion of pts who died due to underlying conditions was 10/99 (10.1%) vs 16/108 (14.8%), respectively; and the proportion of pts who died due to NP was 5/99 (5.1%) vs 5/108 (4.6%), respectively.
CONCLUSION. These exploratory analyses in the vHAP subgroup of the ASPECT-NP trial are limited by their retrospective nature and the smaller sample size. Fewer vHAP patients in the C/T arm died due to fatal AEs/underlying conditions compared with MEM. The difference in 28-day mortality observed in the MEM- vs C/T-treated vHAP pts does not appear to be due to clinically meaningful differences in baseline clinical characteristics, causative pathogens, or antibacterial susceptibility.

INTRODUCTION. Methicillin-resistant *Staphylococcus aureus* (MRSA) and multidrug-resistant *Acinetobacter baumannii* (MRAB) are rising microorganisms in ICUs
OBJECTIVES. We evaluate the utility of the novel loop-mediated isothermal amplification (LAMP) to rapidly detect MRAB and MRSA in bronchoalveolar lavage (BAL) fluids for surveillance of colonization and etiologic diagnosis
METHODS. Two conditions of LAMP reactions that have different limit of detection have been developed using reference strain that target *mecA/femB* gene (Genbank No. AB505630.1/CP010300.1) of MRSA and *bla*OXA-23/*bla*OXA51-like gene (Genbank No. KF305669.1/DQ385606.1) of MRAB by adjusting composition of primers and reaction time. these two conditions of LAMP reaction were applied to 123 of BAL samples from clinically suspected VAP patients and compared it with quantitative BAL fluid culture method
RESULTS. Compared to quantitative BAL fluid culture method, the sensitivity, and specificity of the M-/C- condition of LAMP reaction was 81.8%/65.9% and 84.8%/91.1% in MRSA and 90.2%/97.5% and 71.9%/56.1% in MRAB. And The diagnostic accuracy of the M-/C- condition of LAMP reaction in was 83.73%/82.11% in MRSA and 65.91%/78.04% in MRAB
CONCLUSION. The LAMP assay is promising method to surveillance and etiologic diagnosis of MDR pathogen in VAP patients

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000338

INTRODUCTION. The global incidence and mortality of Tuberculosis (TB) progressively decreased along the past years around the world. However, some patients coursing advanced stages of the disease may require vital support in Intensive Care Units (ICU). Comorbidities, HIV infection, and other community or nosocomial infections are frequently associated and may contribute to decreasing survival. The clinical course could evolve with respiratory failure, circulatory shock, and sepsis with variable organ dysfunction. Patients who need mechanical ventilation show mortality rates higher than 50%. Since ICU admission occurs in a low percentage of the patients, few communications are describing the clinical phenotype and outcome in the critical care setting.
OBJECTIVES. To describe the phenotype and genotype characteristics of critically ill TB patients, and to investigate possible molecular biomarkers of virulence.
METHODS. One hundred and four TB patients were admitted in a general ICU. *Mycobacterium tuberculosis* was suspected based on compatible clinical, radiologic, and epidemiological factors. The microbiologic diagnosis was confirmed by a) Positive cultures; b) Acid-Alcohol Resistant Bacilli in sputum or bronchoalveolar lavage; c) Positive GeneXpert for *Mycobacterium tuberculosis*; d) Histopathological findings in tissue autopsy/biopsy when corresponding.
Molecular genotyping of *Mycobacterium tuberculosis* strains were made by MIRU-VNTR and Spoligotyping techniques. miRNA profiles in serum were studied as potential biomarkers of severity. Clinical, radiologic, laboratory and physiological variables were correlated with ICU mortality.
RESULTS. During the study period, 104 among 6.353 critically ill patients (1.6%) were admitted to the ICU with active TB disease. The patient population was relatively young with male predominance and low HIV-positive incidence (20%). Genotype investigation identified Ghana, Haarlem, Lam10, Lam9, and Lam3 lineages. Haarlem (49.2%) followed by Lam3 (28%) strains predominated in these ICU patients.
The miRNA profiles from 16 patients were compared with normal serum from a public database. Bioinformatic analysis showed that some specific miRNAs significantly enriched in plasma from TB individuals making them as possible biomarkers for diagnosis, prognosis, and virulence.
The global ICU mortality was 50%, but it was higher in patients under mechanical ventilation (64.5%). After multivariate analysis, APACHE II score and cardiovascular dysfunction ($p<0.05$) were independently associated with death.
CONCLUSION. A better phenotype and genotype characterization and the identification of possible miRNA biomarkers of severity could contribute to an earlier and more effective therapeutic intervention in these patients.

Assessment of pleural effusions associated with pneumonia in the ICU

J. Hornsby[1], S. Daly[2], G. Murphy[2], K. Puxty[1]
[1]Intensive care medicine, Glasgow Royal Infirmary, Glasgow, United Kingdom; [2]Respiratory medicine, Glasgow Royal Infirmary, Glasgow, United Kingdom
Correspondence: J. Hornsby
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001515

INTRODUCTION. The incidence of parapneumonic effusion and empyema in the intensive care unit is not well studied. Pleural effusions in ICU are common with some studies suggesting an incidence of 40-60% of which parapneumonic effusions may account for approximately 40% of these effusions. Pleural infections result in a longer ICU stay compared with those without pleural infections. We aimed to review the assessment of pleural effusions associated with pneumonia and diagnosis of parapneumonic effusions in a mixed level 2/3 ICU in a large teaching hospital (Glasgow Royal Infirmary).
METHODS. The Electronic Patient Record (EPR) was interrogated to identify any patient admitted between 01/01/2017 and 01/07/2017 that had a diagnosis of "pneumonia" in the problem list. The radiology reports for these patients were reviewed (Chest X-Ray and CT Thorax) and those that commented on pleural effusion were included for assessment. The radiology was reviewed by two senior respiratory registrars who made a recommendation regarding pleural ultrasound to further assess or facilitate diagnostic aspiration of the effusion. Those patients identified by the electronic search also underwent a case review by a senior intensive care medicine registrar to confirm the diagnosis of pneumonia.
RESULTS. Six hundred patients were admitted during the audit period. Sixty patients (10%) were identified using the electronic search parameters. Of these, 16 (27%) met the inclusion criteria – a diagnosis of pneumonia and radiologically confirmed pleural effusion. Nine patients had a diagnosis of Community Acquired Pneumonia, 5 Hospital Acquired Pneumonia, 1 Aspiration Pneumonia and 1 ongoing pleural infection following a community acquired pneumonia. Two patients were excluded as the imaging reviewed was outside the audit period.
Assessment of effusions: Of the 16 patients; 6 (37.5%) had the presence of the effusion recorded in the notes and 2 (12.5%) effusions were assessed by ultrasound. Pleural fluid samples were sent in 2 (12.5%) patients: one who was assessed by ultrasound and underwent pleural aspiration. One of which had fluid sent from a pre-existing drain. Of the patients with potential parapneumonic effusions in ICU, 10 (62.5%), did not have any assessment or investigation performed.
Complications: Of the 16 patients with an effusion associated with pneumonia, 3 (18.75%), developed a complication from pleural infection. This included systemic sepsis, a multi-loculated effusion requiring a prolonged course of antibiotics and a hospital readmission with recurrence of pleural infection.
Review of imaging by Respiratory Registrars: Twenty-four chest x-ray and 12 CT studies were assessed. Ultrasound assessment was suggested by both respiratory clinicians for 12 patients (75%). Only 2 (12.5%) of these patients underwent ultrasound examination.
CONCLUSION. Pleural effusions occur commonly in ICU patients with potential parapneumonic effusions seen in 27% of the study group. Complications were significant and developed in over one sixth of patients (18.7%, n=3). We believe that most of these patients should have had an ultrasound evaluation and an aspiration with analysis of pleural fluid considered. This occurred in less than 19% of patients in our study. Education on assessment of potential parapneumonic effusions and thoracic ultrasound is ongoing.

INTRODUCTION. Recent studies propose plasma midregional pro-adrenomedullin (MR-proADM) as early marker of organ dysfunction in critically ill patients with infections and sepsis.
OBJECTIVES. As severe microcirculatory derangement has been demonstrated in patients with sepsis-related organ failure admitted to critical care unit (ICU), the primary objective of this study is to assess if a correlation existsbetween plasma MR-proADM and Microcirculatory Flow Index (MFI) in 20 adult patients admitted to ICU with suspected infection. It is also purpose of the study to evaluate the relationship between MR-proADM and Total Vessel Density (TVD), Perfused Vessel Density (PVD), Proportion of Perfused Vessels (PPV) and with organ failure in this group of patients.
METHODS. Prospective observational study articulated in five days of monitoring (T1-T5). Plasmatic MRproADM was dosed for all time-points. At T1, T2 and T5 the sublingual microcirculation was assessed using Incident Dark Field technology. Laboratory and clinical data were collected to calculate the Simplified Acute Physiology Score (SAPS) II and Acute Physiology and Chronic Health Disease

Classification System II (APACHE) scores at admission in ICU and daily Sequential Organ Failure Assessment (SOFA) score. Exclusion Criteria: Age<18 years old, ICU stay>24 hours before inclusion, refusal to consent, conditions that do not allow clear monitoring of sublingual microcirculation.

RESULTS. This is a half-sample preliminary analysis. MRproADM> 1.5 nmol/l showed good discrimination capacity toward SAPS II and APACHE II scores at admission in ICU, Area Under the Curve (AUC) respectively 0.90[CI 0,69-1] p=0.04 and 0.96[CI 0.84-1] p= 0.06 [Fig. 1]. Persistence of MRproADM>1.5 nmol/l at T5 was able to discriminate worsening microcirculation in term of MFI of either small, AUC 0.92[CI 0.73-1] p=0.03 and total vessels, AUC 0.92[CI 0.73-1]p=0.03 and of PPV, AUC 0.83 [CI 0.57-1] p=0.09 [Fig. 2]

CONCLUSION. The preliminary results of the study confirm the association between MR-proADM and severity scores at admission in ICU and they show that a correlation exists between moderate-to-high levels of this marker and microcirculatory dysfunction in critically ill patients with infection.

INTRODUCTION. Serum procalcitonin level is a valuble biomarker for diagnosing infection and sepsis in critically ill patients (1). Recent studies suggest that procalcitonin levels can be increased in non critically ill patients with chronic kidney disease (CKD) without any infection (2). The aim of this study was to investigate the effect of renal failure on serum procalcitonin levels and the value of serum procalcitonin for diagnosis of infection in patients with renal failure

METHODS. Patients who were admitted to our intensive care unit between January 2012 and November 2015 and whom procalcitonin levels were obtained during their hospitalization were examined retrospectively. The diagnosis of renal failure were made according to RIFLE score.

RESULTS. Out of 907 patients included in to the study, 304 patients had normal renal function, 379 patients had acute renal failure (ARF), 133 patients had CKD and 91 patients had ARF on CKD. Serum procalcitonin levels were higher in patients with CKD and in patients with ARF than in ones with normal renal function ($p < 0.05$) (Table 1). According to ROC analysis procalcitonin level was a good predictor for diagnosing infection and sepsis in both patients with and without normal renal function. However higher treshold values were obtained for diagnosing infection and sepsis in patients with renal failure (Table 1).
CONCLUSION. Serum procalcitonin level is a good predictor marker for diagnosing infection and sepsis in patients with and without renal failure. However, higher threshold values should be used in patients with renal failure compared to patients without any failure.

INTRODUCTION. Elder patients are becoming a noteworthy population in-ICU. Tools aimed to predict their performance in-ICU could have a main role to help the clinicians manage ICU resources.
OBJECTIVES. To design predictive models to estimate the risk to acquire different nosocomial infections in-ICU for patients older than 64 years old.
METHODS. Data was obtained from the 2013-2016 ENVIN-HELICS registry, prospective multicentric study of in-ICU acquired infections. Data regarding demographics, comorbidities, used techniques and outcome was gathered. The studied infections were: ventilator associated pneumonia (VAP), catheter related urinary infection (CUI) and primary and secondary bloodstream infections (BSI). The population was geographically divided in two groups, for the model to be developed in the first one and validated in the second one. The factors related to the development of in-ICU infections were determined by multivariate analysis, each of them related to its logical population; its predictive value was evaluated by the AUC and goodness of fit by the Hosmer Lemeshow test (HS).
RESULTS. A total of 37172 patients older than 64 years old were registered in the study period, most of them for medical causes (65.5%). Mean age was 75,1 years (SD 6,5 years). 41.8% needed mechanical ventilation and 76.0% urinary catheter. 165 VAP, 409 CUI, 472 primary BSI and 404 secondary BSI were diagnosed. Overall in-ICU mortality was 11.5%, higher in patients with any in-ICU acquired infection but mostly remarkable in those who suffered VAP (41.9%) or secondary VSI (40.1%). Regarding factors associated to VAP, gender (male vs. female OR 1.7; CI 95%1.4-2.0), malnutrition (OR 1.70; CI 95% 1.3-2.2), devices such as renal replacement therapies (OR 3.0; CI95% 2.8-3.7), tracheostomy (OR 7.4; CI95% 6.2-8.8) or central venous catheter (OR 3,7; CI95% 2,1-6,6), and the acquirement of a MRSA were related to its diagnosis. In the CUI predicting model similar variables were used, and in those regarding both kinds of BSI most of the variables included in the model regarded used devices. The AUC in all of them was higher than 0,78, showing excellent fit according to the HS test (p value over 0.1 in all of them).
CONCLUSION. In-ICU acquired infections are associated to several factors regarding demographics, comorbidities and used devices. The predictive models developed for VAP, CUI and primary and secondary BSI out of the sum of prognosis factors had a good discriminatory power and excellent fit.

INTRODUCTION. Patients admitted to the intensive care unit (ICU) are frequently treated with antimicrobial agents. Optimizing antimicrobial use is imperative to reduce infection-related morbimortality and to limit the emergence of multidrug-resistant microorganisms (MDRMs).
OBJECTIVES. To describe the process of implementation of an antimicrobial stewardship program (ASP) in a 22-bed mixed ICU of a third-level university hospital in Spain (608 beds) and the results of a 6-month pilot experience.
METHODS. A multidisciplinary ASP group was created (intensivist, internist, microbiologist, pharmacist, preventivist, nurse and intensive

care resident). Theorical need for antimicrobial agents use was discussed in daily meetings of the group, whenever a result of a microbiological test was positive, taking into account the clinical setting, infectious syndrome, isolated microorganism and antimicrobial pharmacology. Non-mandatory recommendations concerning better use of antimicrobials were proposed to the intensive care physician after each meeting, including de-escalation (switch to narrower spectrum or discontinuation of treatment), adequacy (change to same spectrum or start a new treatment), optimization (duration, dose or route of administration) and escalation (switch to broader spectrum). We report antimicrobial utilization and expense, expressed as daily defined dose (DDD) per 100 bed-days (BD) and euros (€), respectively, in the ASP period and in the same period of the previous year (baseline period), as an exploratory endpoint.

RESULTS. A total of 120 meetings were held, where 92 recommendations were proposed over 54 patients (54.3% male, age 61±15 years old), with a 90.2% of adherence (77.8% of the rejected interventions were due to severity of the condition). The most common microbiological samples to trigger an intervention were blood cultures (52.2%) and respiratory samples (26.1%), and the most common microorganisms were Gram-negative bacteria (46.7%), Gram-positive bacteria (37.8%) and fungi (17.4%). Most infections were community-acquired (55.4%), with 9.8% of MDRMs, and the most common sites of infection were the lungs (40.2%), abdominal organs (14.1%) and urinary tract (13%). Antimicrobial stewardship was essentially proposed as de-escalation (70.7%), but also as adequacy (18.5%), escalation (7.6%) and optimization (3.2%). Most interventions were advised over carbapenems (imipenem and meropenem) (20.5%), other antibacterials (linezolid and daptomycin) (20.5%) and penicillins (ampicillin, amoxicillin/clavulanic, cloxacillin and piperacillin/tazobactam) (14.5%). Antibiotic and antifungal use increased from 135.8 to 162.4 and from 40.7 to 72.4 DDD/100 BD, respectively, during the ASP period, with a decrease in expense (33,642 to 32,777 € and 152,590 to 99,547 €). A higher incidence of *Aspergillus* during the influenza season and a change of price of echinocandins during the ASP period may limit the interpretation of antifungal utilization results. Differences in terms of severity and reason for admission may limit the comparison of baseline and ASP periods.

CONCLUSION. Implementation of an antimicrobial stewardship program in intensive care is feasible, cost-effective and safe. The most common intervention was de-escalation, with a high adherence rate to the proposed recommendations.

INTRODUCTION. despite macrolides are widely used in chronic respiratory diseases such as cystic fibrosis and chronic obstructive pulmonary disease because of its anti-inflammatory and immunomodulator effects, its use in acute pulmonary infection remains controversial.

OBJECTIVES. the main objective of our study was to evaluate the impact in prognosis of macrolide treatment in critical care patients with severe viral pneumonia.

METHODS. prospective, cohorts and multicenter study in critically ill patients with confirmed viral pneumonia. Study period went from June 2009 to April 2018, and 181 Intensive Care Units participated. Patients admitted to an ICU due to confirmed influenza pneumonia were included. Demographic, clinic and analytic variables, comorbidities, level of severity according to Acute Physiology and Chronic Health Evaluation II (APACHE II) score and antibiotic treatment received were registered, among other variables. We only considered patients who received combined empiric antibiotic therapy and compared those who received combined therapy with macrolides and those who received other combinations. Differences between groups were assessed using Chi-square and T-Student test as appropriate. We performed a multivariate analysis by binary logistic regression to determine which variables were independently associated with mortality. Significant p<0,05.

RESULTS. Of the 4175 patients who presented confirmed viral pneumonia, 2962 (70,9%) received combined empiric antibiotic treatment. Mean age was 54 years with a mean APACHE II score of 17. Global mortality was 22,5%, and it was significantly lower in the group of patients who received macrolides (17,5%) comparing to the ones that received other combinations (25,1%; p<0.05). Receiving macrolides was independently associated with a lower risk of mortality after adjusting the regression logistic model according to age, APACHE II score, need of mechanical ventilation, presence of shock, comorbidities and corticosteroid treatment (OR= OR 0,75, IC 95% 0,60-0,93; p=0,008). Bacterial coinfection was present in 702 patients. Mortality in this group was 29,3% and having received macrolides was not associated with lower risk of mortality (OR 0,92, IC 95% 0,61-1,38, p=0,68). On the other hand, the group of 2260 patients who presented primary viral infection showed lower risk of mortality when receiving combined antibiotic treatment with macrolides (OR= 0,69, IC 95% 0,54-0,89; p=0,005).

CONCLUSION. our results suggest there is a beneficial effect in macrolides treatment in patients with influenza virus infection. This effect does not seem to be related with its antibacterial activity. Its possible immunomodulatory effect in this specific population should be addressed in future studies.

INTRODUCTION. Antibiotic dosing in critically ill patients is difficult because of altered pharmacokinetics (PK) [1,2]. Population PK model based dose adaptation plays an important role in optimizing antibiotic dosing due to its ability to include covariate effects and PK variability. Population PK models are able to describe the time course of drug concentration after administration of a dose. Further, PK models can predict concentrations following the dosage regimens under consideration. These techniques are increasingly applied in clinical care though typically require specialized expertise and software [3]. Moreover, the use of software based dose adaptation has to date not been widely investigated and trials are eagerly anticipated [4]. We developed a clinical decision support system for real-

time bedside personalised dosing, which is being evaluated in an ongoing randomised controlled trial. For this, we required an automated clinical dosing algorithm to determine the recommend dosage regimen.
OBJECTIVES. To develop a clinical dosing algorithm based on PK models to generate real-time antibiotic dosing advices that can be implemented in a software package for personalised antibiotic dosing in critically ill patients.
METHODS. Dose recommendations are based on pharmacokinetic principles. The goal is to inversely find a dose which is able to maintain a needed PK exposure of the target given a dosing time schedule. An important presumption that is made in dose calculation is the linearity of PK. Accordingly, PK exposure is proportional to the dose. Thus, if one measures the area under the concentration-time curve (AUC) for a 500 mg dose, one can estimate the AUC for a 750 mg dose in the same patient as being 50% greater. The Target maintenance dose (MD) can be calculated using the following equation:

$$MD_{\text{target}} = \frac{AUC_{\text{target}}}{AUC_{test}} \cdot MD_{test} \quad (1)$$

Particularly, when the clearance (CL) of a patient is expected consistent over the time period of interest, the target maintenance dose can also be calculated through the following equation:

$$MD_{\text{target}} = AUC_{\text{target}} \cdot CL \quad (2)$$

For adaptive dosing advice it is also required to calculate a loading dose. The design of loading dose (LD) calculation is to derive a dose that enables the concentration right after the administration to achieve the target maximum concentration (Cmax) of MD-maintained steady state. Lastly, a dosing interval needs to be chosen.
RESULTS. Based on these pharmacokinetic principles we devised an iterative method for deriving a clinical dosage regimen. The final advice consists of a start time, if needed a loading dose, a maintenance dose and a dose interval. They are incorporated in a closed looped algorithm while taking safety precautions into account.
CONCLUSION. We successfully developed a clinical dosing algorithm. It is incorporated in AutoKinetics, a clinical decision support system for personalised antibiotic dosing. It alllows for automated adaptive antibiotic dosing regimes. if proven effective in improving clinical outcomes, it could pave the road forward towards true personalised antibiotic dosing.

INTRODUCTION. Ventilator-associated pneumonia due to methicillin-resistant Staphylococcus aureus (MRSA) is associated with excess mortality and costs. Molecular biology test allows rapid identification of MRSA. Our hospital reaches an incidence of 28% of infection by MRSA and is responsible for a high cost in the intensive care unit. Clinical suspicion of VAP is the most frequent cause to use Linezolid as a first antibiotics treatment, in spite of Guidelines recommend considering methicillin-resistant Staphylococcus aureus (MRSA) just in case of hight suspicion of infections, according to the bacterial ecology of the unit. Initially designed to identify MRSA in nasal secretions, its use has been then validated in bronchial aspirations. We hypothesized that use of a rapid diag- nostic test was associated with a decreased use of anti-MRSA antibiotics prescribed for patients with suspected VAP. Using this diagnostic test, we checked how we saved on the cost of antibiotics. This is important not only in what implies a lower cost, since linezolid resistant microorganisms appear every time, posing a challenge for the clinical doctor and serious infections in ICU.
METHODS. We carry out this observational, descriptive and retrospective study. For this, we chose a total of 50 patients admitted to the ICU for any pathology during January 2016 and December 2017 in our intensive care unit. (Reina Sofía University Hospital, Córdoba, Spain) that had developed NAVM and which had been requested PCR in respiratory samples for etiological diagnosis. Age, mortality in the ICU, the date on which the CRP was requested, the APACHE II scale, SOFA, the days of ICU stay, the days of MV and the antibiotic therapy before and after the PCR outcome of the study were collected as variables.
RESULTS. 50 patients admitted during 2016 and 2017 in our ICU, the median age was 56 years and 34 were men (68%) and 16 women (32%). The median length of stay in the ICU was 16 (2-117). Mortality during admission was 48%. We use the APACHE II and SOFA scales as prognostic scales, being 20 and 5 the mean, respectively. The average of the days of mechanical ventilation were 19. With respect to the result of the diagnostic tests by PCR, in 46 of them no bacterial growth was obtained, a sample of MRSA and 3 of MSSA were isolated. The initial antibiotic regimen that included Linezolid was administered in 13 patients prior to the PCR result, of which, it was substituted after the result of the test in 7 patients.
CONCLUSION. The use of PCR as a rapid diagnosis of VAP caused by MRSA resulted in a total cessation of the administration of broad-spectrum antibiotic therapy in a patient whose result was negative. The rapidity with which the microbiological diagnosis is obtained with this type of technique, led us to diagnose in a short period of time that the cause of the pneumonia associated with the ventilator was not MRSA, and therefore, de-escalate antibiotic therapy, with the consequent cost savings and improving the usual clinical practice before the remarkable increase of new resistance against these antibiotics at present.

INTRODUCTION. The results of numerous studies on the implementation of antibiotic stewardship programs (ASP), including intensive care units (ICUs), provide conflicting data on their effect on antimicrobial resistance, antibiotic consumption and secondary outcomes [1-3].
OBJECTIVES. To assess the effect of ASP on antibiotic consumption, antimicrobial resistance and clinical outcomes in patients with infection in the ICU.
METHODS. A prospective interventional single-center study was conducted in the period from January 2011 to December 2017. The intervention: ASP, including multidisciplinary team building, antimicrobial therapy and prophylaxis protocols, infection control measures, personnel training and internal audit. The data from 2012 (pre-intervention) and 2017 (intervention) reports were compared. We assessed consumption of antibiotics in the ICU, antibiotic therapy duration, drug resistance index (DRI) of gram-negative ESKAPE pathogens in the ICU, the share of ESKAPE-bacteremia and candidemia in the ICU, length of hospital stay (LOS) and mortality of the patients with infection, complicated by bacteremia in the ICU.
RESULTS. Total consumption of antibiotics has not significantly changed: 227.3 from 238.6 DDD/100 days. Meanwhile, the structure of consumption significantly changed with the decrease in antibiotics for the treatment of the following infections (DDD/100 days): carbapenems from 46.4 to 34.4, aminoglycosides from 10.0 to 2.2, fluoroquinolones from 29.8 to 21.3. The consumption of 1st generation cephalosporins for perioperative antibiotic prophylaxis increased from 4.2 to 98.1. The average duration of therapy in patients with infection in the ICU decreased from 15.7 to 10.4 days, p<0.01, with bacteremia from 22.7 to 12.8, p<0.001. The dynamics of changes in the DRI of gram-negative ESKAPE pathogens in the ICU and the share of ESKAPE-bacteremia and candidaemia in the ICU are shown in Figures 1 and 2. LOS for patients with an infection complicated by bacteremia decreased from 48.8 days to 35.4 days, p = 0.039, Hospital mortality of ICU patients decreased from 38,8% to 31,5%, p<0.536.
CONCLUSION. The introduction of ASP into the ICU leads to a significant change in the structure of antibiotic consumption shortening the average duration of antibiotic therapy for infections including those complicated by bacteremia. This leads to the reduction of prevalence and antibiotic resistance of nosocomial pathogens, but does not lead to a significant improvement in secondary outcomes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000942

INTRODUCTION. Health care associated infections (HAI) suspicious require immediately empiric antibiotic treatment, most of times with broad spectrum antibiotics. The implementation of Antimicrobial Stewardship Program (ASP) seems to be a useful way to improve antibiotic management, also in HAI.
OBJECTIVES. To compare the evolution of antibiotics used for HAI in Paediatric Intensive Care Units (PICU) from the Spanish registry Paediatric-ENVIN-HELICS, after a progressive ASP implementation.
METHODS. Multicentre, prospective and observational study. HAI diagnosed in 24 Spanish PICU, from April to June of 2013–2017, were included. The ENVIN diagnostic criteria adapted to paediatrics were used, based on CDC recommendations. ASP was consensuated and recommended, with progressive implementation along 2014-2017. SPSS®21 programme was used.
RESULTS. The total number of patients included in 5 years was 8717. Eight PICU (32%) had an Antimicrobial Stewardship Program (ASP) in 2017 compared with none in 2013 (p=0.000). The rate of antibiotics use progressively decreased (4%, p=0.0179).
In 2017 the number of antibiotics indicated per patient was 1.34 and per patient with antibiotics was 1.81. Whereas in 2013 that number was greater: 1.6 and 2.06, respectively.
Regarding the antibiotic indicated for HAI previous PICU admission, there was an increase on meropenem use of 1.64% (not statistically significant), while the use of piperacillin-tazobactam significantly decreased (4.97%, p=0.0123). However, meropenem indication for HAI in PICU patients dropped down (4.62%, p=0.05).
During 2017, the practice of antibiotic stewardship was 13.93% higher (p=0.0048). There was also an increasing tendency for early suspension antibiotic rate (6.78%, not statistically significant). The results also showed a decrease of antibiotic modification due to adverse event (1.19%, p=0,0021), compared with 2013.
CONCLUSION.

1. The rate of antibiotics use was high, with almost 2 antibiotics indicated per patient, but results showed a decreasing trend during 2017.
2. The implementation of ASP in PICU probably has led to a better use of carbapenems, and to an increase of antibiotic de-escalation and early suspension rate.
3. Modifications of the antibiotic regime due to adverse event have decreased.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001062

INTRODUCTION. Although antifungal de-escalation therapy has been previously studied in critically ill patients, few data has been provided about its consequences on antifungal use in this setting
OBJECTIVES. The aim of this study was to analyze the impact of an Antimicrobial Stewardship Program (ASP) on antifungal consume from ICU to ICU.
METHODS. Retrospective study during 24 months from April 2016 to June 2018 with a pre-post intervention design in two ICU in an unique universitary hospital. Medical (16 beds) and Surgical (6 beds) ICUs were included. Preintervention period (Pre ASP implementation) lasted from April 2016 to March 2017 and post implantation period from July 2017 to June 2018. All patients treated with Liposomal amphotericine B, anidulafungin, caspofungin, micafungin, voriconazole and posaconazole were analyzed.in both periods. Clinical and microbiological variables were recorded. Daily doses DDD/100 stays and economic impact (expressed in euros) of the intervention were also studied. Wilcoxon Rank-sum test was performed to compare the pre and post consume of prescribed antifungal drugs.
RESULTS. In Medical ICU there were a clearly decrease of DDD/ 100 stays of all the antifungals studied : posaconazole (100%; 0,16 vs. 0,00), liposomal amphotericine B (93,6%; 14,81 vs. 0,95), micafungine (73%; 0,10 vs. 0,03), anidulafungin (54%; 0,98 vs. 0,45), voriconazole (28%; 1,64 vs. 1,18) and caspofungin (11%; 3,63 vs. 3,25). In Surgical ICU, a clearly reduction of DDD/100 stays was also observed in liposomal amphootericine B (100%; 2,18 vs. 0,00), micafungine (61%; 5,87 vs. 2,31), caspofungin (55%; 12,73 vs. 5,77) and anidulafungine (41%; 11,07 vs. 6,51), whereas voriconazole experimented an increased use (18%; 0,89 vs. 1,94). Posaconazole was not used in SICU in the study period
In economical terms , median of cost was reduced with statistical significance 70% in Medical ICU (10.859,4 (5.083,30-19.785,35) vs. 3.154,15 (1.745,45-6.380,28); p=0,042) and 58% in Surgical ICU (16.041,85 (14.601,75-19.762,75) vs. 6.789,45 (5.382,35-9.630,00); p= 0,0005). As a consequence a cost saving of 67,4% in the antifugal consume in Medical ICU (associated saving cost of 94.500 euros) and 58% (associated saving cost of 115.803 euros) in surgical ICU. A global reduction of cost of 210.303 euros in a year was obtained in critically ill patients setting.
CONCLUSION. ASP from ICU to ICU had an exceptional impact on antifungal use and was associated with a real, significant and important cost saving.

INTRODUCTION. Cancer affects up to 20% of critically ill patients, and sepsis is one of the leading reasons for ICU admission in this setting [1, 2]. No recent formal estimation of outcome changes has however been performed. Studies to appraise outcomes in critically ill cancer patients with sepsis are warranted.
OBJECTIVES. To assess trends in survival rates in cancer patients admitted to the intensive care unit (ICU) for sepsis or septic shock over the last two decades.
METHODS. Data from onco-haematological patients admitted to the ICU for sepsis or septic shock were extracted from the GRRR-OH database (1994-2015). A hierarchical model taking into account the year of inclusion and the source dataset as random variables were used to identify risk factors for day 30 (D-30) mortality. A sensitivity analysis within patients with bacterial pneumonia at ICU admission was performed.
RESULTS. Overall, 2062 patients were included in the study. 1225 (42%) patients were male and the median age was 59 [48-67] years. Underlying malignancies included solid tumors (n= 638; 31%), acute leukemia (n=591; 29%), non-Hodgkin lymphoma (n= 461; 22%) and myeloma (n=244; 12%). Two hundred and fifty patients (12%) underwent allogenic stem cell transplantation and 640 (31%) were neutropenic at ICU admission. Death at day 30 occurred in 812 (39%) patients. After adjustment on SOFA score at ICU admission, the year of ICU admission was significantly associated with mortality, decreasing over time (OR 0.96; 95%CI 0.94-0.98) (**Figure 1**). Mechanical ventilation (OR 3.43; 95%CI 2.73-4.32), vasopressor use (OR 1.51; 95%CI 1.20-1.90) and renal replacement therapy (OR 1.40; 95%CI 1.10-1.78) were independently associated with D-30 mortality, whereas the type of underlying malignancy, allogenic stem cell transplantation and neutropenia were not. Sensitivity analysis in the subgroup of patients with bacterial pneumonia (n=858) found similar results.
CONCLUSION. Survival in critically ill oncology and hematology patients with sepsis improves significantly over time. Studies are needed to identify targets to further improve survival in this growing subgroup of ICU patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000275

INTRODUCTION. Alveolar hemorrhage (AH) is characterized by the acute onset of alveolar bleeding and hypoxemia and can be fatal. Thrombin has been widely used to achieve coagulation and hemostasis. However, the efficacy of thrombin in patients with AH is unclear. Thus, this study aimed to evaluate the efficacy of thrombin administration in patients with hematological malignancy and AH.
METHODS. This retrospective study included 15 hematological malignancy patients (eight men and seven women; mean age 47.7 ± 17.3 years) with AH who were administered intrapulmonary thrombin between March 2013 and July 2018. All patients received bovine-origin thrombin (1,000 IU/ml, Reyon Pharmaceutical Co., Ltd., Seoul, Korea) via a fiberoptic bronchoscope. A maximum of 15 ml of thrombin was injected via the working channel to control bleeding. The ability of thrombin to control bleeding was assessed. Additionally, the change in the PaO2/FiO2 (PF) ratio after intrapulmonary thrombin administration was evaluated.
RESULTS. Intrapulmonary thrombin was administered a minimum of 3 days after starting mechanical ventilation in all patients, and it immediately controlled the active bleeding in 13 of 15 patients (86.7%). However, AH relapse was noted in 3 of the 13 patients (23.1%). The PF ratio improved in 10 of 15 patients (66.6%), and the mean PF ratio was significantly higher after thrombin administration than before administration (p = .03). No adverse thromboembolic complications or systemic adverse events were observed.
CONCLUSION. Thrombin administration was effective in controlling bleeding in hematological malignancy patients with AH. Intrapulmonary thrombin administration might be a good therapeutic option for treating AH.

INTRODUCTION. Surgical reoperation as a complication after cardiac surgery. ARIAM-Andalusia Registry.
OBJECTIVES. To analyze the clinical profile and evolution of reoperated patients after cardiac surgery, as wellas the main causes for reoperation.
METHODS. Retrospective study of patients undergoing cardiac surgery in our hospital during5 years (January-2014 to December-2018), and included in the ARIAM-Andalusia registry. We excludedpatients undergoing TAVI. The demographic and surgical characteristics, causes of reoperation and themoment of it, complications and mortality are collected. The quantitative variables are expressed as x +sd and the qualitative ones as number and percentage. T student was made for comparing v.quantitativeand X2 for v.qualitative, and a multivariate analysis of risk factors for reoperation.
RESULTS. 2152 patients were included during the period of the study. 116 of them (5.4%) were reoperatedat the same hospital admission. The re-operated patients had longer surgical times (ECC: 136 + 60 minvs 115 + 50 min, p <0.05) and higher severity scores (Euroscore I: 13.8 + 13.7 vs 9.7 + 11.3, p <0.05)than the non-reoperated ones. When initial emergent surgery happened, reoperation was more frequent(11.2%). Valve or aortic surgery was a risk factor for reoperation (OR 2.7, 95% CI 1.6-4.6). Mortality wassignificantly higher in reoperated patients (28.4% vs 9.9%, p <0.001), and similarly there were higherrates of renal failure (75.2% vs 48.9%, p <0.05) and prolonged times for mechanical ventilation (62.1 vs15.2). %, p <0.005). Early reoperation (<48 hours) was performed in 62 patients (53.4%), beingtamponade (64.5%) and mediastinal bleeding (30.6%) the most frequent causes. In patients whounderwent a delayed reintervention (> 48 hours), tamponade (46.3%), sternal dehiscence (24.1%) andvalvular problems (14.8%) were the most important causes. There were no differences in age, sex, timeor mortality between the two groups; but early reoperation was more frequent after an emergent surgery(18.3% vs 5.6%, p = 0.05).
CONCLUSION. Reoperation after cardiac surgery associates high mortality and more complications, beingtamponade and mediastinal bleeding the most frequent causes.

Alveolar Dead space fraction and arterial saturation predict postoperative course in Fontan patients

E. Shostak[1], O. Schiller[1], G. Amir[2], G. Frenkel[2], T. Shochat[3], O. Dagan[1]
[1]Pediatric Cardiac Intensive care unit, Schneider Children's Medical Center of Israel, Petah Tikva, Israel; [2]Pediatric cardiothoracic surgery division, Schneider Children's Medical Center of Israel, Petah Tikva, Israel; [3]Epidemiology, Rabin Medical Center, Petah Tikva, Israel
Correspondence: E. Shostak
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000352

INTRODUCTION. The Fontan surgery, the 3rd procedure in single-ventricle palliation, redirects systemic venous blood into the pulmonary

circulation for gas exchange [1]. A decrease in pulmonary blood flow can lead to major complications and grave outcome. Even though data shows that these patients benefit from negative pressure ventilation [2, 3], a delicate balance between sedation & analgesia, pharmacological cardiac support and early extubation may be difficult to achieve. To date there are neither validated protocols nor auxiliary tests to predict tolerability of early extubation and guide clinicians with early postoperative management. Alveolar dead-space fraction (AVDSf) represents the portion of inhaled air that does not participate in gas exchange and quantifies ventilation-perfusion abnormalities in the lung[4]. Increased AVDSf has been associated with prolonged mechanical ventilation and worse outcome after congenital heart surgery [5, 6]. The association of AVDSf with clinical outcomes in patients undergoing Fontan operation has not been reported.

OBJECTIVES. Our goal was to find AVDSf and arterial saturation cut-off values which predicts bad post-operative outcome

METHODS. A retrospective charts review of all pediatric Fontan patients from 6/2010-11/2018 in a tertiary-care pediatric hospital was performed. Associations between AVDSf and SaO2 to a composite outcome (need for surgical\catheter-based intervention, ECMO use, prolonged ventilation, prolonged hospital LOS or death) were explored. Secondary endpoints were parameters of severity of illness, chest drainage duration, and LOS

RESULTS. Of 128 patients undergoing Fontan operation, 34 patients met criteria for composite outcome. AVDSf was significantly higher in the composite groups (0.33±0.14) versus control group (0.25±0.26; p=0.016). AVDSf ≥0.29 indicated a 37% increase in the risk to meet composite criteria. Admission SaO2 was significantly lower in composite versus the control group (93.4% Vs 97.1%, p=0.005). AVDSf was significantly associated with increased durations of mechanical ventilation, ICU LOS, duration of thoracic drainage, and parameters of severity of illness

CONCLUSION. We found that high AVDSf and low SaO2 are associated with more complicated postoperative course in children undergoing the Fontan operation. AVDSf value≥0.29 or arterial saturation≤86% should raise concern that the patient may have complex postoperative course

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000355

INTRODUCTION. ECMO is an emerging rescue therapy for severe cardiopulmonary failure. ECMO treatment is technically demanding and assessment of native cardiac output is difficult.

OBJECTIVES. We performed an in vitro simulation on an ECMO Model to assess whether it is possible to calculate pulmonary blood flow (QLung) from ECMO Blood flow (QECMO) and carbon dioxide elimination (VCO2) by a modified Fick-principle.

METHODS. The in-vitro simulator consisted of two perfusate pumps, simulating QECMO and QLung. Two oxygenators (OxyECMO and OxyLUNG) were used to eliminate CO2 and oxygenate the blood. QLung could be diverted into a shunt, bypassing OxyLUNG. CO2 production and O2 consumption were simulated by two oxygenators in series, rinsed with a mixture of CO2 and N2. The system was filled with discarded human blood and heated to 36.5 °C. The experimental protocol consisted of weaning steps with differing shunt values. Exhaust CO2 was measured with a capnometer. VCO2 was calculated as the exhausted fraction of CO2 times gas flow. The modification of the Fick principle Q_total* Δ_(v-ao) CO2 = Q_LUNG* Δ_(v-LA) CO2+ Q_ECMO* Δ_(v-pm) CO2 can be transferred to ⟦ΔQ⟧_LUNG=⟦ΔQ⟧_ECMO*(-Δ⟦VCO2⟧_LUNG)/⟦ΔVCO2⟧_ECMO. (Δ_(v-ao): veno-aortal, Δ_(v-LA): veno-left atrium, Δ_(v-pm): veno-post membrane). In cases of V/Q ≠1, a normalization factor f was applied to correct VCO2 towards a V/Q of 1: f(V,Q)= (Q*(V/Q+c))/(V*(1+c)). Constant c was calculated from a blood gas sample as a function of temperature T, pH, CO2 solubility and the gas constant R.q

RESULTS.

We normalized both VCO2Lung and VCO2ECMO and calculated QLung. Our QLung calculations showed a small bias with wide limits of agreement and good correlation (Figure 1A, r2=0.6372, p=0.0003). Shunt leads to an underestimation of blood flow and decreases correlation (Figure 1B). Normalizing only QECMO increases bias and reduces correlation (Figure 1C, r2=-0.1576, p=0.4230).

CONCLUSION. Our simulation shows that simulated pulmonary blood flow calculations are possible from VCO2 measurements within clinically acceptable limits. V/Q mismatch and shunt will decrease the precision of the method. Measurements are readily available and non-invasive. We will perform animal and human trials to further investigate this method.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000366

INTRODUCTION. Early identification and treatment of vasoplegia following CF-LVAD implantation is imperative to prepare patients for post-surgery recovery. In the absence of a consensus definition of vasoplegia following CF-LVAD, interventions and outcomes can't be reliably assessed.[1-4]

OBJECTIVES. This study aimed to construct criteria that would be reproducible, standardized, and associated with clinical outcomes. This

study reports incidences and associations with non-favorable discharge disposition (death, hospice, long term acute care, and rehab) for 8 permutations of vasoplegia criteria.
METHODS. This retrospective, cohort study included patients who underwent initial CF-LVAD implantation on cardiopulmonary bypass (CPB) at an academic medical center from 08/2016 through 08/2018. Investigators identified 6 considerations for constructing vasoplegia criteria: (1) **Period of observation:** Observation started at CPB termination and lasted for 72 hours; (2) **Unit of time for measurement:** Analysis was conducted at each 15-minute interval; (3) **Clinical constructs:** Three clinical constructs were chosen: low blood pressure using mean arterial pressure (MAP; mmHg) or systemic vascular resistance (SVR; dynesseccm-5), normal cardiac index (CI; L/min/m2), and vasopressor support using norepinephrine equivalents (NEE; mcg/kg/min); (4) **Threshold logic strategies:** Multiple hemodynamic measurements documented within an interval were categorized as having "ever" or "always" crossed the threshold for detection; (5) **Duration**: The number of consecutive intervals where criteria were sustained were analyzed; (6) **Missing data**: The last documented MAP and SVR were carried forward for 3 intervals, and CI for 288 intervals. We evaluated 8 permutations of criteria: two versions, two threshold logic strategies, and two duration cut points. Version 1 used MAP <60 or SVR <800 combined with CI >2.2 and NEE ≥0.1. Version 2 used MAP <60 or SVR <700 combined with CI >2.5 and NEE ≥0.2.
RESULTS. This study included 98 CF-LVAD recipients, accounting for 28,224 intervals. Version 1 had a larger incidence and risk for non-favorable discharge compared to version 2. Meeting criteria for ≥2 consecutive intervals decreased incidence but increased risk for non-favorable discharge.
CONCLUSION. Version 1 "always" for ≥1 interval and version 1 "ever" for ≥2 consecutive intervals occurred frequently (32% to 40%) and increased risk for non-favorable discharge by 19% to 27%.

Predictive value for survival in pre-ECMO lactate level of VA ECMO in adult cardiogenic shock

DW. Kim, IS. Jeong,
Thoracic and cardiovascular surgery, Chonnam National University Medical School, Gwangju, Republic of Korea
Correspondence: D.W. Kim

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000403

INTRODUCTION. The effectiveness of extracorporeal membrane oxygenation for patients with cardiogenic shock is well-established, and lactate is well known as the biochemical biomarker of end organ perfusion. However there were no sufficient data of correlation between pre-ECMO lactate level and survival. We evaluate the efficacy of pre-ECMO lactate level for prediction of survival in patients with cardiogenic shock.
METHODS. We respectively reviewed the medical records of patients who underwent ECMO for cardiogenic shock between January 2015 and December 2017. Of these, 79 adult patients underwent the venoarterial ECMO for cardiogenic shock. These patients were divided into survivor and nonsurvivor groups, based on survival to hospital discharge. The patient characteristics in pre-ECMO condition were compared between 2 groups.
RESULTS. Mean age was 60.9±14.8 years and the overall survival rate to hospital discharge was 46.8%(n=37). In multivariate analysis, independent predictors of mortality were the pre-ECMO lactate level (OR,1.1703; 95% CI,1.0521-1.3017;P=0.0038). The optimal cut-off value for pre-ECMO lactate was 9.2(AUC 0.696, p=0.0015). Kaplan-Meier survival curves showed that the cumulative survival rate at hospital discharge was significantly higher among patients with pre-ECMO lactate of 9.2 or less compared with patients greater than 9.2 (65.1% versus 28.1%;p=0.0007).
CONCLUSION. We conclude that pre-ECMO lactate of 9.2 or less may be an indicator of favorable outcomes with the use of ECMO in adult cardiogenic shock. However it is still difficult to predict survival with only pre-ECMO lactate levels and to determine whether to apply the ECMO for adult cardiogenic shock. Further research on how to predict reversibility more accurately is essential.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000406

INTRODUCTION. The goals of resuscitation in critically ill patients are to ensure adequate tissue perfusion and cellular metabolism [1]. The gut has been hypothesized as the "motor" of critical illness [2,3]. A mucosal injury surveillance system with a special orogastric tube with four electrodes in the distal tip, Florence (Critical Perfusion Inc., California) [4], has been proposed for surveying the integrity of the mucosal tissue of the stomach, in critically ill patients through the reactance biomarker (XL).

OBJECTIVES. Evaluate the safety and effectiveness of the XL trend measured by Florence in the prediction of morbimortality (cardiogenic shock, excessive bleeding, vasoplegic syndrome, and death) and with hemodynamic variables (CI, MAP, MPAP, CVP, PCWP), lactate, SVO2, and the risk predictors (EUROSCORE II, STS, APACHE II, and SOFA) of patients post-operated of elective cardiovascular surgery.
METHODS. The study was approved by the local ethics committee and regulatory entity (193300912X0085/2019)[5]. Patients with an elective surgery for a coronary artery bypass (CABG) and/or valvular replacement, and complies with the following STS ^{3}6% or EuroScore II ^{3} 6% or LVEF< 45% or TAPSE < 17mm or TSVI < 0.1 m/s, pulmonary artery catheter (PAC) and an orogastric tube were eligible for the study. Subjects with recent gastrointestinal bleeding, paraplegic or hemiplegic, congenital background, maxillofacial malformation, woman in breastfeeding period, were excluded from the study. Following general induction anesthesia and endotracheal intubation, the orogastric tube was positioned in the stomach to measure XL; positioning was confirmed during surgery by aspiration of gastric content and chest radiography after ICU admission. All patients were under cardiopulmonary bypass (CPB), aortic cross-clamp, mechanically ventilated and were monitored during surgery and the first seventy-two postoperative hours or until removal of the orogastric probe during this period. For statistical analysis, we used T-Student and Kruskal-Wallis tests as appropriate considering the significance p< 0.05.
RESULTS. 10 patients were included, with mean age 49.30 ± 13.38 years, 6(60 %) male,4 (40%) female, had 7(70%) undergone valvular surgery, 1(10%) CABG surgery and 2(20%) valvular surgery and CABG, ICU length of stay (LOS): 3.97± 3.82 days, Hospital LOS: 8.86 ±6.8 days, ICU mortality: 8.4%. Seven 7(70%) patients developed complications: 4(57%) required vasopressor (more than 48h), 5(71%) had prolonged mechanical ventilation (more than 24h), 2(29%) underwent re-operation due to excessive bleeding (at the first 72h), 3(43%) cardiogenic shock, 4(57%) excessive bleeding, 1(14%) vasoplegic syndrome, and overall mortality was 71%. No significant differences between complications and without complications in age, sex, ICU LOS, CPB time, LVEF @ICU, EuroScore II, STS, APACHE and SOFA was founded. Significant differences between XL, lactate was founded in Post-CPB and in the first 24h at ICU. Lactate and XL trend shows the same behavior in both groups
CONCLUSION. The results suggest that XL trend is a relevant biomarker during surgery and the first 24h at ICU and has a similar behavior as lactate. The sample size must be completed to obtain the final results.

Pre-shock state: a forgotten condition at immediate cardiac surgery patients

NA. Chávez Ponce, E. Bucio, F. Baranda, M. Ayala
Terapia intensiva cardiovascular, Instituto Nacional de Cardiología "Ignacio Chávez", México City, Mexico
Correspondence: N.A. Chávez Ponce

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000410

INTRODUCTION. The shock index (SI) is calculated dividing the heart rate by the systolic blood pressure, it is a bedside assessment tool that has been used to predict outcomes in different states of circulatory failure as trauma, sepsis, and hypovolemia[1]. Different studies regarding acute coronary syndromes, have proposed distinct cutoffs for SI to predict the development of cardiac shock or mortality (0.7, 0.9, 0.93)[2,3].
OBJECTIVES. To determine whether SI is a reliable tool to identify pre-shock state in the postoperative period, to anticipate the development of cardiogenic shock.
METHODS. A retrospective, observational study was conducted, in which medical information of patients who underwent aortic valve replacement surgery, from January 2017 to December 2018, was collected. The exclusion criteria encompass those patients who had another surgical procedure besides aortic valve replacement in the same surgical time. Additionally, patients in whom an intra-aortic balloon pump (IABP) was placed prior or during surgery, patients with vasopressors in the intensive care unit (ICU), and those who had systolic blood pressure <90 mmHg when the surgery finished were excluded. The data regarding patients with SI ≥0.7 and SI ≥0.9 was analyzed using STATA 12.1, a p value of <0.05 was considered significant.
RESULTS. Total 136 patients were included. Male patients 64.7% and female 35.3%, the mean age was 55 years SD 14.4, mean left ventricular ejection fraction (LVEF) 58.2% SD 8.7. SI: 0.72 SD 0.16, SI ≥0.7 52.9%, SI ≥0.9 13.2%. Pearson correlation between SI and LVEF, mortality, cardiogenic shock, cardiac tamponade, and length of stay after surgery did not show correlation but it correlates with low cardiac output syndrome (LCOS) (R=0.23, p=0.006), bleeding during surgery (R=0.17, p=0.044), and the need for a second surgery during the stay at the ICU (R=0.20, p=0.016). The ≥0.7 cutoff did not demonstrate correlation with any variable, albeit the ≥0.9 cutoff showed correlation with LCOS (R=0.22, p=0.009), the need for second surgery (R= 0.22, p=0.008), bleeding during surgery (R=0.20, p=0.019), and length of stay after surgery (R=0.21, p=0.011). In the multivariate analysis, the SI ≥0.9 only demonstrated significance for the need for a second surgery (OR=3.88, p=0.047, CI=1.02-14.87).
CONCLUSION. Pre-shock state defined by SI ≥0.7 is present in more than a half of our population but this cutoff showed no correlation with mortality or any other factors related to shock state, nevertheless SI ≥0.9 showed correlation with the performing of a second surgery due to major bleeding or cardiac tamponade, and LCOS. This suggests that SI ≥0.9 could be an assessment tool in the ICU to recognize patients at possible risk of development of circulatory failure before arterial pressure reaches shock values. The SI warrants future investigation in cardiac surgery.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000424

INTRODUCTION. The cardiorenal syndrome comprises a spectrum of disorders affecting both the heart and the kidneys, in which acute or chronic organ dysfunction can induce dysfunction in the other, and central venous pressure (CVP) is of paramount importance in its pathophysiology.
OBJECTIVES. To analyze the relation of PVC with acute renal failure in the first 48 hours (ARF-48) and at 15 days (ARF-15) in the postoperative period of cardiac surgery.
METHODS. Patients in the immediate postoperative period of cardiac surgery. Variables analyzed: history of diabetes mellitus (DM), arterial hypertension (HT), stroke (ST) and previous arrhythmias (ARR). CVP in the first hours (h) postoperatively (1, 3, 6, 12, 24 y 36). Presence of ARF-48 and ARF-15 according to AKIN criteria. The results are shown as means and 95% confidence interval in the case of quantitative variables and as a percentage in qualitative variables.
RESULTS. 1016 patients. 65% men and 35% women. Age of 65.3 (64.7-66). Mortality of 6.5%. IRA-48: 31%. AKIN-48 (1: 67,1%; 2: 27,2% y 3: 5,7%). IRA-15: 3.6%. There was a significant relationship of IRA-48 with HT (40,2% vs 22,4%, p= 0.00), DM (45,1% vs 28,5%, p= 0.00), ARR (46,4% vs 29,5%, p= 0.000) and stroke (48,2% vs 33,2%, p= 0.02). CVP was significantly higher in valvular and aortic surgery (p= 0.000). The CVP was higher in the patients who developed IRA-48 (p= 0.00), and with a proportional relation to the AKIN grade, so the greater dysfunction the higher CVP (Table 1). The CVP of the first hours were associated with ARF-15, so that a CVP-12h > 10 mmHg has a risk of up to 10 times higher for ARF-15 (OR: 10.78, 5.08-22,88).
CONCLUSION. The elevation of CVP in the first hours of postoperative cardiac surgery are associated with IRA-48. The CVP at 12 hours postoperatively could predict the persistence of renal failure at 15 days.

Table 1 (abstract 000424). See text for description

Cardiogenic shock in the intensive care unit developing in patients with ST-elevated myocardial infarction

A. Sánchez, M. Celaya, B. Hernandez, J. Salas, B. Marcote, A. Gordillo
Medicina intensiva, Hospital Universitario Puerta del Mar, Cádiz, Spain
Correspondence: A. Sánchez
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000467

INTRODUCTION. Cardiogenic shock is defined as an acute haemodynamic disorder due to a critical reduction of heart's pumping capacity, caused by a systolic or diastolic dysfunction leading to a reduced ejection fraction or impaired ventricular filling. A significant proportion of patients suffering a ST-segment elevated myocardial infarction may develop cardiogenic shock, and the early recognition of these would be very important in order to improve their outcome.
OBJECTIVES. The aim of the current study was to identify the clinical predictors that may lead to this complication, and describe the outcome of these patients with ST-segment elevated myocardial infarction (STEMI) who have developed cardiogenic shock (CS).
METHODS. Data for this study is collected from a prospective cohort of patients admitted to a terciary level ICU after an STEMI from the 1st January 2009 to 31th December 2018. There patients are all included in the ARIAM-ANDALUCIA registry. Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS), version 20.0 (IBM Corp., Armonk, NY).
RESULTS. From January 1, 2009 to December 31, 2018, a total of 1306 patients with STEMI were admitted to the ICU. Upon admission or lately during their stay, 97 of these presented CS.
CONCLUSION. The present study shows that a relevant proportion of patients with STEMI develop CS after presentation (7,43%). This complication occurred more frequently in patients with advanced Killip class, anterior IM, low systolic blood pressure (BP) and higher heart rate (HR) at presentation, history of diabetes or female gender. Unsuccessful and delay reperfusión (PCI/Lysis) also increased the risk of developing CS.

Prevalence and Incidence of Deep Vein Thrombosis in Mixed ICU

J. Benes, R. Skulec, J. Jobanek, V. Cerny
Department of anaesthesiology, perioperative medicine and intensive care, Masaryk Hospital, University J.E. Purkyne, Usti nad Labem, Czech Republic
Correspondence: J. Benes
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000469

INTRODUCTION. Despite prophylactic measures, the reported incidence of deep vein thrombosis (DVT) during ICU stay remains significant and varies between 2 and 15 %[1].

OBJECTIVES. To evaluate the incidence of DVT in the mixed ICU, to assess compliance with the local DVT prophylaxis protocol and to measure the course of anti-Xa activity levels in patients receiving enoxaparin in a prophylactic regimen.
METHODS. We conducted a prospective observational cohort study in mixed ICU from March to December 2017. Patients with expected ICU stay longer than 72 hours were included and screened for the presence of proximal DVT by compression ultrasound test (CUS). Baseline CUS was performed within the first 24 hours of admission to the ICU, patients with positive finding were excluded. Patients with negative baseline CUS were included. CUS was performed twice a week until ICU discharge or until new DVT or pulmonary embolism occurred. Prophylaxis with enoxaparin was initiated on admission (40 mg of enoxaparin QD in body mass index ≤35, 60 mg QD in body mass index >35, half dose in the presence of renal failure requiring hemodialysis) unless a risk of severe bleeding was present. Mechanical prophylaxis with graduated compression stockings were used until enoxaparin could be administered. Compliance with the protocol was assessed by comparing expected and delivered prophylactic regimen on each day of CUS evaluation. Peak anti-Xa activity levels were measured twice a week 4 hours after enoxaparin administration.
RESULTS. A total of 225 patients were enrolled. Two of them were excluded after positive baseline CUS for the presence of DVT (both clinically suspected) and four were not included in the analysis due to failure to obtain baseline CUS. In 219 analyzed patients, mean±SD Simplified Acute Physiology Score II was 60±20. The largest proportion of the patients was medical (38%), 29% were trauma patients, 28% surgical and 8% post-cardiac arrest patients. Median length of ICU stay was 5 days (IQR 3-11). During ICU stay, 6 patients developed deep vein thrombosis, for an incidence of 2,7%. None of the diagnosed DVT was clinically suspected. No new pulmonary embolism developed. The median peak level of anti-Xa activity in patients treated with enoxaparin was 0.2 IU/mL (IQR 0.1-0.3). Up to 29% of the patients were receiving enoxaparin during the first 24h of ICU stay, 68% between the day 2-4 and 85% after day 4. The agreement between the expected and delivered DVT prophylaxis was 94% for pharmacological and 95% for mechanical prophylaxis.
CONCLUSION. We observed a low incidence of deep vein thrombosis in our cohort of mixed ICU patients despite very low levels of anti-Xa activity. Compliance with the DVT prophylaxis protocol was excellent. Therefore, enoxaparin dose adjustment based on regular monitoring of anti-Xa activity is unlikely to result in more effective DVT prophylaxis in a mixed ICU population.

The central venous to arterial CO2 difference (ΔPCO2) is a good marker of tissue hypoperfusion after cardiac surgery

À. Castillo Niell, JM. Morales Pedrosa, S. Foradada Ubach, A. Tache Sala, P. Pujol Valverde, J. Gonzalez Londoño, M. Morales Moli, P. Ortiz Ballujera, JM. Sirvent Calvera
Intensive Care Medicine, Hospital Universitari de Girona Dr Josep Trueta, Girona, Spain

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000473

INTRODUCTION. Venous to arterial CO2 difference is a valid marker to evaluate tissue hypoperfusion after cardiac surgery. A pathological gap (>6) correlates with a reduced cardiac index (CI) and tissue hypoperfusion.
OBJECTIVES. This observational, prospective study aimed whether the CO2 gap was a faster parameter than serum lactate and central venous saturation (ScvO2) in diagnosing tissue hypoperfusion and reduced cardiac index (CI).
METHODS. 62 patients who had undergone cardiac surgery in our centre during 2018 and were admitted to our general Intensive Care Unit (ICU) during the immediate postoperative period and were monitored with VIGILEO or LiDCO. Patients with arrhythmias, extubation <6 hours or death <24 hours were excluded. Demographic variables, type of surgery (valve surgery, CABG), time of extracorporeal circulation (ECC), aortic cross-clamping, SOFA and EuroScore II were collected. The cohort was divided in two groups: initial ΔPCO2≤6 (n=20) and ΔPCO2>6 (n=42). From each we analysed: serum lactate, ScvO2 and CI at the moment of admission (T0) and in six hours (T6); differences in days of admission in the ICU, hospitalization, need of vasopressors, days of invasive mechanical ventilation (IMV) and morbimortality.
RESULTS. From our 62 patients, the CI was remarkedly lower in the ΔPCO2>6 group at T0 and T6 and we observed a tendency of the serum lactate and ScvO2 to worsen during the first 6 hours versus the ΔPCO2≤6 group, although none of it was significantly associated. Days of hospital admission were significantly longer in the ΔPCO2>6 group.
CONCLUSION. Given the results, we concluded that venous to arterial CO2 difference might be faster than serum lactate and ScvO2 in diagnosing tissue hypoperfusion and reduced cardiac index; that patients with ΔPCO2>6mmHg at the moment of admission have a tendency of needing more vasopressors, IVM days, higher SOFA and EuroSCore II punctuation, and longer ICU stay although the p value is not significant. And finally, hospitalization days were significantly longer in the ΔPCO2>6 group.

Table 1 (abstract 000473). See text for description

	ΔPCO2≤6mmHg	ΔPCO2>6mmHg	p
Dobutamine (hours)	2,9±13,1	2,7±10,1	N.S.

INTRODUCTION. Left ventricular (LV) dysfunction is potentially harmful in the critically ill patient as it might compromise circulatory status. LV dysfunction can be triggered by many conditions in the critically ill e.g. myocardial infarction, toxic cardiomyopathy, hypoxia or severe stress (Takotsubo syndrome). Previous studies of LV dysfunction have focused on specific patient categories but the impact of LV dysfunction in the mixed ICU population has not been sufficiently studied. ClinicalTrials identifier: NCT03787810.
OBJECTIVES. To evaluate the incidence, pattern, risk-factors and impact on mortality of LV dysfunction in a mixed ICU population.
METHODS. This is a single center, prospective observational study performed at the Sahlgrenska University Hospital, Gothenburg, Sweden. The study was performed during an eight month period, mainly on weekdays. On study days, all patients admitted to the general or neuro ICU within 24 hours were eligible for inclusion. Included patients were examined using a standard echocardiography protocol [1]. Left ventricular dysfunction was defined as having a global hypokinesia with an ejection fraction <50% or detected regional wall motion abnormalities (RWMA). Patients with LV dysfunction were evaluated for myocardial ischemia, or not, based on findings on coronary angiography, troponin levels, ECG-recordings and distribution of RWMA.

RESULTS. A total of 426 patients were included and fulfilled the study protocol. Mean age was 61 ± 17 years, mean SAPS 3 score was 59 ± 16 and 60% were male. A total of 113 patients (26%) had LV dysfunction of whom 86 (20%) patients had RWMA and 27 (6%) had global hypokinesia. Of the 86 patients with RMWA, 17 (20%) had myocardial infarction and 68 (80%) were regarded as non-infarction hypokinesia. Twelve of these patients (3%) demonstrated a circumferential pattern of hypokinesia in concordance with the Takotsubo syndrome. In a multivariable model, independent SAPS 3 risk factors of LV dysfunction were cardiac arrest, circulatory chock of any cause or respiratory failure as cause of admission (pseudo R-square 0.117). Neither total SAPS 3 score, any of the physiological SAPS 3 variables or surgical status were independently associated with LV dysfunction. Ninety-day mortality was higher in patients with LV dysfunction (41%) vs patients with normal LV function (21%, p<0.001), also when adjusting for SAPS 3 score (p=0.005). Mortality was higher in patients with regional hypokinesia (44%) vs patients with global hypokinesia (33%), but this was not statistically significant (p=0.379). There were no differences in mortality if having RWMA due to myocardial infarction or not (p=0.790).
CONCLUSION. This preliminary analysis suggest that left ventricular dysfunction is common in the critically ill but not easily predicted by the patient SAPS 3 admission status. Regional hypokinesia is more common than global hypokinesia and RWMA is not obviously caused by myocardial ischemia. LV dysfunction is independently associated with an increased risk of death. Future studies need to address the potential causality between LV dysfunction and an increased risk of death to adapt treatment and improve prognosis.

INTRODUCTION. Critical illness is associated with multiple organ failure and increased mortality, potentially due to impairment of the endothelial barrier, resulting in microvascular leakage, edema and disturbances in microcirculatory perfusion. Angiopoietin-2 is a known predictor for organ failure and mortality in critically ill patients. During stress and inflammation, angiopoietin-2 impairs endothelial barrier function via inactivation of the endothelial Tie2 receptor. We previously showed that activation of Tie2 reduced microvascular leakage and restored microcirculatory perfusion in a rat model of critical illness, proposing the angiopoietin/Tie2 system as a promising target in critically ill patients.
OBJECTIVES. To further explore the angiopoietin-2/Tie2 system, we studied the direct effect of angiopoietin-2 administration to WT or heterozygous Tie2+/- mice, expressing 50% of normal Tie2 gene and protein levels, on microvascular leakage and edema formation in mice.
METHODS. Male mice with a 50% reduction of Tie2 expression (heterozygous exon 9 deletion, Tie2+/-) and wild type controls (WT) received either angiopoietin-2 (WT+Ang-2 n=8, Tie2+/-+Ang-2 n=8) or PBS as control (WT+PBS n=7, Tie2+/-+PBS n=7) and were monitored for one hour. Microvascular leakage and edema formation were determined by extravasation of Evans Blue dye (EBD) or wet/dry ratio, respectively, in kidney and lung tissue.
RESULTS. In healthy WT mice, angiopoietin-2 administration did not affect pulmonary or renal EBD extravasation (lung 0.08±0.03 vs 0.06±0.02 μg/g, p=0.15; kidney 0.07±0.02 vs 0.07±0.02 μg/g, p=0.66), but induced pulmonary edema formation (lung 7.0±1.5 vs 4.5±1.4, p< 0.05; kidney 4.8±0.4 vs 4.5±0.5, p=0.20).
Genetically reduced expression of Tie2 did not affect pulmonary and renal EBD extravasation (lung 0.08±0.02 vs 0.06±0.02 μg/g, p=0.10; kidney 0.07±0.02 vs 0.07±0.02 μg/g, p=0.70) compared to WT controls, but increased pulmonary edema formation (lung 8.0±1.8 vs 4.5±1.4, p<0.01; kidney 4.8±0.1 vs 4.5±0.5, p=0.18).
Administration of angiopoietin-2 in mice with genetically reduced Tie2 expression tended to increase pulmonary (0.12±0.05 vs 0.08± 0.02 μg/g, p=0.07) and renal EBD extravasation (0.10±0.03 vs 0.07± 0.02 μg/g, p=0.07) compared to control mice with genetically reduced Tie2 expression, but edema formation remained unaltered (lung 6.9±1.9 vs 8.0±1.8, p=0.30; kidney 4.8±0.2 vs 4.8±0.1, p=0.88).
CONCLUSION. Angiopoietin-2 mediated Tie2 inactivation, as observed during critical illness, leads to microvascular leakage and edema formation in mice. Future studies should reveal whether therapeutically targeting the angiopoietin/Tie2 system reduces microvascular leakage and improves organ function in critically ill patients.

Acute Coronary Syndrome in young patients: predictors of mortality in long-term follow-up

AM. González González, AM. García-Bellón, JA. Cano-Nieto, M. De Mora-Martin
Cardiology, Regional Hospital of Malaga, Málaga, Spain
Correspondence: A.M. González González
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000530

INTRODUCTION. Cardiovascular diseases are the main cause of morbidity and mortality in the developing world, currently occurring at younger ages. Acute coronary syndrome (ACS) has a high prevalence in mortality in long-term in young adults
OBJECTIVES. The purpose of this study was to determine the factors that are associated with poor prognosis in long-term in this population
METHODS. We performed a retrospective analysis with consecutive inclusion of 253 patients admitted with a diagnosis of ACS between January 2011 and January 2013, aged equal or less than 60 years old. We classsified these patients into 2 groups: those who have died (n: 32 (12,7%), 77,8% male), and those who have survived (n: 221 (87,3%); 66,4% male) during the follow- up of 5 years. First, we tested for factors that were associated with mortality during the follow-up. Then, we used a multivariable logistic regression to identify the predictors of mortality in a long-term period.
RESULTS. During the folow-up of 5 years, age-independent predictors factors of mortality were: chronic kidney diseas (OR 30,199; p = 0,02); myocardial reinfarction (OR 14,022; p = 0,041); cardiac arrhytmias (OR 13,922; p = 0,035); heart failure following myocardial infarction (OR: 7,994; p = 0,001); hemorrhagie complications (OR 5,273; p = 0,17); Cardiac shock (OR 4,62; p = 0,001); and diabetes (OR 2,856; p = 0,035). Regarding continous variables isolated were serum creatinine (OR 2,311; p = 0,011); and heart rate (OR 1,027; p = 0,03).
The patients registered higher mortality rate were the ones that were less frequently submitted to angioplasty (OR 0,309; p = 0,003), that were not as promptly selected and treated in the emergency department (OR 0,298; p0 =0,14) and that suspended dual anti-platelet therapy before 1 year (OR 0,276; p = 0,007). Continous variables isolated were hemoglobin (OR 0,717; p = 0,003); and hematocrit values (OR 0,906; p = 0,012).
Then, we analyzed those variables using Logistic regression analysis, and we observed that Killip class at admission ≥ 2, diabetes mellitus,

heart rate; myocardial reinfarction, , serum creatinine were the strongest predictors mortality and standard dual anti-platelet therapy a predictor of survival.
CONCLUSION. Acute cardiac ischemia in < 60 years old, the strongest predictors of mortality during the follow-up of 5 years were admission Killip ≥ 2, diabetes mellitus, myocardial reinfarction, heart rate a serum creatinine. The standard dual antiplatelet therapy during the follow-up of 1 year was an independent survival predictor.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000533

INTRODUCTION. Major bleeding (MB) is a feared complication in patients with Non-ST elevation acute myocardial infarction (NSTEMI) and may have impact in the therapeutic strategy and prognosis of these patients.The aim was to characterize the population of these patients (defined MB by Gusto criteria) and to assess their impact on therapeutic approach and in-hospital complications and mortality
METHODS. We studied 3216 patients with NSTEMI included in ARIA-M(Analysis of delay in myocardial acute infarction)We considered 2 groups:Group 1–Patients with MB(n=67p,2,1%)Group 2–Patients without MB(n=3149p,97,9%)We collected: age,gender,Cardiovascular and non-cardiovascular co-morbidities,laboratory parameters,coronary angiography performed,coronary anatomy and type of implanted stent,in-hospital therapy,ejection fraction(EF)In-hospital complications considered:Heart Failure(HF)and cardiogenic shock(CS);cardiac mechanical complications;stroke;need for mechanical ventilation and need of blood transfusion
RESULTS. Regarding clinical profile of patients: With MB and without MB respectively : Age: 70 +/- 9 vs 65+/-12(p < 0,001); Hypertension 84,2% vs 75,3% (p=0,03); Previous HF 19,2% vs 9,2% (p < 0,001); Chronic Renal Failure 15,2% vs 7,9% (p= 0,03); Peripheral artery disease 14,6% vs 6,8% (p=0,02); Previous bleeding 11,5% vs 2% (p < 0,001).Table 2. In-Hospital therapy and coronary angiography
CONCLUSION. The presence of MB is present in 2,1% of patients with NSTEMI and is associated with an increased in-hospital mortality and heart failure.

Table 1 (abstract 000533). See text for description

	With MB	Without MB	p
Aspirin	93,9%	98,2%	0,036

INTRODUCTION. Major bleeding (MB) is a feared complication and a daily reality in patients with Non-ST elevation acute myocardial infarction (NSTEMI) as a result of pharmaological management. This may have impact in the therapeutic strategy and prognosis of these patients
OBJECTIVES. To characterize the population of patients with NSTEMI and MB (defined by Gusto criteria) and to evaluate possible predictors of the onset of MB
METHODS. We studied 3216 patients with NSTEMI included in ARIAM (Analysis of delay in myocardial acute infarction)We considered 2 groups:Group 1:Patients with MB(n=67p,2,1%).Group 2:Patients without MB(n=3149p,97,9%)We collected :age,gender,Cardiovascular and non-cardiovascular co-morbidities,laboratory parameters,coronary angiography performed, coronary anatomy and type of implanted stent,in-hospital therapy,ejection fraction(EF)We compared the in-hospital mortality and multivariate analysis was performed to identify the predictors of MB
RESULTS.
By multivariate analysis, were identified as predictors of MB : age , previous history of bleeding and unfractionated heparin
CONCLUSION. The presence of major bleeding is present in 2,1% of patients with NSTEMI .
There were identified as major bleeding predictors : age, previous history of bleeding and therapy with unfractioned heparin.

Low cardiac-output syndrome after heart surgery: are there any echocardiographic patterns with prognostic implications?

A. Marcos-Morales, Z. Molina-Collado, N. Quílez-Trasobares, R. Ashbaugh-Lavesiera, E. Renes Carreño, JC. Montejo Gonzales
Intensive Care, University Hospital 12 de Octubre, Madrid, Spain
Correspondence: A. Marcos-Morales
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000548

INTRODUCTION. Low cardiac-output syndrome (LCOS) is a common complication during the first days after heart surgery, increasing the need of circulatory support, length of stay and mortality in the intensive care unit (ICU).(1) This syndrome lacks one precise definition (2), and the role of cardiac ultrasound in its diagnosis and management is also unclear. The purpose of this study is to investigate if any echographic patterns arise in patients with low cardiac-output syndrome after cardiac surgery, and if these findings could have any prognostic implications.
OBJECTIVES. The aim of this study is to evaluate echocardiographic findings in patients who develop LCOS after heart surgery, defined as the sustained need of inotropic support during the first 48 hours of admission. A secondary objective is to study the implications of these findings until discharge from the ICU.
METHODS. This is a unicentric, descriptive, retrospective study, set in an adult surgical intensive care unit specialized in heart surgery, at the Hospital Doce de Octubre in Madrid, Spain. Patients were included if they showed a sustained cardiac index less than 2.2 L/mn/m2 or were in need of sustained inotropic support for at least 48 hours after surgery in the intensive care unit. To be included these patients had to receive a cardiac ultrasound evaluation during the first 3 days of admission, performed by a trained practitioner.
RESULTS. Seventy patients with LCOS were included, 58% were women. Patients were admitted after heart valve surgery (41%), heart transplant surgery (17%), combined procedure of valve repair and coronary artery bypass grafting (CABG) (13%) and isolated CABG (11%). Median length of stay was 10 days (IQR 5-19), and 8 patients died (11%). Median cardiopulmonary bypass time was of 137 minutes (105-168), median aortic cross-clamp time was of 124 minutes (82-147). Median time of inotropic use was 72 hours (48-118). Before surgery, 54% patients had a normal left ventricular ejection fraction, or LVEF ≥50%. After surgery, 25% of this subgroup presented low LVEF <50%, but 74% still had a normal LVEF. Among the latter, impaired right ventricle ejection fraction (RVEF) was found in 68%, and diastolic dysfunction (DD) in 50%. Among patients with low LVEF before surgery, excluding transplants, most of them still had an altered LVEF after surgery. Having a LVEF <30% after surgery was associated with higher mortality.
CONCLUSION. LCOS remains a fearful complication during the first days after heart surgery. Cardiac ultrasound is an important tool in its diagnosis and management. In our findings, reduced RVEF and DD were more common in patients with LCOS who had a normal LVEF after surgery. A higher mortality was associated with a LVEF<30%.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000262

INTRODUCTION. Many instruments have been developed to evaluate hospital mortality, but less attention has been paid to the long-term functional status and quality of life of traumatic brain injury patients
OBJECTIVES. To analyze the evolution of quality of life (QOL) and its different components between the 1st year and 3-4 years of admission to the ICU due to traumatic brain injury (TBI).
METHODS. Prospective cohort study. TBI in Carlos Haya Hospital (Málaga) between 2004-2008. Evaluation of QOL with questionnaire PAECC (Project of Epidemiological Analysis of Critical Patients), We analyzed physiological activities (oral communication, urinary and defecation control, food intake), daily life (mobility, work activity, etc.) and emotional state. (0 normal to 29 major deterioration).
RESULTS. N = 531. Age 40.35 ± 19.75 years, APACHE-II 17.94 ± 6.97, GCS admission 7.53 ± 3.83 points. Hospital mortality: 28.6%. Mortality 1 year: 32.2% (lost: 6.6%). 3-4 years 33% (lost 16.2%) QOL 1st year: 9.44 ± 8.73 points (significant deterioration) and at 3-4 years 6.77 ± 7.70 points, (p <0.001).
At 3-4 years, almost 90% have normalized physiological activities, except oral communication (64.3%), and another 17.2% with difficulty but with coherent dialogue. First year low percentage in work reintegration and capacity for great efforts , improve to 3-4 years without reaching 50% normality. High percentage in tolerance to minimum efforts, precision movements and social relations at year and 3-4 years. Emotional state presents high percentage of abnormality.
CONCLUSION. TCE, a year show significant deterioration of QOL improving to 3-4 years. At one year they present high normality of basic physiological activities, physical ones of small effort, social relation and movements of precision and that even improves something at 3-4 years. First year, normality in ability to make great efforts, work activity and subjective aspects a low percentage that improves to 3-4 years, although it does not reach 50%.

Table 1 (abstract 000262). See text for description

Normal 1º and 3-4 year (%)					
Basic physiological activities			Normal daily life activities		
Oral communication	54,8	64,3	Movements	83,1	89,9
Urinary control	79,1	84	Minor effort	71,2	82,4
Defecation control	81,9	88,2	Major effort	35,3	47,9
Food intakes	81	88,7	Walking	63,8	75,6
Emotional status			Mobility	46,6	68,1
Subjective well being	41,1	49,2	Dressing	63,8	78,2
State of mind	40,2	50	Working life activities	28,5	41,2
Vitality	64,4	73,1	Social relationship	70,2	80,6

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000281

INTRODUCTION. Identification of microcirculatory alterations in critically ill patients using hand-held vital microscopes (HVMs) is commonly applied sublingually. The sublingual area however, contains different types of vessel morphology related to capillaries, salivary gland structures and large veins. Although several studies have shown the importance of sublingual microcirculatory assessment during health and disease, no attention has been paid to the heterogeneity of the microcirculatory morphology in the sublingual cave. This study introduces the anatomy guided area in the sublingual cave, which is called the sublingual triangle. The sublingual triangle is most suited to perform sublingual measurements due to its rich vasculature with content conform the international consensus ESICM guidelines on microcirculatory monitoring. (1).
OBJECTIVES. The objective of this study is to identify the optimal sublingual location for measurement of the microcirculation and to validate that with suitable training this optimal location can be readily identified.
METHODS. A trained observer performed sublingual microcirculation assessments with HVM using incident dark field (IDF) imaging. Measurements were done before and after suitable training aimed at identifying its location(2) , with an interval of 3 months. The instructions consisted of introducing a specific region of interest, guided by the anatomical structure which can be seen adjacent on either side of the frenulum of the sublingual area. Small vessel density (SVD) (vessels <20µm in diameter), Large vessel density (LVD) (vessels between 20 – 100 µm in diameter) and Total vessel density (TVD), of non-instructed (NIM) and instructed (IM) measurements were analyzed and compared. Also the vessel structures were morphologically analyzed, and the appearance of salivary gland structures related microcirculation identified.
RESULTS. A total of 9 healthy volunteers were included. During each time point (T0:NIM and T1:IM) 4 video clips of the sublingual microcirculation were captured. Poor quality videos were excluded according to the microcirculation quality assessment (1) before offline analysis. A total of 53 videos were analyzed with MicroTools(3). TVD, but not LVD and SVD, was higher in IM compared to NIM, indicating a bigger contribution to TVD from capillaries, which are associated with oxygen transport to tissue. (TVD NIM vs IM: 24.76 ± 1.74 vs 27.29 ± 3.1 mm/mm2 p=0.044 , LVD NIM vs IM: 6.6 ± 1 vs 7.6 ± 1.3 p=0.092 , SVD NIM vs IM: 18.19 ± 1.65 vs 19.88 ± 3.07 p=0.103). In the NIM 6 video clips were identified containing salivary gland structure related microcirculation, whereas in the IM videos only small and large vessels were detected.
CONCLUSION. The sublingual triangle identified in this study showed a higher vessel density and avoided salivary gland structure related microcirculation. These findings indicate that the sublingual triangle is the optimal location for measurement since it can be identified by its morphology and contains the optimal vessel content conform the international guidelines. We propose the sublingual triangle to become the target of microcirculatory assessment using HVM to reduce heterogeneity and increase reproducibility of the studies.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000297

INTRODUCTION. Reduced antithrombin-III (AT-III) is an important component in the latest diagnostic criteria for disseminated intravascular coagulation (DIC) established by the Japanese Society of Thrombosis and Hemostasis. However, some severe cases show reduced AT-III, but do not meet the diagnostic criteria for DIC. In our experience, patients with low AT-III levels show very poor outcomes, regardless of their disease or DIC status. However, few reports have examined the prognostic ability of AT-III in all patients admitted to the ICU.
OBJECTIVES. To investigate the relationship between the AT-III level and the outcomes of patients admitted to the ICU and evaluate the prognostic value of the AT-III level.
METHODS. We conducted a retrospective observational study of 672 patients who were admitted to our hospital ICU from January to December in 2018. Cases involving patients of <18 years of age, APACHE II scores of <10 points, cases without AT-III measurement, and cases involving patients who died within 1 day of admission to the ICU were excluded. We divided the included cases into 4 groups based on the AT-III values measured at the early stage of hospitalization: AT-III ≥71% (H group), 70-51% (M group), 50-31% (L group), and ≤30% or less (VL group). We also checked the rates of death within 7 days, 28 days, and at hospital discharge. The accuracy of the predicted prognosis was then compared with the APACHE II score using an ROC curve analysis. The JMP software program was used to perform the multivariate and ROC curve analyses.
RESULTS. The 56 subjects in this study were classified into the following groups: H group, n=13; M group, n=25; L group, n=12; and VL group, n=6. In most target cases, the basic disorders were postoperative patients, sepsis patients, or acute myocardial infarction patients. The APACHE II scores were 20, 24.5, 21 and 30 (groups H, M, L, and VL, respectively). The rates of death within 7 days were 0%, 4%, 8.3% and 50%; the rates of death within 28 days were 0%, 28%, 25% and 67%, and the rates of death at hospital discharge were 25%, 32%, 50% and 100%, respectively. The multivariate analysis revealed that the AT-III value and APACHE II scores were independent predictors of death at hospital discharge. In comparison to the APACHE II

score, the AT-III value appeared an equally or more powerful prognostic predictor for any outcome (Fig. 1). The cut-off values of the for AT-III level and APACHEII score for predicting 7-day mortality were 47% and 26; those for 28-day mortality were 57% and 26, death and those for death at discharge were 56% and 26, respectively.
CONCLUSION. Early morbidly low AT-III values may be a prognostic predictor of hospital mortality in patients admitted to the ICU.

Determining Unmet Need for Critical Care as Part of a Business Case for Expansion of Capacity in a Mid-Sized Acute UK Hospital

L. Sharifi, A. Ackerman, J. Brinsley, R. Maeda, B. Boira, D. Higgins
Critical Care, Southend University Hospital NHS Foundation Trust, Southend-on-Sea, United Kingdom
Correspondence: L. Sharifi
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000336

INTRODUCTION.

- Our medium sized 544 bed acute hospital lacked a dedicated HDU for many years. Accordingly patients were admitted to ITU with higher APACHE scores, and the hospital had an outlying mortality rate. This data led to the construction of a new 8 bedded HDU facility, opened at 50% capacity in May 2018.
- Six months after opening, and encouraged by a fall in admission APACHE to ITU, we audited the degree of unmet need throughout acute and elective care. We present this audit so others can use our methodology to assist in their cases for expansion of Critical Care (CC) capacity within their institutions.

OBJECTIVES.

- To identify: Adult patients who would benefit from admission to Critical Care (HDU and ITU) but are not actually admitted, where CC beds are occupied by patients who have recovered but cannot leave due to a shortage of hospital beds
- To determine if additional HDU capacity would help mitigate this problem

METHODS.

- 14 day 24 hour data collection of CC bed state, record of all referrals / escalations to CC, record of all theatre / recovery patients potentially requiring CC

RESULTS.

- CC services were in high demand, ITU being at 100% capacity for 43% time
- HDU capacity was the biggest cause of delayed discharge from ITU
- 25% of all HDU bed hours were filled with patients fit for step down to the ward
- Elective surgery was cancelled more often than usual due to CC capacity constraints
- Surgical patients were less likely to get a bed on CC than medical patients, with patients being nursed in areas lacking CC resources and training

CONCLUSION.

- Surgical patients are being cancelled or nursed in innapropriate areas. Seperately, national data shows below average admission of high risk emergency laparotomies to CC. Thus both elective and emergency patients are experiencing suboptimal care.
- Capacity pressures on wards block HDU discharges, in turn blocking ITU
- This audit informed the business case for additional HDU capacity, and our materials made it repeatable for the audit cycle. We hope this model may be of use to others.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000358

INTRODUCTION. There are numerous studies describing the adverse long-term physical, mental and cognitive outcomes among ICU survivors. However, their pre-ICU health status is often not taken into account.
OBJECTIVES. To assess patients' physical, mental and cognitive health status before and one year after ICU admission.
METHODS. Adult patients admitted for ≥12 hours to a university hospital ICU between July 2016 and December 2017 were included (MONITOR-IC study, clinicaltrials.gov NCT03246334). Moribund patients were excluded. Patients (or proxies) rated their health status before and one year after ICU admission, by completing the Short Form-36 Physical and Mental Component Summary (PCS and MCS) (range 0-100; higher scores indicate better physical or mental function), Hospital Anxiety and Depression Scale (HADS) (range 0-21; higher scores indicate more symptoms of anxiety and depression) and abbreviated Cognitive Failure Questionnaire (CFQ-14) (range 0-100; higher scores indicating more cognitive failure). Moreover, new physical symptoms within the first year were noted.
RESULTS. A total of 1300 patients was included: mean age 61.5 (± 14.8 years), 65% male. Median ICU and hospital stay were 1 [IQR 1-2]

and 9 days [IQR 6-15] respectively, with mainly elective surgery admissions (65%).
One year after ICU admission, mean SF-36 PCS score was significantly higher compared to baseline; 42.6(±11.4) to 45.2(±10.8); p <.001, with a mean difference score of 2.60 (95%CI, 1.79 to 3.41), while 41% of the patients experienced a physical decline. Reported new physical symptoms within the first year were impaired physical function (70%), joint stiffness, dizziness, muscle weakness and/or shortness of breath (40%). Sexual problems were experienced by 25% of the ICU survivors.
Mean SF-36 MCS score increased significantly from 48.5 (±11.3) to 50.0 (±10.3); p<.001, mean difference score 1.55 (95% CI, 0.75 to 2.35), while 46% of the patients experienced a mental decline. Depression scores decreased from median 4 [IQR 1-7] to median 3 [IQR 1-7]; p=.057, and anxiety scores decreased significantly from median 4 [IQR 2-7] to 3 [IQR 1-7]; p<.001.
Contrary to the improvements in physical and mental health, the cognitive status decreased significantly from median 21 [IQR 11.3-29.5]) to median 23.7 [IQR 13.6-33.2]); p<.001, and 60% of the patients reported a cognitive decline.
CONCLUSION. Although statistically significant, improvement in physical and mental outcomes and decline in cognitive outcomes were small after one year. Nevertheless, the vast majority of patients experienced new physical problems, such as impaired physical function, muscle weakness and/or shortness of breath. Identifying patients who are at risk of these adverse long-term outcomes may lead to better and tailored care for ICU patients and survivors.

In-hospital mortality in the older old patients admitted at Intensive Care Units. Predictive factors

D. Díaz Díaz, M. Villanova, L. Lopez, B. Bueno Garcia, G. Andrade, E. Palencia
Intensive care units, Hospital Universitario Infanta Leonor, Madrid, Spain
Correspondence: D. Díaz Díaz
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000369

INTRODUCTION. Ageing of the world's population is influencing in an increase in the number of elderly patients admitted to intensive care units (ICU). However, invasive treatments tend to be avoided in elderly patients. The identification of predictive mortality factors for older old patients (older than 80 years) admitted to the ICU could assist the medical team, patients and families in planning advanced care and decision-making.
OBJECTIVES. Our main objective is to identify predictive factors for hospital mortality in patients older than 80 admitted at an ICU in a community hospital
METHODS. Retrospective Study in a cohort of consecutive patients over 80 years admitted to the ICU during the year 2018. We collected the demographic data, comorbidity, Barthel Index prior hospitalisation, reason for ICU admission, severity (SOFA, APACHE II, SAPS III), therapy received in ICU, in-hospital mortality, and in the group of survivors we also collected data on destiny at ICU discharge
RESULTS. A total of 71 patients older than 80 years were admitted at the ICU, representing 15.56% of all ICU admissions. The average age was 83.5 years (SD 2.3), 52.1% were women. In hospital mortality was 24 patients (33.65%), being mortality at ICU of 16 patients(22.5 %), the 75% of them due to limitation of therapeutic effort.Patients with in-hospital mortality had non-significant higher frequencies of diabetes , chronic obstructive pulmonary disease, chronic renal disease , cognitive impairment, previous oncological history, as well as higher body mass index than survivors.Up to 70% of survivors came from the emergency department as compared to 50% of non-survivors. The most common reason of ICU admission in the non-surviving group was septic shock (50% vs10, 6%, P = 0,000), followed by cardiogenic shock (20.8% vs 8.5%, P = 0.015). The Severity Indexes at ICU admission (SAPS III, SOFA and APACHE II) were significantly higher in the non-surviving group compared to survivors (P = 0.000). The use of vasoactive drugs was significantly more frequent in non survivors (95.8%vs 61.7%,P= 0.000), with a trend to higher need for invasive/non-invasive mechanical ventilation and for renal replacement purification therapy. For survivors, the Barthel index at discharge remained above 85 (mild disability).
CONCLUSION. Older old patients represent up to 15.56% of ICU admissions. The main predictive factor for in-hospital mortality is severity at ICU admission by SAPS III, APACHE II or SOFA,as well as the need for vasoactive drugs. However, survivors had low rates of dependence.

INTRODUCTION. Starting work as a junior doctor in critical care can be intimidating and overwhelming1. Junior doctors starting a clinical placement in intensive care medicine (ICM), can come from a variety of specialties2, with differing levels of knowledge and practical skills. We were unable to find any institution that offers specific training to address these issues.
METHODS. We developed a standardised one-day course for novices, timed before their first clinical shift, free of cost to them, and integrated into their normal working hours. We constructed a programme of lectures and practical workshops, covering core knowledge and themes in; mechanical ventilation, non-invasive ventilation, cardiac output monitoring, inotropes and vasopressors, sedation and delirium, renal replacement therapy and airway management - "Intensive Care Essentials (I.C.E)". Allowing comprehensive, protected teaching, to new starters in intensive care, we aimed to improve key knowledge and skills, and, allay anxiety amongst doctors new to ICM. Candidates were asked to rank how strongly they agreed or disagreed with pre-defined questions and statements along a numerical scale (0 (strongly disagree) - 5 (strongly agree)), before the course (n=26), and then after course completion(n=24). Data were compared using independent t-tests.
RESULTS. Candidates indicated that they felt significantly more prepared for their first shift in ICU after attending the course (mean pre-course score 2.4 (SD=0.76) vs mean post-course score 3.74 (SD= 0.45), p=<0.0001). In addition, they felt their knowledge was more sufficient to start on the critical care unit (mean pre-course 2.28 (SD= 0.68) vs mean-post course 3.7 (SD=0.56), p=<0.0001), and were more confident in tackling problems encountered in each of the clinical scenarios.
CONCLUSION. It is both feasible and beneficial, to deliver a targeted teaching programme covering basic knowledge and practical skills, required for safe practice in the critical care environment. Furthermore, we have demonstrated that this can be delivered within the framework of the UK Junior Doctors Contract, as protected, mandatory education, built into rostered working hours.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000438

INTRODUCTION. Registration of quality indicators is crucial for accountability and quality improvement. However, nurses and physicians suffer from the amount of administrative tasks. Clerical burden is a cause of physician burnout.
OBJECTIVES. To analyse the nature and consequences of registration burden experienced by nurses and physicians working in the ICU.
METHODS. A mix-methods observational study in an academic hospital in 2017, including a questionnaire survey (N=158), individual semi-structured interviews (N=5), and participative observations (3 days).
RESULTS. On average, physicians and nurses spend 54.9 (SD±43.1) minutes per day on quality registrations; nurses more than physicians, median 45 (min-max 0-241) and median 29 (min-max 0-119) respectively. They register 102 quality indicators and 1438 underlying variables for several stakeholders, including government bodies (Healthcare Inspectorate and National Health Care Institute), accreditation institutes, professional societies and registries, and internal demands from the board of directors. In total, 20% is registered for accountability purposes, 25% for institutional governance, and 54% for quality improvement. Almost half (48%) of the quality indicators were requested by multiple stakeholders, but the timing and content (operationalisation of definitions) of the demands were not aligned. Of all 102 quality indicators, 34% was perceived as useful for quality improvement in daily practice.
In the interviews, eight types of registration burden were identified, such as excessive amount of quality registrations, low efficiency of quality registrations to achieve quality improvements, feelings of distrust by mandatory registrations, registrations are not relevant for clinicians and nurses, and ICT-problems. The interviewees mentioned that the amount of registrations and other types of registration burden diverts time and focus from patient care and improving quality, with, paradoxically, lower quality as a consequence.
CONCLUSION. In sum, registration burden perceived by physicians and nurses can be classified into four main categories: 1) time spend on quality registrations; 2) amount of quality indicators; 3) usefulness for quality improvement, and 4) inefficiencies in the registration process. Registering less quality indicators, but more what matters (usefulness) is paramount to increase the efficiency of quality registrations, and to mitigate the registration burden and its consequences on nurses, physicians and their patients.

Quick-Link Learning: introduction of rapid-access educational resources on the intensive care unit

AM. Amphlett, S. Heaton, N. Freeman-Fielding, C. Bourdeaux
Department of intensive care, University Hospitals Bristol NHS Foundation Trust, Bristol, United Kingdom
Correspondence: A.M. Amphlett
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000440

INTRODUCTION. UK Intensive care units (ICUs) have a high turnover of junior staff across the multidisciplinary team (MDT)1. Our general ICU has a regular intake of new staff who are inexperienced in critical care and in this hospital's specialties. They enter a high intensity, high risk environment and need rapid access to supporting information and resources2. Current information systems within our hospital are not streamlined enough for effective point of care use.
OBJECTIVES. Our purpose was to improve access to educational resources and support for junior staff across the MDT. The use of mobile devices to support learning is recognised as a strong emerging educational technology3. Quick Response (QR) codes offer a shortcut to provision of information and we aimed to site them appropriately on the ICU, seeking improvements in assessed confidence and knowledge among medical and nursing staff.
METHODS. We took a two-part approach, siting QR codes on posters and on equipment. The posters took a question/answer format, each QR code linking to the appropriate educational source (protocol, guideline etc). We assessed new groups of junior medical staff in their knowledge and confidence about each poster topic at the beginning of their rotations and again after the introduction of the posters. Multiple choice and multiple answer questions were used in the quiz and a seven point Likert-type scale was used to assess confidence.
A QR code was sited on the ABG machine: this linked to an independent website which tests understanding of blood gas results in a quiz format. We assessed nursing staff confidence in blood gas interpretation before and after introducing the code.
RESULTS. Both quiz performance and confidence improved among junior doctors after the introduction of the educational posters. Across eight quiz questions, the average number of respondents answering correctly improved from 48% to 75%. Confidence among the same respondents also improved across all topics assessed: there was an average improvement of 1.6 points on the seven point Likert-type scale.
The initial survey of nursing staff showed a wide range of confidence in blood gas interpretation. The QR code on the ABG machine received more than 60 hits in the study month and the post-intervention survey showed an increase in confidence among nursing staff of an average 2.6 points on the Likert-type scale.
CONCLUSION. The ICU is challenging for new staff, who are faced with a steep learning curve in a specialised and complex environment. Many aspects of ICU care are highly protocolised, and therefore well suited to independent learning if the appropriate resources can be easily accessed. QR codes facilitate this learning using readily available mobile technology. Introducing QR codes to make resources immediately available at the point of care has shown improvements in both knowledge and confidence, for all tested topics, among staff across the MDT.

Three-year trajectory of patients discharged from ICU: Quality of life and healthcare resource utilization

R. Hauwaert[1], S. Castro[2], L. Melão[2], A. Binnie[1], C. Granja[2]
[1]Departamento de ciências biomédicas e medicina, Universidade do Algarve, Faro, Portugal; [2]Serviço de medicina intensiva 1, Centro Hospitalar Universitário do Algarve, Faro, Portugal

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000448

INTRODUCTION. Critical care is associated with significant consumption of health resources, both in the intensive care unit (ICU) and after ICU discharge. The number of critically ill patients is anticipated to rise over the coming years, and healthcare systems will need to adjust to meet increasing demands.
OBJECTIVES. The aim of this study was to assess the impact of critical illness on patients and the healthcare system during the three years following ICU discharge, including determination of long-term mortality, analysis of patients' healthcare utilization, and assessments of HR-QOL (Health-Related Quality of Life) at six months and three years after ICU discharge.
METHODS. The study was a mixed retrospective/prospective observational study conducted at the Centro Hospitalar Universitário do Algarve, a tertiary-level university hospital and regional trauma and neurosurgical centre in Faro, Portugal. All patients admitted during the year of 2015 were eligible (n = 415). Patients were subdivided by prior health status (healthy, chronic non-disabling disease, chronic disabling disease). HR-QOL was assessed using the Euro Quality of Life – Five Dimensions (EQ-5D) questionnaire. Six month EQ-5D results were extracted retrospectively from 2015 follow-up records while three-year EQ-5D telephone assessments were performed prospectively by the same investigators. Patients' trajectories during ICU stay and after ICU discharge were evaluated through hospital and national records and summarized in schematic form.
RESULTS. Our results reveal that out of 271 patients who survived to hospital discharge, nearly 20% were discharged to post-acute facilities and 10,7% remained institutionalized at three years (Figure 1). Patients admitted to the ICU with septic shock, emergent neurosurgery and neurologic emergencies were more likely to remain institutionalized. Hospital readmissions during the three years following the critical event were frequent (46,5% of patients) as were emergency department visits (73,4% of patients). At 3 years, cumulative survival was 60% for patients with a "healthy" premorbid status and <20% for patients with pre-ICU chronic disabling illness. Results of the EQ-5D questionnaire applied three-years after hospital discharge revealed a deterioration in HR-QOL relative to the evaluation completed at six months.
CONCLUSION. Survivors of critical illness show persistently high healthcare resource utilization during the 3 years after hospital discharge along with a deterioration in HR-QOL at 3 years relative to 6 months post-discharge. Further research in this field is required to better support healthcare systems, improve care for ICU survivors, and contribute to gains in HR-QOL.

Humanizing care in the intensive care unit: Perspectives of clinicians on using the Get to Know Me board

S. Ahmad, G. Ognjen, L. Karnatovskaia
Division of Pulmonary and Critical Care, Mayo Clinic, Rochester, United States of America
Correspondence: S. Ahmad
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000452

INTRODUCTION. Over a third of critical illness survivors manifest significant psychological impairments following discharge from the intensive care unit (ICU). Memories of frightening delusional experiences and in-ICU psychological distress are the strongest potentially modifiable risk factors. Our prior surveys and interviews of physicians, nurses, patients and their families revealed that inadequate communication was universally viewed as the key aspect contributing to patient distress and fear. The Get to Know Me Board is one of the tools adapted from palliative medicine that can be used to overcome anonymity of the critically ill patient.
OBJECTIVES. Given known challenges in communication with critically ill patients and their families, we explored providers' knowledge of the 'Get to Know Me board' as a tool to help facilitate such communication.
METHODS. We administered a web-based survey consisting of multiple choice and open ended questions to critical care physicians and nurses in medical and surgical ICUs at the Mayo Clinic.
RESULTS. 170 clinicians responded to the survey (23% response rate); of those 118 were nurses (69%) and 52 physicians (30%). All used the Get to Know Me board, although a third were not aware of where the blank forms were located. 152 (89%) found the board helpful in communication, such as in seeing the human side of the patient, being able to apply things patient may like in their interactions, and creating bridges with families. Most common information clinicians found helpful was the knowledge of patient's favorite movie, sport or food, hobbies, and achievements as well as their stressors and de- stressors. Ninety four (55.4%) respondents expressed no difficulty in incorporating the board as a part of routine clinical care, whereas the rest reported some level of difficulty. When asked about barriers to incorporating the board in clinical practice, the most common response was getting too busy with clinical duties (85 or 50.6%) followed by 'whether it gets filled out depends on who is on staff' (73 or 43%); 40 (23.8%) encountered no barriers. Most

participants 102 (61%) expressed that the best time to fill out the board was anytime during the stay, particularly when the family arrives or upon admission. About 7% of providers cautioned that patients should be stabilized first. See Figure 1 for an example of the filled out Get to Know Me board.
CONCLUSION. The Get to Know Me board is not a consistently utilized instrument in our critical care unit environment. However, when applied, it can be helpful to providers to get to know their patient as a person and not a disease, develop therapeutic relationship with them and their families, thereby improving communication and potentially outcomes. Further studies will be needed to measure effects on patient specific outcomes and ICU experiences of patients as well as providers.

Clinical characteristics of patients with very prolonged ICU-stay (≥ 90 days)

K. Roedl[1], D. Amann[1], L. Eichler[1], V. Fuhrmann[1], S. Kluge[1], J. Müller[2]
[1]Department of intensive care medicine, University Medical Center Hamburg-Eppendorf, Hamburg, Germany; [2]Department of anesthesiology, Tabea Hospital Hamburg, Hamburg, Germany

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000483

INTRODUCTION. An increasing number of patients are surviving the acute critical illness, however prolonged critical care treatment may be necessary. A prolonged ICU-stay from weeks to months is associated with increased mortality of up to 50%. Data on outcome and functional status of patients with an ICU-stay ≥90 days are scarce. The aim of this study was to investigate mortality and functional outcome of patients with a very prolonged ICU stay.
METHODS. Single-center retrospective study at the University Medical Center Hamburg-Eppendorf, Germany including all critically ill adult patients with an ICU stay ≥90 days treated at our institution between January 1st 2008 and December 31st 2016.
RESULTS. 65,249 patients were treated during the study period, of these we identified 96 (0.1%) patients with a very prolonged ICU stay. Median age was 61 (49.8 – 67) years, 30 (31%) patients were female. Reason of ICU admission were abdominal/gastroenterological (28%, n=27), followed by sepsis (23%, n=22) and transplantation (15%, n=14). All patients needed mechanical ventilation (MV), with a median duration of 74.1 (55 – 95.1) days. 63 (66%) patients survived the ICU-stay, of these 95% (n=60) had unfavourable overall outcome (Overall performance category III/IV) at ICU discharge. One-year survival rate was 28% (n=27), 44% (n=12) had overall performance category III/IV. Severity of illness (SOFA, SAPS II) on admission were comparable in ICU-survivors and non-survivors. Length of MV, use of renal replacement therapy (both $p < 0.01$) and maximum lactate (5.3 vs 11.5 mmol/l; $p < 0.001$) were significantly higher in ICU non-survivors. ICU-stay was significantly longer in ICU non-survivors (137 vs 107 days; $p < 0.05$)
CONCLUSION. Only a small proportion of critically ill patients requires ICU-therapy ≥90 days. Although two-third of these patients survive the ICU stay, almost all of these patients have an unfavourable overall outcome.

Discordance between online process and patient care as an important source of patient safety events in the intensive care setting: Exploration from the institutional incident reporting system

JS. Jerng[1], LC. Chen[2], YT. Li[2], SF. Huang[3], JS. Sun[2]
[1]Department of internal medicine, National Taiwan University Hospital, No. 7 Zhongshan South Road, Taipei, Taiwan; [2]Center for quality management, National Taiwan University Hospital, Taipei, Taiwan; [3]Department of nursing, National Taiwan University Hospital, Taipei, Taiwan
Correspondence: J.S. Jerng
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000491

INTRODUCTION. Patient safety events (PSEs) are commonly reported in the ICU setting, despite the advent of information technology with the proliferation of corresponding online processes to be connected to the real-world patient care tasks. Increasing work burden, complex care environment, and high variety of the patients' condition might render the probability of discordance between the corresponding online and real-world processes, threatening safety.
METHODS. We retrieve the case records of PSEs from the institutional incident reporting system of the intranet at an academic medical center in Taiwan. Cases related to the care of ICU patients were selected, and the investigators reviewed the reporting contents including the descriptions on the occurrence of PSE, provisional causes for the occurrences, and recommendations and suggestions on the improvement of the processes and further prevention of event occurrence. Online processes related to discordance with the real-world patient are were identified and classified by investigators, who also provided the possible causes related to discordance.
RESULTS. From 2011 to 2018, a total of 20,032 PSEs were reported to the institutional incident reporting system. Of these reports, 2,300 were related to the patient care of the ICU setting, resulting in patient harm of varying severity in 723 (31.4%) cases. We identified 832 cases to have corresponding online processes; 559 (67.2%) of them had at least one online process harboring discordance with the real-world patient care tasks, including 412 (74%) errors of the real-world tasks, 80 (14%) wrong timing in performing tasks, including delays and too early provision of care, and 67 (12%) omissions of tasks. The most common related patients care process for the discordance included medication administration (n=312, 56%), transfusion (n=92, 16%), laboratory tests (n=53, 9%), care of tubes (n=33, 6%), and transportation (n=21, 4%). For cases with discordance, errors were found in 90% of events of medication administration, 48% of transfusion events, and 70% of the laboratory test events. Analysis showed that for all 2,300 reports ICU cases, those with a corresponding online process had fewer patient harm than those without a corresponding online process (14.5% vs. 41.0%, $p<0.001$). However, for the 832 reported ICU cases with corresponding online processes, the cases with discordance with real-world tasks had significantly more patient harm than those without discordance (21.1% vs. 2.6%, $p<0.001$).

CONCLUSION. Although the provision of corresponding online processes for real-world patient care tasks might generally enhance efficiency and safety in the healthcare setting, the discordance of the online process and real-world patient care is an important source of patient harm due to the occurrence of patient safety events at the ICUs. Timely cross-validation between the online and offline process during patient care should be strongly considered in future designing and modification of the implementation of information technology in the intensive care setting.

INTRODUCTION. The idea of shared decision making(SDM) was first proposed in 1972, with gradually increasing its importance as the upsurging interest in patient centredness and autonomy in health care interactions since the 1970s. Tracheostomy creation has long been poorly accepted, though with superiorly odds to pros, owing to cultural mis-understanding.
OBJECTIVES. Retrospective cohort study from single tertiary medical center adult ICU revealed introducing shared decision making on early Tracehostomy in prolonged intubated critical patient might improve total Tracheostomy rate, reduce ventilator days and length of hospital stay, and shorten the Tracheostomy decision time delay.
METHODS. Medical record of tertiary medical center adult ICU admitted respiratory failure patient from Jan. 1st, 2016 to Dec. 31th, 2017 was retrospectively reviewed, and further subdivided into pre-SDM and post-SDM(after Jan. 1st , 2017) intervention period for analysis. Prolonged intubation was defined as using mechanical ventilation support more than 14 days and sub-acute respiratory care center transferral needed. Early and late Tracheostomy were defined as created within 14 days and beyond the 14th day since being intubated and ventilated individually. Patient who was successful weaning, chronic ventilator dependent before admission, post Tracheostomy creation surgery, or expired was excluded. Data including total Tracheostomy rate, early and late Tracheostomy rate, ventilator weaning rate and ventilator days, in-hospital mortality, and length of hospital stay were collected. SPSS was applied for statistically analysis, and a p value less than 0.05 was considered significant difference.
RESULTS. Medical records from total 1253 patient from Jan. 1st , 2016 to Dec. 31th , 2017 were reviewed, and total 7137 patient ventilator days were recorded. Among the total 1253 patients, the pre-SDM(2016) total Tracheostomy rate was found 8.8%, in compared to post-SDM(2017) total Tracheostomy rate 9.6%, and 9.1% improvement impressed. By inclusion and exclusion, 128 patients from year 2016 and 112 patients from year 2017 were considered prolonged intubated left for further analysis. Pre-SDM early and late Tracheostomy rate were 42% and 58% individually, with ventilator weaning rate(43(79.6%) v.s 46(62.2%), p: 0.034), ventilator days(35.3+/-18.1 v.s 47.2+/-16.1, p< 0.001), in-hospital mortality(1(1.9%) v.s 6(8.1%), p: 0.237), and length of hospital stay(59.7+/-35.1 v.s 69.2+/-24.6, p: 0.091) of prolonged intubated patient. Post-SDM early and late Tracehostomy rate were 39% and 73% individually, with ventilator weaning rate(27(69.2%) v.s 56(76.7%), p: 0.389), ventilator days(34.6+/-17.6 v.s 47.5+/- 28.4, p: 0.004), in-hospital mortality(4(10.3%) v.s 6(8.2%), p: 0.737), and length of hospital stay(57.2+/-21.8 v.s 68.4+/-26.8, p: 0.028) of prolonged intubated patient. After SDM was introduced, ventilator days and length of hospital stay of prolonged intubated patient was found reduced 13 days and 11 days individually in compared in between early and late groups. The Tracheostomy decision making time delay was found 5 days less after SDM introduced.
CONCLUSION. Our retrospective cohort study from a single tertiary medical center adult ICU revealed introducing shared decision making on early Tracheostomy in prolonged intubated critical patient might improve total Tracheostomy rate, reduce ventilator days and length of hospital stay, and shorten the Tracheostomy decision time delay.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001481

INTRODUCTION. The improvement in the treatment of critical pathologies has increased the survival of patients admitted to intensive care units. Secondarily, some of these patients present psychic and emotional physical alterations encompassed in Post Uci syndrome (PICS)
OBJECTIVES. To know the quality of life of patients who survive an ICU admission nine months after discharge through the SF-36 survey to establish the incidence of the post-ICU syndrome in our intensive care unit.Relate these values with the pre-existing clinical situation to obtain risk factors associated with this syndrome.To assess if there are intra-ICU interventions that favour the appearance of the Post-ICU Syndrome.
METHODS. Prospective and longitudinal observational study of a cohort of patients during the months of March and April 2018 in a polyvalent ICU.We recorded demographic data (sex, age, weight), comorbidity (Barthel, Charlson), psychopathology (psychiatric history, psychotropic, treatment and toxic habits), as well as the reason for admission to our unit and associated severity (APACHE II and SAPS II).The days of admission to the ICU, death in ICU or hospital, the need for mechanical ventilation and complications (pneumonia associated with mechanical ventilation, cognitive impairment and pain at discharge) were documented.We recorded interventions performed intra-ICU such as treatment with benzodiazepines and its maximum dose, corticosteroids, muscle relaxants or anxiolytics by nasogastric tube.In a second phase, 9 months after discharge, patients who could be contacted by telephone were evaluated,discarding the deceased patients and those residing abroad, and SF-36 survey was conducted for the evaluation of the quality of life (by pone)
RESULTS. Out of a total of 50 patients, the survey could be performed on 29, of which 24 answered it. The overall results of the SF-36 survey showed that 95% of our patients obtained values between 56.10 and 75.40, so our patients nine months after discharge had a positive state of health. No intra-ICU intervention was associated with a worse SF-36 score. The only item prior to admission that is related in a statistically significant way to a worse score of SF 36 is previous psychiatric treatment.
CONCLUSION. The post-ICU syndrome is a low-frequency entity in our unit.
Although the sample from our study is small, we cannot demonstrate that any intra-ICU factor influences the presence of a post-ICU syndrome. The only factor that is related in a statistically significant way to the presence of the post-ICU syndrome, is previous psychiatric treatment

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000018

INTRODUCTION. Pulmonary embolism (PE) may lead to the release of brain natriuretic peptide (BNP) due to right ventricular (RV) pressure overload, or troponin (Tn) due to transmural RV infarction with patent coronary arteries. Although cardiac biomarkers (CB) have been associated with worse prognosis, correlation with imaging techniques might not be strong.
OBJECTIVES. To describe the relationship between angio-CT, transthoracic echocardiography (TTE) and CB in the assessment of RV function and acute pulmonary hypertension (aPH) in patients with PE admitted to the Intensive Care Unit (ICU).
METHODS. We conducted a retrospective observational study in the ICU of a single university hospital. All the patients who were admitted to the ICU with PE as a primary diagnosis were included, over an 8-year period. Angio-CT, TTE and admission CB were recorded. Mann-Whitney U test was applied, as CB were not normally distributed.
RESULTS. A total of 82 patients were included, 43% male, aged 64 (44-77), APACHE-II 12 (8-17), 42% fibrinolytic therapy, 15% hospital mortality. Angio-CT, TTE and CB were performed in 92%, 84% and 100% of the patients, respectively. Thrombus was located in main pulmonary arteries (74%) or lobar/distal arteries (26%). TTE detected 52% RV systolic dysfunction and 59% tricuspid regurgitation, with an estimated pulmonary artery systolic pressure (PASP) of 53±15 mmHg. 48.4% of patients with thrombus in main or lobar arteries developed aPH, whereas no patient developed aPH with more distal thrombus (OR 14, 95%CI 0.8-257.1, p=0.07). TTE findings and their relationship with CB, expressed as P50 (P25-P75), are summarized in the Tables.
A cut-off point of troponin I ≥1 ng/mL showed 89% specificity, 18% sensitivity (53% NPV and 37% PPV) for the diagnosis of right ventricular disfunction.
CONCLUSION. Patients with PE in main or lobar arteries on angio-CT were more likely to develop aPH. In our series, CB did not correlate with RV function or aPH, although patients with highly abnormal levels of troponin were more likely to develop RV dysfunction. Performance of a TTE may be necessary to diagnose RV dysfunction or aPH in the setting of acute PE.

Readmission in Intensive Care - Review to Improve

P. Campos, C. Torrão, D. Mano, R. Antunes, T. Cardoso, I. Aragão
Unidade de cuidados intensivos polivalente, Centro Hospitalar e Universitário do Porto, Porto, Portugal, Portugal
Correspondence: P. Campos
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001490

INTRODUCTION. The readmission rate in the intensive care unit (ICU) is associated with an increased mortality risk and is identified as a quality indicator. Several predictors of readmission are described in the literature, such as age, gender, severity of disease, type of admission, comorbidities and length of stay in ICU. However, these factors are not modifiable. Therefore, an appropriate analysis of potentially modifiable factors that may influence the readmission of these patients is lacking.
OBJECTIVES. This study aims to determine the rate of readmission, analyze the population of patients readmitted, and evaluate the determinants of the readmission rate.
METHODS. Retrospective and observational study conducted at Centro Hospitalar e Universitário do Porto, from January, 2016 to December, 2018.
All patients discharged alive from their first ICU admission were included. The exclusion criteria were age bellow 18 years, not at risk of readmission in the same hospital, due to transference to another center and patients with limitation of care after ICU discharge. Readmission to the ICU was defined as any return of a patient to the ICU after ICU discharge during the same hospitalization. A multivariate logistic regression analysis for determinants of readmission at any time during the same hospital episode was performed.
RESULTS. A total of 750 patients were included, of which 54 were readmitted during the same hospital episode (7.2%).
When conducting the univariate analysis, the factors independently associated with readmission were admission from emergency service and operating room; admission due to urgent surgery or medical problem without infection; confirmed infection at admission; lower Glasgow Coma Scale (GCS) at admission; acute kidney injury (AKI) during ICU stay; fever, lower GCS and delirium at ICU discharge; and higher Stability and Workload Index for Transfer (SWIFT) Score. In a multivariate model the retained variables were SWIFT score, AKI during ICU stay, lowest GCS at admission, confirmed infection at admission and operating room source of admission. The overall model with readmission at any time during the same hospital episode had a moderate performance with the Area Under an ROC Curve (AUC) of 0.75, 95% CI, 0.686–0.824; $p < 0.001$.
CONCLUSION. Several factors can be related to readmission in ICU. In our study, the variables associated with readmission were SWIFT score, AKI during ICU stay, lowest GCS at admission, confirmed infection at admission and operating room source of admission. These variables are patient related and non-modifiable, showing that in our population this indicator is not very useful in quality of care and is not probably potentially modifiable.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001493

INTRODUCTION. The Intensive Care Unit (ICU) occupies 7% of the hospital beds, representing 20-30% of the hospital cost, equivalent to 62 billion dollars per year in the United States (REF). Studies have demonstrated a relationship between discharge criteria, length of stay and patient outcome (refs), so it is in the interest of physicians and managers to study the topic to avoid excessive patient time in the ICU and the scheduling of expenditures for rehospitalization, both related to increased mortality.
OBJECTIVES. To evaluate the early rehospitalization rate and the main associated characteristics in Neurological ICU in the period of 4 years, from 2014 to 2018.
METHODS. A review of all early rehospitalizations (<48 hours) was carried out in the period from 2014 to 2018 through a database of the hospital management system and evaluated compliance with the discharge criteria according to the ICU discharge protocol and its correlation with readmission.
RESULTS. In the analyzed period, 9,319 patients were admitted to the unit with 25 readmissions (0.32%), 7 in 2014, 7 in 2015, 4 in 2016 and 2 in 2017 and 5 in 2018. Of the 25 patients, only 1 (4%) did not present criteria according to ICU discharge protocol. Patients who were readmitted had increased length of stay when compared to the unit profile (8.4 days x 5.6 days), and there was no correlation with increased mortality in the analyzed sample. Average age: 64.78 years Occupancy Rate: 88.14% SAPS 3: 43.41 SOFA: 2.28. Surgical: 39.57%
CONCLUSION. Despite the high complexity, there is a low rate of early rehospitalization in the unit, which evidences a safe process of high and quality care.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001501

INTRODUCTION. Several studies have evaluated the impact of sodium disturbances on outcomes in critically ill so far but although chloride (Cl–) abnormalities are also very common, the number of studies reporting the relevance of dyschloremia and its association with intensive care (ICU) outcomes, are still limited. We aimed to investigate the prevalence of dyschloremia at the time of ICU admission and its relation with severity of illness and outcome implications of dyschloremia in critical care settings.
OBJECTIVES. The primary objective of our study was to evaluate the incidence of dyschloremia in critically ill and its relationship with ICU mortality and length of ICU stay, while the association between dyschloremia and severity of illness and organ failure were the secondary objectives.
METHODS. Non-surgical, adult patients who required ICU for more than 48 hours were included in our retrospective study, conducted in three ICUs, between 2015-2018. Demographic data, Acute Physiology and Chronic Health Evaluation (APACHE)II and Sequential Organ Failure Assessment (SOFA) scores, admission Cl – levels and blood gas analyses were abstracted from clinical information systems (MetaVision, iMDsoft and Consult, Orion Health) within first 24 hours of ICU admission. Patients were classified into three groups (Cl*normo*=97-108 mmol/L, Cl*hypo*<97 mmol/L and Cl*hyper*>108 mmol/L) accordingly their worst Cl– values measured within 24 hours. One-way ANOVA, Chi-square, Kruskal Wallis tests were used to analyze data while the association between ICU mortality and chloride levels was examined using multivariate logistic regression. (p<0.005 was considered to be statistically significant)
RESULTS. Of 3985 patients, 909(22.8%) were hyperchloremic and 475(11.9%) were hypochloremic. Cl*hyper* had higher ICU mortality (p<0.001; p=0.008, respectively) and longer length of ICU stay (p=0.001; p<0.001, respectively) when compared to Cl*normo* and Cl*hypo*. APACHE II scores were higher in Cl*hypo* when compared to Cl*normo* and Cl*hyper*. (p<0.001; p<0.001, respectively), on the other hand SOFA scores were higher in Cl*hyper* when compared to Cl*normo* and Cl*hypo* (p<0.001; p<0.001, respectively). *(Table 1)* We also evaluated baseline sodium levels in these patients and found an statistically significant association between dysnatremia and higher ICU mortality rates; while length of ICU stay was not associated with sodium disturbances. *(Table 2)* Multivariate analysis showed that dyschloremia and dysnatremia was independently associated with increased ICU mortality and longer length of ICU stay (OR 0.99, 95% CI 0.98-1; p=0.02, OR 1.01, 95% CI 1-1.02; p=0.03, respectively) as well as APACHE II (OR 0.97, 95% CI 0.96-0.98; p<0.001) and SOFA scores (OR 0.88, 95% CI 0.86-0.9; p<0.001).
CONCLUSION. Chloride disturbances are associated with severity of illness, organ failure and poor patient outcomes in critically ill. This study suggests that the both sides of the moon is the real picture to be seen by underlining the clinical importance of chloride.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001527

INTRODUCTION. Mechanical ventilation can induce lung injury, phenomenon known as VILI. An important mechanism of the VILI is the excessive global strain. Even more, regional strain is spatially correlated with regional inflammation. Information on regional strain could help to develop protective ventilatory strategies. The standard for this evaluation is computed tomography (CT), which does not allow continuous assessmentand exposes to radiation. Electrical impedance tomography (EIT) is able to monitor changes in regional lung ventilation and it could become a surrogate for CT-measured strain
OBJECTIVES. To compare the global and regional strain measured by CT with the change in electrical impedance (ΔZ) adjusted by anthropometric measurements in pigs and ARDS patients
METHODS. The study was approved by Ethics Committee. Three pigs, mechanically ventilated using VT of 250 and 500 mL, underwent whole-lung CT at end-inspiration and end-expiration with PEEP 10 and 20 cmH2O, before and after lung injury induction. Eleven ARDS patients also underwent whole-lung CT during at end-expiration and end-inspiration with PEEP 5 and best PEEP according EIT. A biomechanical analysis was employed to construct 3D maps of the volumetric strain. CT and EIT examinations were performed simultaneously. Strain maps were divided into 4 regions of interest "ROI" (Upper and Lower, Right and Left), coinciding spatially with the regions upon which inflation was calculated for EIT. Due to repeated measures in pigs an humans, linear mixed effect models were performed to predict lung strain and aeration measured by CT from ΔZ obtained by EIT, adjusting for known confounders. For all models, individual pigs or humans were considered as random effects, and PEEP as repeated measures. Diagnostic performance of EIT-based predictions of lung strain was evaluated by the Lin's concordance coefficient (LCC) and Bland-Altman Graph
RESULTS. In pigs, linear association for global strain was acurate (R = 0.974, p-valor<0,001), and large positive relations were found at different regions of interest. In humans, linear association at global, as well as in many lung ROI were high and positive with R > 0.932. Agreement of lung strain measured by CT and predicted by EIT-based models were excellent in overall terms in humans (LCC >0.95).
CONCLUSION. The change in electrical impedance provides a noninvasive assessment of global and regional strain, without radiation at bedside.

Impact of providing laboratory tests data on clinician ordering behavior in the Intensive Care Unit

MD. Bosque, M. Martínez, S. Barbadillo, J. Lema, R. Tomás, M. Ovejero, A. Olmo
Intensive care medicine department, Hospital Universitario General de Cataluña, Sant Cugat del Vallés, Spain
Correspondence: M.D. Bosque
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001530

INTRODUCTION. Unnecessary laboratory test ordering in the Intensive Care Unit can be a prominent source of patient discomfort, morbidity, increased workload and wasteful spending.
Providing blood tests order data to physicians has been considered a promising strategy to reduce unnecessary procedures in the intensive care unit but its impact on patterns of care remains unclear.
OBJECTIVES. The purpose of this study is to determine whether providing complete and personalized laboratory tests data could change clinicians practice behaviors.
METHODS. We conducted a preliminary study in a 16-bed polyvalent intensive care unit from April 2017 to April 2019 with a pre-intervention and post-intervention design.

1. Pre-intervention: during a baseline period (April 2017 through January 2018) a randomized non-consecutive 8 day follow up of the blood tests prescribed was carried out.
2. Intervention (January 2019): the intervention consisted of sending by e-mail to all the Intensive Care physicians relevant information about the prescription of blood tests performed in the last year which included:
   - Number and type of tests ordered by each physician
   - List of laboratory test costs per physician, from highest to lowest.
3. Post-intervention: after the intervention (February through April 2019) a randomized non-consecutive 9 day follow up of the blood tests prescribed was carried out.

Descriptive statistics include frequencies and percentages for categorical variables. Chi- squared test were used to compare variables during pre-intervention and post-intervention periods.
RESULTS. Six attending physicians provided input for a total of 229 patient-days. Results are shown in this table:
CONCLUSION. There is a global decrease in ordering and prescribing behavior after laboratory information was provided to the Intensive Care physicians.
This intervention may reduce the number of unnecessary blood tests specially in the most critical patients.

INTRODUCTION. Intra-hospital transport is related to a high incidence of adverse events and negative outcomes. The objective of this work is to describe the incidence of clinical and non-clinical events during in-hospital transport of critical patients and to analyze the associated risk factors
OBJECTIVES. To describe the incidence of clinical and non-clinical events during in-hospital transport of critical patients and analyze the associated the risk factors.
METHODS. A cohort study with retrospective collection, from October 2016 to October 2017, which analyzed all intrahospital transports for diagnostic and therapeutic purposes in a large hospital, and evaluated the adverse events and related risk factors.
RESULTS. : In the period, 1559 intrahospital transports were performed in 1348 patients, with a mean age of 66 ± 17 years, with mean transport time of 43 ± 34 minutes. 19.8% of patients were on vasoactive drugs; 13.7% in sedatives and 10.6% in mechanical ventilation. Clinical events occurred in 117 transports (7.5%) and non-clinical in 125 transports (8.0%). Communication failures were prevalent, however, by applying multivariate analysis, the use of sedatives, noradrenaline, nitroprusside and time of transport were associated with clinical adverse events. Use of dobutamine and transport time have been associated with non-clinical events. At the end of transport, 98.1% of the patients presented clinical conditions unchanged in relation to their baseline state
CONCLUSION. Intrahospital transport is related to a high incidence of adverse events, and the time of transport and use of sedatives and vasoactive drugs have been related to these events.

INTRODUCTION. Ultrasound (US) is increasingly recognized as an essential tool in the ICU setting. The safety and utility of bedside ultrasonography by an appropriately trained ICU physician has now been well demonstrated.[1] Despite the worldwide routine use of ultrasound in ICUs, a large number of ICU physicians remain unacquainted with US techniques. Following the 2011 international expert statement, the training of every ICU physician should incorporate basic level of critical care ultrasonography (CCUS).[2] We decided to investigate how the evolving CCUS paradigm of ICU physician skills and competencies is applied in our country.
OBJECTIVES. To summarize knowledge on the current use of CCUS and attitudes towards its utilization in the ICUs of a university teaching hospital.
METHODS. Our study focused on the ICU physicians (n=55) of the university teaching hospital. Data collection was performed with the help of an electronic survey.
RESULTS. The response rate of the survey was high (90%). 66% of the respondents were young specialists. The majority (61.7%) had no previous experience in CCUS and only 36.2% were aware of the locally organized training programs. The most useful CCUS modalities reported were pleural/lung US, vascular US for access, FAST, nerve block and vascular US-DVT. All of the respondents recognized the existence of barriers to CCUS training, citing lack of training, curriculum and financial costs as the most significant ones. Although CCUS remains the prerogative of the on-call radiologists, it was not perceived as a training barrier.
CONCLUSION. While Ukraine is lacking a formal CCUS training program, there is an unmet demand for it in the ICU. Our survey has demonstrated a prevailing lack of US skills among the young ICU physicians. At the same time there was a general consensus on the list of core US modalities that should be incorporated in such training as well as on the barriers that prevent ICU physicians from mastering them. The young demographics of the study has also highlighted the potential for international training programs and initiatives. Due to the limited number of respondents in our survey, further study across hospitals is required to fill in the knowledge gap on the country-specific state of CCUS training. In future perspective, we hope to impact awareness of the ICU physicians and stimulate the activity of the locally organized training programs. In a broader sense, we expect this study to start a cross-country conversation on the challenges of CCUS standards implementation and the possible ways forward.

INTRODUCTION. Virtual Reality Exposure Therapy (VRET) is effective in treating several psychiatric disorders like combat-related posttraumatic stress disorder (PTSD). In recent years, follow-up studies demonstrated that ICU survivors suffer frequently from loss of quality of life due to long term psychiatric morbidity, especially symptoms of PTSD. An effective strategy is currently lacking to prevent and treat psychiatricsequelae in intensive care (ICU) survivors despite it is known that post-ICU patients are motivated to undergo VRET in the aftermath of critical illness (1). To date, the safety and feasibility of ICU specific-VRET is unknown.
OBJECTIVES. To evaluate the feasibility, safety, and suitability of a newly developed ICU-specific VRET module compared to 2D exposure in healthy adults.
METHODS. Forty-fivehealthy adults were randomly assigned into three groups to receive a newly designed ICU-specific exposure therapy module on different platforms; a 2D flatscreen (n=15; 2D group), VR-goggles (n=15; VR group) and a crossover group that first watched the video on a 2D flatscreen followed by the VR-goggles (n=15; crossover group). Safety was assessed using the cyber sickness questionnaire (SSQ) and by monitoring vital signs (mean arterial pressure, heart rate, respiratory rate and saturation). Feasibility and suitability were assessed through the feeling of presence (immersion) with the Igroup Presence Questionnaire (IPQ).
RESULTS. Mean age was 57.7 years (SD 7.1) and 30 out of 45 adults were woman (66.7%). Adults experienced a higher sense of presence using VR (IPQ; VR to 2D group, mean difference [SE], 0.967 [0.345], p=0.01; crossover group, mean difference [SE], 2,787 [0.183], p < 0.001) (figure 1).There was no difference in total cyber sickness, nausea or oculomotor score in adults in the crossover group. Comparing the VR group with the 2D group, adults in the VR group showed higher total cyber sickness (mean difference [SE], 2.067 [0.599], p<0.01) and nausea score (mean difference [SE], 0.667 [0.319], p<0.05) (figure 2). All participants scored their cyber sickness as clinically irrelevant and no session was stopped early because of side effects. No differences were found in vital signs during the intervention and between groups.
CONCLUSION. We demonstrated that ICU-specific VR exposure is more immersive compared to 2D. This increased feeling of presence (immersion), suggests that VR may be a suitable medium to treat the psychological sequelae of an ICU stay, such as PTSD. Although VR demonstrated to befeasible, safe and well tolerable, one must be aware of the well-known side-effect: cybersickness.

INTRODUCTION. Integrated health services are embedded in a process that provides a continuum of care and have been advocated by the World Health Organisation (WHO) as the vehicle to improve health outcomes worldwide (Regional Office for Europe of the WHO, 2016). The health loss to injuries, conditions and risk factors are quantified using an index called the global burden of disease (GBD). The three leading causes of GBD in the 1990-2016 period have been ischaemic heart disease, cerebrovascular disease, and lower respiratory infections (GBD 2016 DALYs and HALE Collaborators, 2017), all conditions that often need intensive care. The GBD and sequelae in Intensive Care Unit (ICU) survivors depends on the number of critically ill patients, the resources available to treat them and the morbidity protracted after discharge (Stevens et al., 2014). It is hypothesised that low resources limit the possibility of admitting patients to intensive care units and the services offered after ICU discharge.
OBJECTIVES.

- To identify how critically ill patients are triaged in Low-Middle-Income Country (LMIC) compared to High-Income Country (HIC) to determine whether triage practice is linked to resource settings;
- To evaluate which post discharge services are available to critically ill patients in LMIC compared to HIC to detect if there is a difference in service provision;

- To explore barriers and facilitators of continuity of critical care and identify potential opportunities for quality improvement initiatives driven by cross-country learning.

METHODS. 14 intensive care doctors from Europe, Africa, America and Asia participated in a online survey and five of them in in-depth interviews. The survey included three sections in order to collect data on the services' context, the triage and the post ICU practice. The interviews were conducted to explore barriers and facilitators of ICU triage and post ICU care in different settings. Descriptive statistics and thematic analysis have been used to analyse data. Triangulation has been applied to identify convergence, complementarity or discrepancy between data collected via the two research methods.
RESULTS. Nine of the 14 participants who completed the questionnaire described practice in a LMIC, while five respondents provided examples of HIC practice. Globally, there are several models of care: public, governmental funding (6 LMIC and 4 HIC study units); private funding (1 LMIC unit); fee-for-service model where family/relatives contributes (2 LMIC units); access to health insurance (1 HIC unit). According to study results, when family needs to contribute financially there may be no other choice than limit treatment during and after intensive care. Also, lack of standardised end of life procedures in LMIC make triage a challenging process. Post discharge services are limited by resources according to the majority of participants with a tendency to holistic care in the LMIC units. Staffing, bed availability, and infrastructures (equipment, logistics) have been named as potential barriers to triage and discharges from ICU in all resource settings. Outreach services have been advocated for appropriate triage and after discharge monitoring
CONCLUSION. Barriers and facilitators of triage are similar between LMIC and HIC study units despite resources available. Capacity of triage and post discharge services are limited in settings where relatives need to contribute to cost of care. Indeed, triage may be easier in the context of low resources because there may be no other choice than refusing admission. Therefore deciding which patient to admit or not should be planned as soon as possible. Outreach and post discharge services could facilitate the prevention of deterioration and therefore help to decrease the global burden of critical illness.

INTRODUCTION. The need for critical care service is on the increase; however, ICU services are not readily available and accessible. Lagos, Nigeria with a steaming population of approximately 21 million, who have access to only four government owned ICU centers with 13 beds. This has led to private initiatives in critical care services.
OBJECTIVES. We determined the indication and outcome of ICU admission in a private critical care center in Lagos, Nigeria.
METHODS. This is a prospective observational study of critically ill patient admitted between January, 2016 and March, 2019. The case note and ICU charts for all patients referred to our center were reviewed.
RESULTS. A total of 162 patients were admitted, of whom females were 92 (56.8%), the most common specialist of admission was surgery 50% followed by medicine with 29.2%. The median apache score was 19.8 (25th -75th percentile, 14.5-26.7).
There was delay in referral in 82.2% of patients, with a median period of 34 hours (2-72hours). The most common reason for delay was unavailability of ICU bed space in 63.7% followed by no ICU facility at referral center 26%. The ICU survival at our center is 106 (65.4%).
CONCLUSION. There is an urgency need for provision of critical care services to meet the teeming population in Lagos, Nigeria. The most common reason for delay in ICU services is lack of bed space.

Does cognitive, behavioural or mindfulness therapy lead critical care patients to feel more confident in their ability to cope with psychological symptoms?

C. Lambert, J. Preller, Z. Martin
Critical care, Addenbrooke's Hospital, Cambridge, United Kingdom
Correspondence: C. Lambert
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001584

INTRODUCTION. Critical Care patients often experience pronounced psychological distress during intensive care treatment due to its extremely disempowering nature (e.g. Wade et al., 2013). As such they are highly at risk of developing low self-efficacy regarding influencing negative psychological states. This passive attitude can slow their rate of recovery, and is also strongly predictive of future psychological problems (Wade et al. 2012, Davydow et al. 2009)
METHODS. A sample of 64 critical care patients from the Intensive Care and Neurological Intensive Care Units of Addenbrooke's hospital was offered cognitive, behavioural or mindfulness therapeutic input. At the beginning of treatment a focus was agreed with each patient on a main problem area: depression, anxiety or stress (early post-traumatic response, pain response, or agitation). Patients rated their level of confidence that they could improve their psychological symptoms on a 5-point scale at the end of each treatment session. This scale consisted of the options: '1 = low', '2 = quite low', '3 = moderate', '4 = quite high', and '5 = high'. The resulting data was analysed using match-pair T-tests in order to investigate if patients self-rated levels of confidence changed from the beginning to the end of treatment for: (a) all patients in the sample, (b) for patients within each area of psychological distress, and (c) for patients within each modality of treatment (cognitive, behavioural, or mindfulness). Variance amongst means for (b) and (c) was also examined using one-way ANOVA.
RESULTS. T-test (a) was significant at $p<0.0001$; the T-tests for (b) and (c) were all significant at $p<0.05$ apart from when applied to those offered behavioural input $p>0.05$; the ANOVA conducted for (b) and (c) were all non-significant apart from when this test was applied to the problem experienced at the end of treatment $p<0.05$.
CONCLUSION. The finding that (other than patients offered mainly behavioural treatment) all treatment conditions measured showed a significant increase in self-rated levels of self-efficacy suggests that cognitive and mindfulness techniques are effective for this purpose. These results also indicate that this treatment is very effective in this area for patients overall, and at a lower level of significance, for

psychological problems considered individually. However, although the use of behavioural techniques showed a signal for improvement in self-rated patient self-efficacy, this did not reach significance within this cohort, a finding which if substantiated, could indicate that cognitive and mindfulness techniques possess self-efficacy boosting properties for this patient population which behavioural techniques do not stimulate.
The ANOVA results indicate that, both in terms of psychological problem experienced and modality of treatment offered, the patients in this sample do not display statistically significant differences in levels of self-efficacy at the beginning of treatment. This finding maintains to the end of treatment for treatment modality, but does not for problem experienced. This suggests that one or more of the psychological problems responds differently to treatment than the others, which may indicate that patient self-efficacy in this area can be altered more for certain psychological problems than others.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001589

INTRODUCTION. Prolonged length of stay (LOS) in the intensive care unit (ICU) is associated with severe morbimortality (1) and high cost of care. Nevertheless, there is no consensus regarding the exact definition of prolonged ICU stay (2), with studies ranging from 3 days to 14 days. There is a lack of evidence regarding even longer periods of stay (30 days), and which factors and critical care outcomes are associated with such duration.
OBJECTIVES. 1. Analyse predictors for prolonged ICU stay.
2. Understand the impact of prolonged ICU stay on critical care outcomes.
METHODS. Case-control study of the 1509 patients admitted to a polyvalent ICU between 2016-2018. Cases were defined by a LOS in the ICU superior to 30 days.
Forty-two cases were identified and 84 controls were chosen randomly on a 2:1 ratio.
RESULTS. During the study period, 2.7% of patients had a prolonged LOS. Median length of stay was 10 days [IQR 7-15] for the control group and 35 [IQR 33-45] for the case group. Average age was 57 years (20-83). There were no statistically significant differences regarding age, gender, time to ICU admission, APACHE II and SAPS II between study groups.
Cases had significantly lower Charlson Comorbidity Index values (p= 0.047), needed more antibiotic regimens (p= 0.047) and longer duration of antibiotic therapy (p<0.01).
They also had significantly longer duration of ventilation (p<0.01). and required more frequently tracheostomy for invasive ventilation weaning (p<0.01; OR 16.0).
Similarly, cases needed more frequently vasopressor support (p=0.07; OR 10.403) and for a longer duration (p<0.01).
The readmission rate was significantly higher in the case group (p=0.01).
Cases also had and days of vasopressor support (p<0.01)
On multivariate analysis, admission because of urgent surgery was a predictor of prolonged ICU stay (p= 0.039; OR 2.47) and an ICU LOS superior to 30 days was a significantly associated with ICU mortality (p=0.045; HR 13.594) in the survival analysis.
Regarding post-discharge outcomes, cases were more prone to be discharged to an institution for continued care and rehabilitation (p= 0.002; OR 4.167). There were no differences in 6-month mortality between study groups (p=0.768). On univariable analysis, the only variable associated with 6-month mortality post-ICU discharge was the need for tracheostomy (p= 0.016; HR 3.871).
CONCLUSION. Prolonged ICU stay is associated with a higher rate of tracheostomy and reduced survival in the ICU setting, but similar mortality rate at 6-month post-discharge. Prolonged ICU stay is associated with higher institutionalization rates and, as such, these patients probably require a more intensive rehabilitation care program to ensure adequate quality of life post-ICU stay.

Practice of inhaled bronchodilator therapy during mechanical ventilation in Thailand: a national survey

N. Kongpolprom
Department of internal medicine, Faculty of Medicine, Chulalongkorn University, King Chulalongkorn Memorial Hospital, Bangkok, Thailand
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001620

INTRODUCTION. Background: The aerosol therapy during mechanical ventilation is simplified through technological advances however the scientific knowledge about optimal implementation is infrequently applied.
OBJECTIVES. To determine the practice and knowledge of inhalation therapy during mechanical ventilation.
METHODS. A questionnaire was sent to nurses taking care of mechanically ventilated patients who attended 5 regional respiratory care conferences.
RESULTS. Totally, 401 nurses responded to the questionnaire and 84.8% of them were the general nurses working in general medical and surgical wards. Majority of them worked in secondary and tertiary public hospitals with the median experience-year of taking care of ventilated patients of 4[2, 11] and the median numbers of ventilated patients of 15 [4, 30] per month. Of the total responders, 241(60.1%) used metered dose inhaler (MDI) and 295 (73.5%) used nebulizers in mechanical ventilation. Of the 241 nurses who used MDI, only 54% placed the MDIs on the correct position (15 cm. from endotracheal tube). Most of them (93%) did not know how often MDIs needed to be primed. Approximately, 87.5% of them shook MDI before providing to the patients however only 10.6% knew MDI needed to be shaken for 8 actuations. Additionally, 14.5% of them administered MDI at the wrong point of time (at the end of expiration or mid inspiration). Noticeably, 9.2% of them turned off heat humidifier, 28.3% of them did not remove heat moisture exchange and 7.2% of them ignored to check and remove fluid in ventilator circuits before MDI administration. Moreover, 35.4 % did not know an appropriate actuation interval for MDI therapy.

Of the 295 nurses who used jet nebulizers, 70.5% placed the generators on the appropriate position (45 cm. from endotracheal tube), but only 49.5% diluted medication to 4 ml. to maximize aerosol delivery. Additionally, 22.4% of them did not remove heat moisture exchange before nebulization and 24.2% of them used inappropriate flow rates during nebulization.
CONCLUSION. The knowledge of inhalation therapy needed to be improved, suggesting the future educational programs focusing on aerosol therapy during mechanical ventilation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001641

INTRODUCTION. Point-of-care ultrasound (PoCUS) became increasingly used to assess critically ill patients[1,2]. Appropriate training is required and should integrate anesthesiology and intensive care residency programs. The purpose of this study is to assess the current state of PoCUS training in Anesthesiology and Critical Care residency programs[3].
OBJECTIVES. To assess methods, adequacy and limitations of PoCUS teaching during anesthesia and critical care residency in Italy.
METHODS. On-line anonymous survey sent to all residents, as approved by the CPAR (Collegio Professori Anestesia Rianimazione), concerning the actual teaching practice for: vascular access (VA), lung ultrasound (LUS), transthoracic echocardiography (TTE); focused-assessment sonography trauma (FAST); transcranial Doppler (TCD); regional anesthesia (RA) and diaphragm ultrasound (DUS).
RESULTS. 340 residents from 21/41 universities filled the survey (first year 17.4%, second 20.3%, third 23.8%, fourth 23.5%, fifth 15.0%). Bedside teaching is the most frequent tool for all techniques (Tab.1); frontal lecture is the second one. LUS and DUS teaching more frequently includes research activities. Overall, the most neglected ultrasound technique is FAST. 47.1% of residents never attended an extra-curricular ultrasound course; residents are mentored by attending physicians (73.5%) and/or older residents (46.2%). Acquisition of ultrasound competences is mainly evaluated during bedside activity (64.1%); in only 12.1% a theoretical-practical certification is performed. Ultrasound knowledge is considered extremely important by residents for VA (67.0%), RA (60.9%), FAST (51.8%), TTE (51.2%), LUS (50.3%), DUS (27.9%), TCD (27.6%); the impact of ultrasound technique is mainly perceived to guide procedures (VA and RA) and to improve patient's understanding (LUS, TTE, TCD, DUS, FAST). The training is mainly considered as adequate or more than adequate for VA (62.7%) and RA (42.7%), and nearly sufficient or inadequate for LUS (40.3%), DUS (37.1%) TTE (50.0%), FAST (52.9%) and TCD (44.4%). The main perceived limiting factor is the absence of a standardized didactic process.
CONCLUSION. PoCUS teaching is present although not optimal for all the techniques in Italian critical care residency schools. Standardizing resident's ultrasound curriculum is suggested to improve ultrasound teaching.

Table 1 (abstract 001641). Teaching instruments adopted for different ultrasound techniques (VA: vascular access; LUS: lung ultrasound; TTE: transthoracic echocardiography; FAST: focused-assessment sonography trauma; TCD: transcranial Doppler; RA: regional anesthesia; DUS: diaphragm ultrasound)

	Bedside teaching	Online modules	Frontal lectures	Simulation	Research activities	Not faced yet	Nothing
VA	**89.9%**	5.6%	38.3%	**17.4%**	7.0%	3.9%	3.5%
LUS	77.7%	**10.5%**	**51.9%**	14.3%	20.6%	10.8%	2.9%
TTE	63.8%	7.0%	40.8%	7.7%	9.4%	16.7%	9.4%
FAST	43.9%	5.2%	22.3%	7.0%	2.4%	24.0%	**20.9%**
TCD	46.7%	6.6%	29.6%	3.8%	7.0%	**26.8%**	14.3%
RA	78.8%	6.6%	49.8%	13.2%	7.7%	10.1%	4.9%
DUS	53.3%	7.7%	35.2%	10.1%	**21.6%**	18.5%	14.6%

Immature granulocytes : Early markers for outcome prediction in patients admitted to emergency departement

K. B.ismail, K. Zaouch, Y. Yahia, R. Baccouche, R. Boubaker, H. Maghraoui, K. Mejd
Urgences, Hospital Rabta, Tunis, Tunisia
Correspondence: I.K. Ben
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001646

INTRODUCTION. The presence of immature granulocytes was originally assigned to the diagnosis of sepsis. Thereafter their rate was correlated with the severity of sepsis. The aim of our study was to assess its prognostic value in patients admitted to emergency department.
OBJECTIVES. The aim of our study was to assess its prognostic value in patients admitted to emergency department.
METHODS. We conducted a case-control study over a period of two months from march 1st to april 30, 2014. In the group (GI+), we included patients which had immature granulocytes on their blood count. Then, by frequency matching, we included patients of the group (GI-) which had not immature granulocytes. Our primary endpoints were in-hospital mortality and the length of stay in emergency department. Our secondary endpoints were the presence of organ dysfunction and elevation of CRP level over 100 mg/l.
RESULTS. We included 122 patients. 61 in the GI+ group and 61 in the GI- group. There were 58 women and 64 men. The sex ratio was 1.1 without difference between the two groups (p=0.46). Sepsis was diagnosed in 84 patients (68.8 %). The two groups had similar past medical history and consultation patterns. Patients in GI+ had Ambulatory Simplified Acute Physiologic Score (ASAPS) significantly higher on admission (5.1 vs 4.1 in GI-, p=0.035) and at least one vital distress at the first examination (p=0.029). Blood glucose level greater than 1.40 g/l was found in 22.1 % of patients. 66.7 % of them belonged to GI+ (p=0.01). In GI+. 45.9% of patients had a creatinine level higher than 17 mg/l (p=0.008, OR =2, [CI=1.17 - 3.41]). Acidemia was found in 90.7 % of patients in GI+ (p=0.008). For an anion gap value greater than 22 mmol/l. the difference was significant in GI+ (p=0.005, OR = 3.1, [CI=1.3 – 6.97]). The average value of ASAT was 50.6 mmol/l in GI+ vs 28.1 mmol/l in GI- (p=0.03). 55.7% of patients in GI+ had a CRP rate greater than 100 mg/l vs 36.1% of patients in GI- (p=0.029). The average length of stay was 78.2 ± 65.7 hours in GI+ vs 54.4 ± 31.9 hours in GI- (p=0.01). Mortality was 16.3% in GI+ vs 8.2% in GI- (p=0.16).
CONCLUSION. The presence of immature granulocytes on blood count of patients admitted to emergency department, regardless of diagnosis, is associated with a significantly longer length of stay and a higher number of organ dysfunction. Mortality is twice as high in

this group of patients. Immature granulocytes can be a useful prognostic biomarker in emergency department.

New scoring criteria for ESICM NEXT fellowship evaluation: toward improved equality

M. Greco

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001656

INTRODUCTION. ESICM NEXT fellowships are an intense 5 days learning program held at center of excellence. Fellowships are promoted by NEXT, the ESICM Committee representing young members in-training or within 3 years of training, which is responsible for the fellowship application and selection process. As recently published, inequity leads to major loss of potentially important contribution and should be avoided (1). To improve equity in the fellowship application evaluation and to standardize the process, a new scoring system based on 6 criteria was developed through a Delphi-Consensus process (2) on June 2018, and compared with the previous evaluation system.

OBJECTIVES. To compare the performance of the new fellowship application scoring system with the previous one.

METHODS. Applications of candidates for an ESICM NEXT fellowship were evaluated by two independent raters using the previous scoring criteria, and by two raters per item using new scoring criteria. Data are described as percentage, or median and IQR. Skewness was assessed by skewness and kurtosis test. Interrater agreement was assessed using weighted Cohen's Kappa. Data were specifically assessed in terms of gender and geographical distribution of successful applications. Study obtained IRB approval.

RESULTS. A total of 100 applications were included, with 54% male and a median age of 34 (IQR 32-38). Old scoring displayed a right skewed distribution, while the new scoring system was normally distributed (skewness and kurtosis test 0.01 vs 0.6, respectively. Fig. 1). Inter-rater agreement between old and new scoring was 67% (p= 0.001 to refuse agreement by chance), using weighted-Cohen's kappa. New criteria allowed selection of about 30% different applicants compared to old criteria (Fig 2) . Involvement in teaching was the most discriminative variable, followed by quality of published research and quality of recommendation letter**.** There was no difference in gender (45.6% successful female application over all female application in both scores). There was variation in geographical distribution, with the highest reduction in successful application from Italy and UK.

CONCLUSION. The gaussian distribution of new evaluation system, based on more objective criteria selected through a consensus process, reflects a higher discriminative power, compared to the former right skewed distribution. This is mainly related with assessment of personal teaching activity and personal research. The new scoring selected about 30% different candidates compared to the previous system, with no difference in gender selection and no clear pattern in geographical distribution.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001661

INTRODUCTION. To measure quality is a delicate task and there are a lot of quality indicators (QI) from different countries. A previous report (1) showed that among 111 QI there was only nine that had a consensual agreement of 90%. The Swedish Intensive Care Registry (SIR) have formed national QI since 2005 and a thorough revision was performed 2014-2016.

OBJECTIVES. To describe some data from the new Swedish QI number one, "National guidelines in Intensive Care".
METHODS. The revision of all QI focused on the improving characteristics and (QI 1) is describing nationwide resources and how well the different ICU:s fulfills the goals of the national guidelines in intensive care. Results concerning academic profile, EDIC I+II for the head of the ICU and the level of nurse's education altogether with number of beds, isolation rooms and staffing ratio was reported 2016 for the first time.
RESULTS. The results from 2018 showed and described here, are from all ICU:s that report data to SIR (83/84) in Sweden. In the University ICU:s the head of the ICU had EDIC I+II in 55% and 18/29 (62%) had an academic grade of at least PhD. The guideline stipulates 100%.
In 35 of 83 ICU:s there was a discrepancy between what has been reported by the head of the ICU concerning data delivered to SIR for the eight QI and what was actually found in the database (Table 1).
CONCLUSION. To be able to report ICU resources available nationwide including academic profile, education level and how many ICU:s that reach the goals of the guidelines open for public can be a powerful tool for improvement both for the individual ICU and for the intensive care in Sweden.

Incidence and clinical implications of late onset hyperlactatemia after cardiac surgery

JA. Sanchez Giralt, B. Muñoz Molina, M. Trigueros Genao, J. Lázaro Gonzalez, F. Suárez Sipmann
ICU, Hospital de La Princesa, Madrid, Spain
Correspondence: J.A. Sanchez Giralt
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000627

INTRODUCTION. Hyperlactatemia (HL) during cardiac surgery is common, occurring in 10-20% of patients (1). The most studied mechanism is tissue hypoperfusion usually a marker of impaired outcome. There are however, other less well-known causes of perioperatrive HL (2).
Surgical stress response involves metabolic changes aimed at mobilizing different energetic substrates. Lactate is a well-known and important source of energy in different tissues. Most previous studies on HL have focused on the role of intra- or early post-operative hypoperfusion associated HL on morbity and mortality. There are however few studies analyzing the prevalence and clinical significance of delayed HL occurring several hours after surgery in the absence of clinical evidence of shock or tissue hypoperfusion.
OBJECTIVES. Analyze the incidence and clinical implications of late onset hyperlactatemia (LOH) after cardiac surgery.
METHODS. Observational retrospective study in a tertiary university hospital. We analyzed patients scheduled for cardiac surgery between January 2016 and December 2018. LOH was defined as an increased in lactate ≥3mmol/l after the first 4hours of ICU admission. We excluded patients with intra- or early postoperative HL, those with cardiac arrest, severe arrhythmia or needing reintervention or cardiac assistance in the first 4 hours of ICU admission. We analyzed mortality, prolonged mechanical ventilation, ICU and hospital length of stay (LOS) and occurrence of post-operative adverse events by comparing LOH cases with a matched control population. We also analyzed the presence of hyperglycemia and inflammation as potential mechanisms of LOH.
RESULTS. Of the 744 patients analyzed, we detected 55 (7%) cases of LOH that were compared to 52 matched controls. We did not find any differences in mortality (P=0.618 CI95%) and in ICU and hospital LOS (P=0.116 and P=0.063 CI95 respectively). In addition, there were no differences in renal failure, continuous renal replacement, arrhythmias or prolonged ventilation (P=0,77 P=0,16 P=0,14 P=0,44).
We found a significant increase in glucose (p<0,0001) being 52% of those non-diabetics. There was a positive correlation between glucose and lactate levels (r 0.45 Pearson P=0.001 r2 0.21,). Also, we found an increase in leucocytes levels at 4 hours in the LOH group but it was not significative (P=0,29 CI95%).
CONCLUSION. LOH is neither associated with a worse prognosis (mortality, ICU and hospital LOS) nor with post-operative adverse events. It seems to represent a secondary postoperative metabolic-inflammatory response that does not require any specific therapeutic intervention other than metabolic control.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000654

INTRODUCTION. Kidneys are important organs in regulation of vascular tone via several circulating systemic mediators Chronic Renal Disease (CRD) has systemic effects, including accelerated atherosclerosis, affecting also the microcirculation (1). We made sublingual IDF imaging video sequences analyzed by new automated analysis software to investigate the microcirculation called MicroTools deveoped by us (2) in healthy volunteers, dialysis patients, and kidney transplant recipients.
METHODS. This study was registered at the ClinicalTrials.gov Protocol registration system (ID: NCT02412839 and NCT02940275). A total of 270 patients were recruited in the study with different groups, yielding a total of 1983 videoclips. Analysis of the image sequences was performed by our newly developed automatic software called Microtools. To validate the use of this software on the present data set, two researchers compared image from randomly selected 17 patients independently from each other using the gold standard AVA analysis and showed agreement between their values. Then these results were run through MicroTools for analysis. Bland Altman analysis between AVA data and MicroTools data showed agreement within levels of agreement. After this validation step, 1373 videoclips out of 1983 were excluded due to poor quality based on the existing criteria. The remaining eligible 610 videoclips were run through the MicroTools software providing the following parameters: Total Vessel Density (TVD), Functional Capillary Density (FCD), Capillary Blood Volume (CBV). Quantitative RBC velocity was calculated from Space Time Diagrams of each capillary in a videoclip provided by MicroTools, conform the international consensus.
RESULTS. TVD and FCD of Dialysis patients was significantly lower compared to healthy volunteers, and renal transplantation reverted this vascular reaction. Systemic vasoconstriction was shown in reduced capillary blood volume in dialysis patients, which was again improved by renal transplantation. Mean Red Blood Cell Velocity was increased both dialysis and renal transplantation patients, suggesting permanent structural change in extended disease progress.
CONCLUSION. CRD affects systemic microcirculation and these effects are relieved to some extent by renal transplantation.

Methylene blue in vasoplegic patients after cardiac surgery

E. Bucio[1], EA. LAZCANO DIAZ[2], NA. Chávez Ponce[3], F. Baranda[4]
[1]Terapia intensiva cardiovascular, Instituto Nacional de Cardiología "Ignacio Chávez", México City, Mexico; [2]Cardiovascular intensive therapy, National Institute of Cardiology Ignacio Chavez, Ciudad de México, Mexico; [3]Terapia Intensiva Cardiovascular, Instituto Nacional de Cardiología "Ignacio Chávez", Mexico City, France; [4]Terapia intensiva cardiovascular, Instituto Nacional de Cardiología "Ignacio Chávez", Ciudad de México, Mexico
Correspondence: E.A. LAZCANO DIAZ
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000691

INTRODUCTION. The vasoplegic syndrome is a condition characterized by low systemic vascular resistance, low blood pressure, as well as normal or elevated cardiac output. It has been found in many contexts, including postoperative state. The pathophysiology coincides with the activation of different intrinsic vasodilation pathways, as well as the poor response to intravenous fluids and vasopressors. [1] The importance of Vasoplegia in Cardiac surgery with extracorporeal circulation lies in its high frequency, its high morbi-mortality, as well as its association with multiple organ failure. [2] Despite being a relatively common syndrome in critical patients, the absence of a definition makes its study, and management more difficult. Historically the cornerstone for the management of vasoplegia has been based on hemodynamic support with vasopressors, giving the best profile to the vasopressin. [3] However, with advances in the study of the pathophysiology, the methylen blue has been proposed as an alternative management. The action of methylene blue is based

on the inhibition or limitation of the inflammatory response by the blockade of nitric oxide. There is evidence that suggest that the use of methylene blue as management of vasoplegia after cardiac surgery reduces morbidity and mortality, as well as the time of vasoplegia. [4].

OBJECTIVES. To assess the effect of methylene blue in terms of morbidity and mortality in patients who have undergone cardiac surgery complicated with vasoplegic syndrome.

METHODS. A retrospective, observational study was conducted. The data of the patients diagnosed with vasoplegic shock , was collected between 2014 and 2018. Those patients were divided in two groups, those who were treated with methylene blue (MB) 2mg/kg, and those who did not received it (they receive the standard treatment ov vasoplegic shock). The criteria used to determine vasoplegic syndrome was hypotension <65mmHg, vascular systemic resistance <1600 dynes, cardiac index >2.2, high doses of vasopressor needed. The exclusión criteria includes patients who did not fulfill the criteria for vasoplegic syndrome, and those with incomplete clinical record. The information was analyzed using STATA 12.1, a p value of <0.05 was used as significant.

RESULTS. A total of 50 patients were collected. In the MB group the mean age was 59.6 years SD 14.37, the 59.26% were male, 40.74% had hypertension, 14.81% had diabetes mellitus type II (DM), 22.2% had atrial fibrillation, and 51.85% underwent non elective surgery. In the non MB group the mean age was of 58.4 years SD 13.6, 73.91% were male, 43.48% had hypertension, 34.78% had DM, 4.35% had atrial fibrillation, and 73.91% were of non elective surgery. Non of this data had significant difference. A Pearson correlation did not show any significant difference between the 2 groups regarding mortality, duration of the vasoplegia, neumonia, mediastinitis, reexploration, and lenght of stay.

CONCLUSION. Our results suggest that the use of methylene blue as a management of vasoplegic syndrome in post-operative patients of cardiac surgery, did not reduce mortality, duration of vasoplegia, length of stay in intensive care, days of in-hospital stay, or postoperative complications.

Clonidine as a sedative in the intensive care: Optimizing dosing regimens with population pharmacokinetics

M. Cloesmeijer[1], H. van den Oever[2], M. Zeeman[3], A. Kruisdijk-Gerritsen[2], R. Mathôt[1], M. Arbouw[4]

Correspondence: H. van den Oever

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000705

INTRODUCTION. Clonidine is an α2-agonist that is registered for the treatment of hypertension. It is also used as an off-label drug for sedation in the intensive care unit (ICU). However, no standardized dosing regimens are available for this indication [1]. Based on previous studies [2], we defined a target plasma concentration for sedation between 1.5 to 4.0 μg/L.

In order to achieve clonidine levels in the target range, we did a population pharmacokinetic study in ventilated and sedated patients, using various doses of clonidine.

OBJECTIVES. To develop a population pharmacokinetic (PK) model to optimize dosing regimens for clonidine as a sedative.

METHODS. Mechanically ventilated patients receiving intravenous sedation were included after informed proxy consent. Clonidine was added to standard sedation. Three cohorts of eight patients received continuous infusions of intravenous clonidine in doses of 600, 1200, and 1800 μg/24 h for seven days or less. The second half of each cohort received a loading dose of 300, 600 and 900 μg of clonidine, respectively, infused over 4 h. Biometric and biochemical data were recorded and plasma was sampled at fixed times.

A population nonlinear mixed effects model was constructed using NONMEM 7.3. One, two and three compartment models were tested. The following covariates were tested on the PK parameters: body weight, body surface area, body mass index, age, gender, creatinine clearance, albumin, bilirubin and time after start infusion. After univariate selection, covariates were liberally introduced into the multivariate model using linear and power functions, and then stepwise eliminated using more rigid criteria. The stability of the model was tested by goodness-of-fit plots, bootstrapping and a visual predictive check. After modelling, Monte Carlo simulations were performed to find optimal dosing regimens.

RESULTS. We collected 287 plasma samples from 24 patients. Ages ranged from 25 to 83 years (median 67); body weights ranged from 53 to 113 kg (median 84).

A two-compartment model fitted the concentration-time data best. Time had a significant influence on the clearance (CL), which increased with 0.21% per hour. Body weight was a significant covariate on the central volume of distribution (V1), using allometric scaling.

Population PK parameters (relative standard errors) were: CL 17.1 L/h (10%), V1 123 L/70kg (33%), Q (inter-compartmental CL) 84.4 L/h (31%), and V2 (peripheral volume of distribution) 179 L (18%).

Simulations with the final model showed that a continuous infusion of 1200 μg/day resulted in 90% of the population reaching target concentrations during steady state, irrespective of body weight or kidney function.

Without a loading dose, 50% of the population reached the target concentration in 14 hours. After a 450 μg loading dose infused over 4 hours, 50% of patients reached the target concentration within 4 hours. Loading doses below 300 μg had little effect on the time to reach target concentration. After 4 days of continuous infusion, serum half-life was 12 hours.

CONCLUSION. The developed population PK model allowed the optimization of dosing regimens for clonidine as a sedative agent in ICU patients.

Delirium in the intensive care unit: analysis of non-pharmacological measures and risk factors

M. Bersaneti[1], I. Whitaker[2]

[1]Instituto Sírio-Libanês de Ensino e Pesquisa, São Paulo, Brazil; [2]Escola paulista de enfermagem, UNIFESP, São Paulo, Brazil

Correspondence: M. Bersaneti

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000712

INTRODUCTION. The recommended strategy for the prevention and treatment of delirium are non-pharmacological approaches combined and focused on reducing modifiable risk factors in order to

improve and optimize patients' cognition, sleep, mobility, hearing and vision. The use of multiple combined strategies is a plausible recommendation, since the etiology of delirium is multifactorial.
OBJECTIVES. To verify the impact of non-pharmacological interventions in the development of delirium in the ICU, according to the hypothesis that natural light, mobilization, presence of family member and absence of physical restriction reduce the risk of delirium.
METHODS. Prospective and longitudinal study. Inclusion criteria: patients over 18 years old, hospitalized in the ICU for a period longer than 24 hours. Exclusion criteria: patients with delirium at the time of admission to the ICU, those with a stay in the unit less than 24 hours, transferred to another institution, as well as those that could not be reliably assessed for delirium, such as sustained coma , inability to understand the predominantly spoken language in the ICU, aphasia, or severe auditory or visual disturbances. On a daily basis, the patients were evaluated using CAM-ICU, applied in two moments. To verify the predictive factors of delirium, a logistic regression model was constructed, with odds ratio calculation and respective 95% confidence intervals. We included in the multivariate model all variables that had p <0.10 in the univariate analysis
RESULTS. The study sample consisted of 356 patients, 55.9% were males and the median age was 69 years, with a predominantly independent functional capacity (89.0%), admitted to the ICU more frequently from the surgical center (49, 4%) and emergency room (27.8%), with median SAPS3 of 39 points, median SOFA of 2 points and ICC of 2 points. Of the total number of patients, delirium was observed in 64 patients (18.0%) during ICU stay. Natural light, present in 18.8% of the sample, was not associated with the occurrence of delirium (p = 0.297). Physical restraint was observed in 12.4% of the sample. There was an association between physical restraint and occurrence of delirium (p <0.001). After adjustment of covariates (age, gender and mechanical ventilation), the multivariate analysis revealed that age, type of patient, SOFA, family presence (OR=0,15; 95% CI = 0,06-0,41; p<0,001) and mobilization (OR=0,07; 95% CI = 0,03-0,16; p<0,001) were independent variables associated with the development of delirium.
CONCLUSION. Mobilization and presence of family members are protective factors for the development of delirium.

INTRODUCTION. To reduce patient discomfort and pain in ICU, intravenous opiates, e.g. morphine bolus, are used routinely (1). These analgesics have side effects, one of the most potent is respiratory inhibition (2).
OBJECTIVES. To measure acute changes in respiratory drive in response to a morphine bolus.
METHODS. Preliminary results for 12 ICU patients on weaning mechanical ventilation modes in prospective observational study. Informed consent and ethical approval were obtained in all cases. Arterial blood gases, ventilation and respiratory drive were measured prior to and 15 minutes following an intravenous 5 mg morphine bolus. Respiratory drive parameters of central chemoreflex threshold in hydrogen ion concentration (TC) and cerebrospinal fluid strong ion difference (SIDcsf) were estimated using a model-based method (3) implemented in a decision support system (Beacon Caresystem, Mermaid Care, Nørresundby, Denmark). This system estimated pulmonary gas exchange parameters (shunt and ventilation/perfusion mismatch) prior to morphine bolus for use in respiratory drive measurement (3). Pre- and post-morphine measurements were compared using paired t-test or Wilcoxon signed rank test, according to normality as assessed by Shapiro-Wilk test.
RESULTS. Pre-morphine levels and (average ± SD) or (median (interquartile range)) change from pre- to post-morphine bolus were for SIDcsf 31.9 (0.3 ± 1.0) mmol/L, TC 41.1 (-0.2 ± 2.3) nmol/L, respiratory rate (RR) 27.8 (-3.3 ± 4.8) min-1, alveolar ventilation (VA) 7.6 (-0.4 ± 1.2) L/min, minute ventilation 13.7 (-1.1 ± 2.3) L/min, tidal volume 515 (30 (-14 – 134)) mL, effective respiratory system compliance 39.8 (-0.2 ± 4.5) ml/cm H2O, end-tidal CO2 3.7 (0.1 (-0.1 – 0.4)) %, CO2 production 291 (-8 ± 31) mL/min, O2 consumption 333 (3 ± 41) mL/min, arterial PCO2 5.03 (0.19 ± 0.34) kPa, pH 7.45 (-0.01 ± 0.02) and PO2 12.8 (-0.8 ± 3.0) kPa. Significant RR reduction followed morphine bolus (p = 0.036). Although no systematic changes were observed in other variables (p > 0.05), most patients showed a VA reduction, increasing arterial PCO2 and decreasing pH. Largest changes in VA were associated with opposite changes in TC.
CONCLUSION. Predominant acute response to morphine bolus was a reduction in RR. Larger studies are necessary to understand the different observed individual responses.

Age and Outcome: ICU Admissions in the Elderly post Emergency Laparotomy

M. De Bono[1], N. Singh[2]
[1]Intensive care medicine, King's College London, London, United Kingdom; [2]Intensive care medicine, King's College Hospital, London, United Kingdom
Correspondence: M. De Bono
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000743

INTRODUCTION. More elderly patients are receiving emergency treatment and undergoing unplanned surgical procedures with increasing comorbidities and infirmity. Risk stratification tools are utilized to predict outcomes. P-Possum is used by the National Emergency Laparotomy Audit (NELA) database in the UK. However, these measures have been criticized for not adequately quantifying frailty and morbidity burden of an elderly population. It remains unclear if surgical and ICU management are beneficial in consideration of long-term outcomes in this population.
OBJECTIVES. This evaluation of service aims to view 6 and 12 month mortality for our elderly patients and assess predictive scores currently used. Secondary objectives include the age stratification of post-operative recovery in terms of length of stay on the ICU, duration of ventilation and necessity for organ support.
METHODS. All patients older than 70 admitted to ICU after an emergency laparotomy at a British district general Hospital between August 2015 and November 2017 were included. Data was collected from the NELA Database, ICU charts and electronic patient records. Survivorship was measured at 6 and 12 months. T-Test analysis was performed between surviving and non-surviving groups, then stratified into decades (patients 70, 80, and 90) and ANOVA analysis was performed.

RESULTS. 98 patients were identified, of which 18 were excluded due to incomplete documentation. Of the 80 remaining 63 (79%) survived to both 6 and 12 months. The average age of the surviving group was older than the non-surviving group and lacked significance (81.8.4±6.2 yrs vs. 80.5±5.5 yrs; p=0.43). All patients, (n=8) older than 90 were alive at 12 months.
NELA's measure of Operative Severity did not yield a significance in mortality (p=0.16). Other measures employed by NELA were found to be more predictive. Physiology Severity Score (P<0.005) and P-Possum Mortality (18.0±20.6% vs. 34.0±27.4%; p<0.01, 95% CI 3.9 to 28.1%) were good markers of outcome irrespective of age. Length of time mechanically ventilated was associated with poor outcome (1.4±2.3 days vs. 5.1±8.0 days; p<0.01, 95% CI 1.4 to 5.9 days) but not duration of ICU stay (P=0.13). ANOVA stratification between decades saw a reduced length of stay on ICU (F=4.77; P<0.05) and number of days ventilated (F=3.60; P<0.05) as age increased.
CONCLUSION. Our results reveal that for patients over the age of 70 admitted to the ICU, age itself is not predictive of outcome. This group demonstrated a 12 month survival of almost 80%. Therefore, in our institution very elderly patients who have been selected for emergency operations can expect to do well after surgery and ICU admission. Future work should be carried out to describe the features of patients declined for surgery.

Transfusion practice in the non-bleeding critically ill; an international online survey – The TRACE Survey

S. de Bruin[1], T. Scheeren[2], J. Bakker[3], A. Vlaar[1]
[1]Department of intensive care medicine, Academic Medical Centre, Amsterdam, Netherlands; [2]Department of anaesthesiology, University Medical Centre Groningen, Groningen, Netherlands; [3]Department of intensive care medicine, Erasmus University Medical Center, Rotterdam, Netherlands
Correspondence: S. de Bruin
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000755

INTRODUCTION. The last decade several randomized controlled trials (RCTs) studied different transfusion strategies in critically ill patients. In several studies the safety of restrictive transfusion strategies was proven. Due to the lack of international transfusion guidelines specific for the intensive care unit (ICU), we hypothesized that a large heterogeneity in transfusion practice in this patient population exists.
OBJECTIVES. To quantify the variety of current transfusion practices and identify knowledge gaps in critically ill non-bleeding patients.
METHODS. An online, anonymous, worldwide survey among physicians working in the intensive care (intensivists and non-intensivists) was performed, in which red blood cell (RBC), platelet and plasma transfusion practices were questioned, including questions regarding transfusion thresholds, transfusion triggers and blood conservations measures. Furthermore, the presence of a hospital or ICU specific transfusion guideline was asked. Only completed surveys were analysed.
RESULTS. In total 947 respondents participated of which 725 could be analysed. Hospital transfusion protocol available in their ICU was reported by 53% of the respondents. Only 29% of the respondents used an ICU specific transfusion guideline. The applied haemoglobin (Hb) threshold for the general non-bleeding ICU population was 7 g/dL IQR (7-7 g/dL). For subpopulations including patients on ECMO and patients with traumatic brain injury the highest variance was observed (8 g/dL IQR (7.0-9.0 g/dL)). For patients with acute coronary syndrome (ACS) highest Hb threshold was applied (9.0 g/dL IQR (8-9.7 g/dL)). Thrombocytopenia was treated at a median level of 20x109 cells/L IQR (10-25 x109 cells/L). However, prior invasive procedures significantly higher platelet count thresholds were applied (p< 0.001). In non-bleeding critically ill patients with a vitamin K induced international normalized ratio (INR) >1.5, 43% and 57% of the respondents would consider plasma transfusion without any upcoming procedures or prior a planned invasive procedure respectively. Finally, doctors with base specialty anaesthesiology transfused critically ill patients more liberally compared to internal medicine physicians.
CONCLUSION. Current RBC transfusion practice in the general non-bleeding ICU population is restrictive while for different subpopulations higher Hb thresholds are being used. There is a high need for well powered randomised trials investigating the optimal Hb threshold for subpopulations in the critically ill. Furthermore, current practice in plasma and platelet transfusion is liberal and local transfusion guidelines are lacking in the majority of the ICUs.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000766

INTRODUCTION. Cardiac surgery is at high risk of bleeding, inducing additional morbidities and costs. Post-operative fibrinogen plasma levels have been described as associated with enhanced bleeding but very few data are available for pre-operative leves, whereas its correction could may prevent the occurence of bleeding.
METHODS. Retrospective cohort study at Rouen University Hospital from January 2016 to July 2018 including patients scheduled for a cardiac surgery with cardiac bypass. EB was defined as a blood loss > 1.5 mL/kg/hour during the first 6 postoperative hours or a need for reoperation [1]. Preoperative, perioperative and postoperative data were collected. Results are presented as medians with first and third quartiles. Comparisons between EB group and no-EB group were realized using a Mann and Whitney test or a χ^2. A multivariable analysis was then realized using a logistic regression model (backward process). $P < 0.05$ was considered as significant.
RESULTS. 1822 patients were included, 107 showed significant bleeding (EB group).
Preoperative data: No difference was observed between no-EB and EB groups concerning age, gender, preoperative cardiac and renal functions, antiplatelet therapies. A significant difference was observed for Body Mass Index (BMI) (27.8 [24.7-31.2] vs 25.3 [22.1-28.4] kg/m², p<0.0001), past history of cardiac surgery (4.8 vs 13.1%, p=0.01), anti-vitamin K therapy (10.7 vs 18.7%, p=0.02), prothrombin time (PTT) ratio (91 [80-100] vs 85 [70-100]%, p=0.001), platelets count (221 [185-263] vs 200 [160-243] G/L, p=0.001) and fibrinogen plasma level (3.5 [3.1 vs 4.0] vs 3.3 [2.6-4.1], p=0.04).
Peroperative data: excessive duration of cardiac bypass (80 [60-112] vs 118 [79-155] min, p<0.0001] in EB group.
Postoperative data: rised PTT (59 [54-65] vs 55 [48-62]%, p<0.0001), diminushed platelets count (145 [119-177] vs 133 [104-170] G/L, p< 0.0001) and fibrinogen plasma level (2.5 [2.1-3.0] vs 2,3 [1.9-2.7] g/L, p<0.0001) in EB group. EB group presented more frequent complications: higher plasma troponin (969 [610-1835] ng/dL vs 607 [385-1032], p<0.0001) and lactate (2.3 [1.7-3.5] vs 1.7 [1.2-2.4], p<0.0001), kidney failure (KDIGO score $\geq$ 1 : 17 vs 8%, p=0.003). ICU Length of stay and mortality were higher (5 [3-8] vs 3 [2-5] days, p=0.002 and 5 vs 1%, p=0.02).
Elements independently associated with a lower risk of EB were BMI $\geq$ 30 kg/m² (OR 0.46 IC95% [0.45-0.78] p=0.006) and preoperative fibrinogen (OR 0.98 IC95% [0.95-1.00] for each 0.1 g/L, p=0.04). Cardiopulmonary bypass was independently associated with a greater risk of EB (OR 1.11 IC95% [1.07-1.15] for each 10 min, p<0.0001). A preoperative fibrinogen level greater than 3.035 g/L (Se 45%, Sp 71%) appear to be protective factor against EB (Area Under the Curve 0.557 [0.492-0.623]).
CONCLUSION. Low levels of fibrinogen before cardiac surgery is associated with an excessive postoperative bleeding. Further randomized study may explore the effect of pre-emptive administration of exogenous fibrinogen to prevent excessive bleeding during cardiac surgery.

The use of a machine-learning based algorithm to reduce hypotension during surgery: a randomised clinical trial

M. Wijnberge[1], B. Geerts[1], N. Lemmers[1], L. Hol[1], M. Hollmann[1], A. Vlaar[2], D. Veelo[1]
[1]Department of anaesthesia, Academic Medical Centre, Amsterdam, Netherlands; [2]Department of intensive care medicine, Academic Medical Centre, Amsterdam, Netherlands
Correspondence: M. Wijnberge
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000779

INTRODUCTION. Intraoperative hypotension (IOH) is a frequently occurring event associated with an increased morbidity and mortality.[1,2] Current treatment of IOH is mostly reactive. A machine-learning algorithm was developed to predict IOH minutes before the blood pressure actually decreases. This algorithm, the hypotension prediction index (HPI), was internally and externally validated with good sensitivity and specificity.[3] However, no randomised studies testing the effectivity of HPI to prevent IOH have been performed. We hypothesise, that use of IOH will reduce the time weighted average (TWA) spent in hypotension during surgery.
OBJECTIVES. Our primary objective was to determine whether the use of a machine-learning based algorithm can reduce IOH, measured as the TWA during surgery. TWA combines both the time and depth of IOH.[4] Our secondary objectives were to assess whether the use of this algorithm increases the TWA of hypertension and whether it increases the cumulative dose of vasopressors and fluids given during anaesthesia. We also assessed the compliance with the algorithm by the number of protocol violations.
METHODS. This was a single center trial in a tertiary academic center consisting of two phases, an observational phase and a randomised clinical trial phase. Adult patients (aged 18 years and older) scheduled to undergo an elective non-cardiac surgical procedure under general anaesthesia and requiring an arterial line were eligible for inclusion. IOH was defined as a MAP < 65 mmHg for more than 1 minute. A HPI alarm was defined as a HPI value above 85%.
RESULTS. A total of 100 patients were included between November 2017 and January 2019. The TWA of IOH in the intervention group was 0.13 compared to 0.46 in the control group, p=0.001. Patients suffered from IOH 3.3% versus 10.5 %, p<0.001 of their duration of surgery. The TWA of hypertension was 0.09 versus 0.06, p=0.548. Patients experienced hypertension 1.67% versus 0.98%, p=0.379 of their duration of surgery. Neither the cumulative dose of vasoactive medication given nor fluid balance was significantly different between groups. 80% of all HPI alarms were treated according to protocol.
CONCLUSION. This is the first randomised clinical trial employing a machine-learning based tool in the field of anaesthesia. Use of the algorithm resulted in less hypotension without an increase in hypertension or the cumulative of vasoactive medication and fluids given during anaesthesia. Future studies should assess clinical endpoints.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000806

INTRODUCTION. Objetives: Presenting clinical and epidemiological data of patients with cytoreductive surgery and hyperthermic intraperitoneal chemotherapy who are admitted in ICU.
METHODS. Retrospective, descriptive study of patients admitted in ICU from January 2018 to December 2018. Clinical, epidemiological and result-related variables were analyzed. Quantitative variables are expressed as mean and standard deviation, while qualitative variables are expressed as ratios and absolute value.
RESULTS. A total number of 14 patients took part in this study; mean age was 57.71± 8.90 years, 78.6% were females. APACHE II at the admission was 17.21 ± 6. SOFA 3 6.85±2.95
78.6% of the patients presented comorbidities; the most frequent was high blood pressure (28.6%), followed by dyslipidemia (21.4%) and smokers (14.3%). 57% had chronic disease: Pulmonary 14.3%(OCPD and asthma), Cardiac 7.1%, and others 42.9%.
Gynecological tumors were the most usual, 57.2% (6 ovarian cancer, 2 uterine cancer); follow by gastrointestinal tumor, 42.8% (3 colon adenoacarcinoma, 3 gastric tumor) Metastasis were presented in 28.6%, been hepatic location the most frequent (75%).
Cytorreduction were successful in all of the patients. Peritonectomy was done in 78.6% of the cases, Omentectomy in 35.7%. 71.4% of the patients need intestinal resection, 21.4% gastrectomy, 14.3% cholecystectomy, and 7.1% appendicectomy. In one case spleen removal was needed, and another patient needed nephrectomy. Oophorectomy was done in 28.6% of the women and same frequency was observed in hysterectomys. Cytoreduction at other levels, such as lymph nodes, pancreas or muscles, was done in 57.1% of the patients. The most used chemotherapic drug was Paclitaxel(50%), next was Cisplatin combined with Doxorrubicin(14.3%). Mitomycin, Fluorouracil and Oxaliplatin were used only once. The treatment was kept and average of 53.57± 12.77 minutes, with a mean temperature of 41.92 ± 1.07 ºC.
At the ICU admission, in the firsts few hour 64.3% of the patients needed *Norepinephrine* and intensive fluid resuscitation. Amoxicilin-Clavulanic was the most frequent antibiotic used as prophylaxis (92.9%). Early complications were found in 50% of the cases, the main one was hemodynamic shock (50%). In 14.3% of the cases ARF was observed, as well as pleural effusion and infections. Two patients had wound dehiscence. And other two needed re-intubation and mechanical ventilation support; CVVHDF was needed in 14.3%.
Length of stay in UCI was 7.78±7.07 days. Three patients were re-entry due to wound dehiscence, two of them with sepsis associated, none of them present renal failure neither respiratory failure; with an average UCI stay of 7.33± 3.51 days. The average hospital stay was 18.88±10.66 days.
CONCLUSION. The profile of the patient admitted to the ICU, after Cytoreductive surgery and HIPEC, was a 58 year old female, with comorbidities and gynecological or gastrointestinal cancer; who need Norepinephrine and intensive fluid resuscitation due to initial shock,

as well as prophylactic treatment with Amoxicillyn-Calvulanic; with good progress in 24h and without needing to be re-admitted in ICU

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000812

INTRODUCTION. Resolution of acute inflammation requires a newly discovered group of lipid Specialized Pro-resolving mediators (SPMs) derived from omega-3 fatty acids to control the inflammatory response and avoid transition to chronic inflammation. Little is known about the kinetics of SPMs in response to an acute inflammatory insult in humans. Few surgeries are associated with more inflammation than left ventricular assist device (LVAD) implantations.
OBJECTIVES. The aim of this study was to determine if and when the SPMs Resolvin D1 and D2 are detectable after a major inflammatory insult.
METHODS. After IRB approval/consent, the plasma of 10 patients undergoing LVAD implantations was analyzed for resolvin D1 and D2 using liquid chromatography and mass spectrometry (LC-MS) preoperatively and then daily until postoperative day 10. Arterial lactate concentrations were determined as an indicator of inflammation.
RESULTS. Ten patients were studied from August to October 2018. Resolvin D1 was 827 +/- 187 pg/mL at baseline, decreased initially to then 327 /- 185 pg/mL and then increased again with a peak on postoperative day 4 of 960 +/- 308 pg/mL. Mean Resolvin D2 levels were 169 +/- 44 pg/mL at baseline and fluctuated around 180 to 340 pg/mL postoperatively with no discernable trend. The lactate concentrations were elevated preoperatively and decreased to normal levels within 4 days.
CONCLUSION. We were able to detect SPMs after acute inflammation: Resolvin D1 peaked at day 4 at a time when inflammation decreased as indicated by normalizing lactate concentrations. However, Resolvin D2 remained unchanged throughout the postoperative period.
Patients undergoing LVAD implantation are in end-stage heart failure with other end-organ failures and, therefore, already have high levels of inflammation prior to surgery. Thus, it may be more difficult to identify a pattern of resolution.

Circadian Rhythm Disturbance in Intensive Care and Long-term Cognitive Outcomes

R. Cusack, O. Tujjar
Anaesthesiology and intensive care, Sligo University Hospital, Sligo, Ireland
Correspondence: R. Cusack
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000813

INTRODUCTION. Patients admitted to the intensive care unit (ICU) are subject to sleep disturbance[Devlin et al, 2018]. Inadequate quality sleep or restlessness at night requiring sedation is a marker of circadian dysfunction in critical illness[Drouot et al, 2008; Pandharipande PP, et al., 2013]. Circadian rhythm disruption is increasingly implicated as a key factor leading to ICU delirium[Madrid-Navarro CJ,et al., 2015]. ICU-related delirium has been associated with ongoing sleep disturbance and cognitive morbidity after critical illness[Orwelius L., 2008].
OBJECTIVES. The aim of this study was to evaluate the risk factors associated with long term cognitive dysfunction in patients after ICU admission.
METHODS. We conducted a retrospective review of patients admitted to our ICU from January to December 2018. Inclusion criteria were age >18 years, Length of stay>48 hours, mechanical ventilation and use of sedatives. Demographics, comorbidities and known risk factors for ICU-delirium were collected. Patients' overnight state, sleep quality and symptoms of delirium, as documented by nurses each day were also recorded. Patients or Next of Kin were then contacted by telephone for interview, when consent was obtained. Health-related Quality of Life (HRQoL) and Post-traumatic Stress Disorder (PTSD) screening Questionnaires were administered over the phone.
RESULTS. Of the 87 patients who met the inclusion criteria, 24 did not survive ICU, 6 were transferred elsewhere and 12 deceased since discharge. Therefore 45 were available for phone interview, with a 62% response rate and one declining consent. Of the 27 patients included, 11 had Mental Component HRQoL scores at 6 months below the population average (42±7 vs 58±3). Patients with lower Mental Component HRQOL scores at 6 months had a higher rate of blood transfusions (6/11 vs 3/16, p=0.056), and circadian rhythm disruption (5/11 vs 14/16, p=0.018) in ICU. They also presented a higher rate of PTSD screen score at 12 months (5 [3,7] vs 1 [0,1.25], p=0.011).
CONCLUSION. Long-term cognitive dysfunction is common after ICU admission. These patients had circadian rhythm disturbance in ICU and were transfused more frequently. They were also more prone to develop long-term PTSD. This small retrospective study encourages further investigation of this interesting relationship.

INTRODUCTION. New or worsening cognitive impairment occurs in up to 58% of survivors of critical illnesses and is long-lasting, with significant disability and socioeconomic cost[1]. There are currently no known interventions that reduce the incidence of cognitive impairment after critical illnesses. Immersive Virtual Reality (IVR) is the use of technology to create a perception of presence in a three-dimensional, computer-generated interactive simulated environment[2]. A prior clinical study has demonstrated potential efficacy in cognitive rehabilitation of severe traumatic brain injury [3,4]. Clinical data on the use of virtual reality in the critical care unit is limited to case report[5], paediatric population[6] or non-immersive virtual

reality[7]. It is not known if the use of IVR is safe and tolerable in mechanically ventilated adult patients.
OBJECTIVES. The primary aim of this study is to evaluate the safety and tolerability of immersive virtual reality for potential early neurocognitive stimulation in critically-ill, mechanically ventilated patients.The secondary aim of the study is to evaluate the potential of 4-channel electroencephalogram (EEG) headbands in detecting differences in attention during the use of immersive virtual reality.
METHODS. Patients aged above 21, admitted to the intensive care unit for acute respiratory failure or septic shock, were evaluated for recruitment from 1st July 2018 to 1st April 2019. Recuited patients were randomised into the control or intervention groups. Patients in the intervention group would have two 15-minute sessions of IVR daily for up to a maximum of 3 days. The IVR videos were specially curated for this study and comprised of a combination of nature scenary coupled with soothing classical music. In both intervention and control groups, a 4-channel EEG headband would be applied over the subject's forehead. Assessment of safety involved monitoring for physiological derangements in heart rate, respiratory rate, pulse oximetry and blood pressure during the IVR session, compared with the control group. Assessment of tolerability involved monitoring for increased agitation.
RESULTS. 6 patients were randomised into the intervention group and 5 patients were in the control group. There were no significant differences between both groups in the baseline variables such as age, gender, race, Charlson Co-morbidity Index, APACHE II scores. The patients in the control group required more days of mechanical ventilation compared to the intervention group (5.4 ± 3.6 days vs. 2.8 ± 1.2 days). Use of vasopressors, renal replacement therapy and sedatives were similar in both groups. 2 of 6 patients in the intervention group had delirium during and after the ICU stay compared with 1 of 5 patients in the control group. The intervention group completed an average of 1.3 ± 0.8 IVR sessions compared to the control group, which completed 3.0 ± 1.9 session. In the intervention group, 83.3% (5 of 6) patients did not have significant physiological derangements compared to 100% (5 of 5) patients in the control group. However, 50% (3 of 6) patients in the intervention group demonstrated increased agitation compared to 20% (1 of 5) patients in the control group.
CONCLUSION. The use of IVR in mechanically ventilated patients is safe, however, it may not be tolerated in some patients, resulting in increased agitation. It is uncertain if it can provide neurocognitive stimulation, further correlation with EEG data is required.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000919

INTRODUCTION. Acute pancreatitis (AP) can lead to an increase in the intra-abominal pressure (IAP) that, if it is not recognized, can develop an abdominal compartment sindrome (ACS), causing multiple organ failure and a high mortality rate.
OBJECTIVES. To evaluate if intra-abdominal pressure (IAP) can determine the therapeutic attitude and contribute to increase the survival rate in patients diagnosed with critical acute pancreatitis admitted to a medical ICU in a second-level Hospital in an eight-year period (January 2011- December 2018)
METHODS. Descriptive and retrospective study of patients with acute pancreatitis admitted to a medical ICU in eight years (2011-2018). Acute pancreatitis was classifed accordig to the determinant-based classification of acute pancreatitis severity published in Annals of Surgery[1] : mild-moderate (AP-MM), severe (AP-S), critical (AP-C). In critical acute pancreatitis the following parameters were analyzed: gender, age, etiology, APACHE II score (within 24 hours of admission), Balthazar CT severity index, type of early nutrition (within 48 hours), multiple organ failure (MOF): respiratory (Rp: PaO2/FiO2 ratio<300), cardiovascular (Cv: inotropic support required), renal (R: creatinine >2 mg/dL), need for mechanical ventilation (MV > 5 days), renal support (continuous renal replacement therapy (CRRT)), IAP value[2] (maximum value maintained for at least 12 hours), laparotomy performed (Lap-P) : if IAP>30 mmHg and MOF (> 1), laparotomy notperfomed (Lap-noP): IAP<30 mmHg and MOF (>1), and mortality rate. Statistical analysis: quantitative variables are expressed as mean and standard deviation (SD) and qualitative variables as percentages (%). The difference between qualitative variables are expressed using chi-square test and quantitative using an ANOVA analysis.
RESULTS. 88 patients diagnosed with AP were admitted: type AP-MM 26, type AP-S 30 and type AP-C 32. Of critical AP: 21 male (11 female), age: 59,5±15,3 years old, etiology: gallstone-related 15, alcohol abuse 10, idiopathic 4 and other 3. APACHE II score: 14,7±6,3, Balthazar: 6,1±2,5, nutrition: parenteral 15, enteral 10, mixed 4, none 3. Need for mechanical ventilation: 20 (62,5%) and CRRT required: 12 (37,5%). In group Lap-P (20 patients): 8 with Rp+CV, 8 with Cv+R and 4 with Rp+Cv+R. In the Lap-noP group (12 patients): 6 with Rp+Cv, 3 with Cv+R and 3 with Rp+Cv+R. Mortality in Lap group: 6 patients (1 Rp+Cv, 3 Cv+ R, 3 Re+Cv+R), and in group Lap-noP: 4 patients (1 Rp+Cv, 2 Cv+R, 1 Rp+Cv+R).
CONCLUSION. According to our series, in group Lap-P, 80% of the patients with critical AP had failure of at least two organs, whilst the Lap-noP had 75%. In terms of mortality rate, it was 30% in the Lap-group compared with 33,3% in the Lap-noP group

INTRODUCTION. Delirium in general intensive care unit (ICU) patients has been associated with prolonged ICU and hospital length of stay (LOS), more ventilator days, increased short- and long-term mortality and long-term cognitive impairment [1-3]. However, knowledge on delirium in oncological ICU patients is scarce.
OBJECTIVES. To assess the frequency of delirium and its impact on resource utilizations and outcomes in ICU patients with malignancy.
METHODS. This retrospective, single-center longitudinal cohort study included all patients with malignancy admitted to ICUs of a University Hospital during one year. Delirium was diagnosed by an Intensive Care Delirium Screening Checklist (ICDSC) score $\geq$ 4. Group comparisons were made with Fisher's exact and Mann-Whitney U tests. Multivariate analysis was performed with binary logistic regression, Cox regression with hazard ratios < 1 indicating longer LOS, and multiple linear regression. Results are given as number (percentage) and median (interquartile range).
RESULTS. Of the 488 ICU patients with malignancy, 176/488 (36%) developed delirium during their ICU stay. Delirium showed high frequencies in patients with hepatic (13/21 [62%]) and lung malignancies (29/65 [45%]) as well as lymphomas (7/15 [47%]). In addition, it was particularly frequent in patients from thoracic (27/47 [57%]) and abdominal surgery (54/136 [40%]) and internal / general medicine (16/29 [55%]). Delirious patients had higher age (66 [55-72] vs 61 [51-69] years, p = 0.001), Charlson Comorbidity Index (4 [2-8] vs. 4 [2-8]), p = 0.034) and SAPS II (41 [27-68] vs 24 [17-32], $p < 0.001$), and more often a sepsis (26/176 [15%] vs 6/312 [1.9%], $p < 0.001$) and a shock (30/176 [6.1%] vs 6/312 [1.9%], $p < 0.001$). Univariate and multivariate analysis show that delirium was independently associated with longer LOS in ICU (HR [95% CI] 0.295 [0.234-0.371], $p < 0.001$) and hospital (HR [95% CI] 0.619 [0.500-0.765], $p < 0.001$), as well as higher ICU nursing workload (B [95% CI] 1.917 [1.665-2.206], $p < 0.001$) and ICU (B [95% CI] 2.077 [1.811-2.382], $p < 0.001$) and total costs per case (B [95% CI] 1.442 [1.301-1.597], $p < 0.001$). However, while being a strong marker of in-hospital mortality in univariate analysis (OR [95% CI] 5.909 [2.872-12.160], $p < 0.001$), delirium did not independently increase in-hospital mortality in multivariate analysis (OR [95% CI] 2.263 [0.925-5.537], $p = 0.074$).
CONCLUSION. In ICU patients with malignancy, delirium was a frequent complication independently associated with high resource utilizations, but it was not an independent risk factor of in-hospital mortality.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000939

INTRODUCTION. Red blood cell (RBC) transfusion is a frequently applied intervention at the intensive care unit. However, transfusion is associated with adverse outcome including organ failure and thrombo-embolic events, the mechanism of which is not known, but may be related to the underlying disease severity.
OBJECTIVES. The aim of this study was to investigate the effect of RBC transfusion on endothelial cell activation and coagulation markers in critically ill patients.
METHODS. In 74 non-bleeding patients admitted to the ICU of a tertiary academic hospital receiving one RBC unit, biomarkers of endothelial cell activation, inflammation and coagulation (von Willebrand Factor (vWF) antigen, soluble ICAM-1, soluble thrombomodulin (sTM), soluble syndecan-1, TNFa, IL-6, d-dimer, fibrinogen, APTT and PT) were measured before transfusion, at one hour after transfusion and 24 hours after transfusion. The impact of disease severity was assessed by comparing septic and non-septic patients and by correlation of biomarkers with organ injury score (SOFA).
RESULTS. Included patients were predominantly male (55%) with a median age of 63 years. 55% of the patients was septic according to Sepsis-3 criteria. Levels of vWF antigen, soluble ICAM-1, sTM, fibrinogen and d-dimer were already high at baseline. VWF antigen levels increased significantly 24 hours after RBC transfusion (478% vs 526%, p = 0.02). The other biomarkers did not change. Post transfusion change of the measured biomarkers was not different between septic and non-septic patients and was not correlated with SOFA score.
CONCLUSION. RBC transfusion in critically ill patients was associated with an increase in circulating vWF antigen levels, suggesting a further increase in activation status of the endothelium, a finding that was independent of sepsis status or organ injury level.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000553

INTRODUCTION. In recent, intravenous immunoglobulin(IVIG) has been used as one of the adjunctive therapy for septic patients. Although IVIG is not recommended in the Survival Sepsis guideline, it has still debate to be estimated as an effective treatment for sepsis.
OBJECTIVES. The authors tried to evaluate the effect of IVIG in the critically ill patient who got abdominal surgery due to pan-peritonitis.
METHODS. It is a retrospective study analyzing 646 patients' electrical medical record from March 2013 to June 2018. The patients who had been diagnosed as secondary pan-peritonitis and managed in the ICU after getting emergency operation were indicated in this study. In this population, the comparison was made between patients who were injected with IVIG and those who did not administer IVIG. As outcome variables, mortality curve, 30-day mortality, hospital mortality and ICU duration were evaluated in each group. Of the 576 patients who were operated for pan-peritonitis during the study period, 169 were analyzed, excluding 307 patients who had left ICU within three days due to minor severity and 100 patients with contraindications. 44 patients were injected with IVIG and 125 patients were treated with conventional management without IVIG. After propensity scoring matching adjusted by APACHE II score and SOFA score, IVIG group (34 patients) and non-IVIG group (34 patients) were compared to each other.
RESULTS. There was no significant different outcome between the IVIG group and non-IVIG group however the hazard ratio of the non-IVIG group was higher than the IVIG group significantly in mortality and hospital mortality. (Overall mortality, Crude HR 1.68 (0.68~4.12), Adjusted HR 1.75 (0.69~4.44); Hospital mortality, Crude HR 1.83 (0.61~5.47), Adjusted HR 2.12 (0.68~6.67)) In the survival curve, there was a trend to separate completely between the IVIG group and non-IVIG group as the time went on. (Overall mortality, P=0.105; Hospital mortality, p=0.093)
CONCLUSION. In septic patients with pan-peritonitis, the use of IVIG after proper surgery and the use of antibiotics could affects the risk of overall mortality and hospital mortality.

Should blood cultures be done for all patients who are admitted to the Intensive Care Unit with septic shock?

L. Denholm[1], S. Drysdale[2], A. Puxty[2]
[1]NHS GGC, Glasgow, United Kingdom; [2]Intensive care unit, NHS GGC, Glasgow, United Kingdom
Correspondence: L. Denholm

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000557

INTRODUCTION. Blood cultures are part of the septic shock protocol for patients admitted to the Intensive Care Unit (ICU) at Glasgow Royal Infirmary (GRI) Hospital. This aims to identify causative organisms quickly and guide or refine antibiotic therapy. However, patients with sepsis should rarely be admitted to ICU without blood cultures and antibiotic therapy initiated. As per surviving sepsis guidelines, these cultures should have been carried out prior to treatment with antibiotics. Recent antibiotic therapy reduces positive culture rates, therefore it's possible that repeating cultures does not contribute to patient care.
OBJECTIVES. To evaluate the clinical value in carrying out blood cultures routinely in all septic shock patients and to determine the frequency at which new causative organisms idetntified.
METHODS. This was a retrospective analysis of 241 patients with vasopressin dependent septic shock admitted between Jan 17-Nov 18 to our ICU. Mean age of the cohort was 60.8 yrs (range 19-92) and 56% were male. We recorded blood cultures performed up to 24hrs pre and 24hrs post ICU admission.
RESULTS. Of 241 patients, 144 (59.7%) had cultures prior to ICU admission. 45 (31.25%) were positive. Post ICU admission, 115 (47.7%) patients had blood cultures, 13 (11.4%) of these were positive for an organism.
A total of 65 (56.5%) out of 115 patients who were cultured post-ICU admission had not had cultures previously. 8 (6.9%) of these cultures grew micro-organisms. Three (2.6%) patients had cultures which reported no growth prior and became positive following admission cultures. Two (1.7%) patients had blood cultures which were positive before and after admission, however the second set of cultures did not provide any new information only confirming the initial result. 30 (12.45%) of 241 patients had no cultures taken.
CONCLUSION. While new information was gained from repeat cultures the yield was low. There remains a significant number of patients who don't have cultures taken prior to ICU admission. Given that septic patients' outcomes are time sensitive and early cultures are more likely to be positive, efforts to improve yield should be concentrated here. This project supports the notion that there is value in post-ICU admission blood cultures, though the number of new positive results is relatively low.

Evaluation of risk factors for the development of Carbapenem Resistance among Gram-Negative Bacilli

DN. Mukherjee[1], S. Seal[2]
[1]Clinical microbiology & id, Woodlands, Kolkata, India; [2]Clinical microbiology, Woodlands , Kolkata, India
Correspondence: D.N. Mukherjee
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000577

INTRODUCTION. Carbapenem resistance among Gram-negative bacilli (CR-GNB) has been increasing over the past several decades, particularly in *Enterobacteriales* species. Infections due to CR-GNR are increasing in frequency and result in high morbidity and mortality. Overuse/misuse of carbapenems as initial antibiotic therapy is a risk factor to develop carbapenem resistance in hospitalized patients.
OBJECTIVES. To find out the correlation between early carbapenem exposure and other risk factors in the development of carbapenam resistance amongst Gram negative bacilli.
METHODS. We have conducted a retrospective study of all patients with positive cultures from any source over a 2-year period at a tertiary care hospital from 2016 to 2018 to develop a comprehensive model for risk of infection or colonization with CR-GNB, with separate analyses for Ertapenem resistant (ER-GNB) and antipseudomonal carbapenem resistant (ACR-GNB) isolates. Routine susceptibility testing was performed by the either the CLSI reference broth microdilution method (BMD) or using a Vitek 2. All antimicrobial susceptibility data were interpreted using current CLSI breakpoints for carbapenems.
RESULTS. A total of 2450 GNB isolates from 1320 patients were analyzed, of which 412 were CR (ER 130 and ACR 282). The majority of ER-GNB were *Klebsiella* species, whereas the most common ES-GNB were *Escherichia coli*; the most common ACR-GNB were *Acenetobacter* species. Risk factors for CR-GNB were, receipt of any carbapenem in the prior 30 days, any surgical intervention in recent past, admission from another health care facility, ventilation at any point before culture during the index hospitalization, any invasive device including foley's catheterization and receipt of any anti-MRSA agent in the prior 30 days.
CONCLUSION. Initial choice of antibiotic remains a challenging and high-stakes decision. Early exposure with carbapenem is a risk factor for development of CR-GNB infection in later days of hospitalization. Delayed antimicrobial therapy in carbapenem resistant infections has higher mortality, highlighting the need for rapid identification of patients at high risk for CR-GNB. Rational antibiotic therapy and antimicrobial stewardship is the need of the hour.

The combination of cold exposure training and a breathing technique attenuates the inflammatory response in humans in vivo

J. Zwaag, N. Rick, P. Pickkers, M. Kox
Intensive care, Radboud University Medical Center, Nijmegen, Netherlands
Correspondence: J. Zwaag
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000581

INTRODUCTION. We previously showed that an intervention developed by 'Iceman' Wim Hof enables voluntary activation of the sympathetic nervous system, reflected by profoundly increased plasma adrenaline levels, which subsequently caused profound attenuation of the inflammatory response during experimental human endotoxemia. The intervention consisted of a training program encompassing several elements that may have contributed to the observed effects, namely two different breathing techniques performed during the endotoxemia experiments, and exposure to cold in the days before endotoxemia.
OBJECTIVES. For possible future clinical application, we aimed to determine the contribution of the different elements of the training program to the effects observed in our previous study. Furthermore, we assessed if the duration of the training is of relevance, and whether it can be provided by an independent trainer instead of Mr. Hof.
METHODS. To determine the optimal breathing technique to induce adrenaline release, 40 healthy male volunteers were randomized to training in both techniques (cycles of hyperventilation followed by either muscle tightening for 10 seconds or breath retention for several minutes) for either 4 days or 1 hour, by either Mr. Hof or an independent trainer. In a subsequent endotoxemia study, 48 healthy male volunteers were randomized to four groups: 4-day cold exposure training (CLD group), training in the optimal breathing technique (BRT group), a combination of both interventions (CBR group), or no intervention (CON group). The CLD and CBR groups were subjected to cold exposure in snow and water of 1 oC. All 48 subjects were subsequently challenged with 2 ng/kg LPS to induce endotoxemia.
RESULTS. In the first part of the study, arterial blood saturation levels and pO2 were significantly lower when subjects performed the breathing technique with breath retention (both $p<0.001$), but plasma adrenaline levels increased to a similar extent immediately after initiation of both breathing techniques (0.48 nmol/L [-0.01-1.2] vs. 0.50 nmol/L [0.25-0.91] upon the breath retention and muscle tightening techniques, respectively). No effects of training duration or trainer were observed on adrenaline levels or any other parameters. In the second part of the study, we therefore employed a short training in the breathing technique without breath retention, and all training procedures were provided by an independent trainer. Peak endotoxin-induced flu-like symptom scores were significantly lower in the CLD group (4.1±0.6 vs. 7.9±1.4 in the CON group, $p=0.02$), and resolved more rapidly. In the CBR group, plasma levels of pro-inflammatory cytokines were attenuated (TNF-α: -33%, $p=0.03$, IL-6: -58%, $p=0.03$), whereas concentrations of the anti-inflammatory cytokine IL-10 were increased by 73% ($p=0.02$) compared with the CON group. In the BRT group, similar, but less pronounced effects on plasma cytokines were observed, whereas no differences in cytokine levels were observed between the CLD and CON groups.
CONCLUSION. The combination of cold exposure and the breathing technique without breath retention attenuates the *in vivo* inflammatory response most potently. These results demonstrate that the immunomodulatory effects of the intervention developed by Wim Hof can be reproduced making use of short standardized protocols and an independent trainer.

INTRODUCTION. Early prognostic assessment of septic patients in the Emergency Department (ED) is crucial. Therefore, identification of patients at high risk of organ failure or shock is key to prevent deterioration and reduce mortality. Currently, no prognostic tool seems efficient to identify these patients. The infection site could represent a major factor of heterogeneity in the prognostic performance of biomarkers in septic patients.
OBJECTIVES. To evaluate the prognostic performances of biomarkers to predict the clinical deterioration of patients with sepsis in ED according to their site of infection.
METHODS. TRIAGE was an international multi-centre (France and Belgium) prospective observational study (ClinicalTrials.gov: NCT02739152) designed to evaluate a panel of prognostic biomarkers in adult septic patients admitted in ED (SIRS criteria). Blood samples were collected at 0, 6 and 24 hours after ED inclusion. Main outcome was subsequent deterioration (death, ICU admission, 1-point increase of SOFA score) within 72 hours. The diagnosis of sepsis and the evolution criteria were centrally validated by an independent adjudication committee of sepsis experts. The prognostic performances of endothelial biomarkers (sVEGFR2, sUPAR) were assessed according to the site of infection using logistic regression models. AUC were calculated using the DeLong method.
RESULTS. Overall 462 patients were analysed, 124 patients were confirmed as deterioration and 338 patients without deterioration. Sites of infection were mainly lungs (29%), urinary tract (27%) and abdomen / pelvis (25%). Patients with pulmonary infection were significantly more severe (qSOFA, and Charlson score) ($p<0.001$) than the other patients. These patients were also the ones who deteriorated the most within 72 hours and had a higher D28 mortality ($p=0.0047$). Expression of biomarkers was significantly associated with the risk of deterioration regardless of the site of infection (Lung: OR = 1.9 [1,24-2.86], Urinary: OR = 2.6 [1.3-5.82], Abdomen-pelvis: OR = 2.4 [1.26-4.97], Others: OR = 1.67 [1.05-2.74], $p<0.05$). Nevertheless, the predictive performance of short-term deterioration by the biomarkers was higher in patients with urinary and abdominopelvic infections (AUC = 0.70, sp=51, NPV=95 and AUC = 0.81, sp=51, NPV=93, respectively) compared to lung infections and other sites of infection (AUC = 0.66, sp=19, NPV=79).
CONCLUSION. Although biomarkers were associated with a risk of deterioration of septic patients, the predictive performance of sVEGFR2 and sUPAR was significantly lower in patients with pulmonary infection when compared to those with urinary tract or abdominopelvic infection.

INTRODUCTION. Accurate prognostic assessment of septic patients is challenging in the emergency department (ED). Identification of patients at high risk of organ failure or shock could help to prevent deterioration and reduce mortality. Clinician's assessment is based on initial severity, scoring, social context, hospital bed capacity, and on personal experience. The performance of emergency physicians in predicting septic patient's outcome has been scarcely described, and the additional value of a prognostic biomarker has not often been evaluated in the ED.
OBJECTIVES. To calculate the prognostic performance of emergency physicians to predict clinical deterioration of septic patients during their initial management in the ED and to evaluate if adding biomarkers information could improve this clinical prediction.
METHODS. This is an ancillary study of the TRIAGE study (ClinicalTrials.gov: NCT02739152) designed to evaluate a panel of prognostic endothelial biomarkers (sVEGFR2 and sUPAR) in a cohort of adult septic patients admitted to the ED. The analysis was performed on non-severe patients (SOFA<2) of two teaching hospitals. The risk of clinical deterioration was assessed by an adjudication committee composed of three independent emergency physicians (blinded from deterioration outcome) according to the emergency medical records and the first conventional biological and imaging results. This first judgement allowed to calculate the clinical emergency physician's performance. Then, adjudicators were unblinded from the results of biomarkers (which helped classifying patients into two groups: "high risk" or "low risk") and were asked to keep or revise their first judgement. This second judgement allowed assessing the additional value of biomarkers. Finally, the performance of biomarkers alone was calculated.
RESULTS. Analyses were performed on 145 patients (age = 50±20 yr; Charlson score: 1.7 [0-3]; SOFA score: 0.5 [0-1]; lactates: 2.03 [1.17-2.41]; site of infection: pulmonary 12.4%, urinary 32.4%, abdominopelvic 34.5% and 30 patients deteriorated (21%). The clinical performance of emergency physicians to predict deterioration was: Sensitivity=80; Specificity=21; Negative Predictive Value=80; Positive Predictive Value=21. Adding the biomarkers improved the clinical prognostic performance of emergency physicians (Sensitivity=90; Specificity=19; Negative Predictive Value =88; Positive Predictive Value =23). Biomarker alone was the best predictor of deterioration (Sensitivity =93; Specificity =50; Negative Predictive Value =97; Positive Predictive Value =33).
CONCLUSION. This study confirms that predicting the clinical deterioration of septic patients in the ED remains challenging. Adding prognostic biomarkers (sVEGFR2 and sUPAR) to clinical evaluation could be helpful in early assessing the risk of deterioration of septic patients, and safely ruling out patients after ED admission due to its high negative predictive value.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000645

INTRODUCTION. Calcium can be considered an adjunctive rescue therapy for refractory septic shock, but research on calcium use is limited. In this study we aimed to investigate short-term hemodynamic response after calcium supplementation in patients with refractory septic shock.
METHODS. This was a single-center, retrospective study of patients who presented to the emergency from October 2014 through February 2018. Patients with refractory septic shock requiring norepinephrine-equivalent (NE) dose $\geq$ 0.5 μg/kg/min and receiving calcium supplementation were included. Patients were categorized into a response group and no-response group based on the changes in NE doses and MAP after calcium administration. A multivariable logistic regression model was used to evaluate the association between hemodynamic response and 28-day survival.
RESULTS. A total of 66 patients were included. Among them, the response group included 34 (52%) patients and the no-response group 31 (48%) included 17 patients who deteriorated and 15 patients who had no significant changes in clinical status. The 28-day mortality

was 44% in the response group and 63% in the no-response group (P = 0.14). Multivariable analysis revealed that the response group had a significant association with lower 28-day mortality (the adjusted OR, 0.23; 95% CI, 0.06–0.89; P = 0.03).
CONCLUSION. Short-term hemodynamic changes after calcium administration were variable in patients with refractory septic shock. Hemodynamic improvement after calcium supplementation was associated with better survival. Further studies are needed to determine when calcium should be considered and how it impacts patient-centered outcomes in refractory septic shock.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000664

INTRODUCTION. Community-acquired pneumonia (CAP) is the primary cause of infectious death in developing countries. During CAP, infected patients initiate immune responses that promote local and systemic inflammation. While several proinflammatory molecules have been described and linked to a greater risk of complications, longer hospital stays and mortality; novel biomarkers are still required for superior identification of disease severity. TNF-like weak inducer of apoptosis (TWEAK) is a member of the TNF-alpha superfamily, involved in immune response, cell growth, angiogenesis, NF-kB activation and apoptosis induction in tumor cells. It is known that serum-TWEAK promotes inflammation in diseases such as multiple sclerosis, atherosclerosis and pancreatitis. Importantly, its role in disease severity of CAP patients is still unknown. Therefore, this study aims to determine whether there is a relationship between serum concentration of TWEAK and prognosis in CAP patients.
OBJECTIVES. To determine the relationship of serum concentration of tumor necrosis factor (TNF)-like weak inducer of apoptosis (TWEAK) and mortality in community-acquired pneumonia (CAP) patients.
METHODS. This is a multicenter 2-year cohort study in Spain, designed to better understand the role of sTWEAK concentrations in CAP patients. A total of forty-three patients were enrolled in two University hospitals (10 healthy users, 10 uninfected controls and 23 CAP patients). sTWEAK was measured within the first 24 hours of ICU admission. Samples were collected and stored for laboratory analyses. To detect sTWEAK in human samples, we used a commercially available ELISA kit following manufacture's instructions. Demographic patients' characteristics and ICU mortality were prospectively collected. Descriptive statistics and logistical regressions were used to assess the proposed aims.
RESULTS. In comparison to healthy volunteers, patients admitted to the hospital (both, infected and non-infected) had lower level of sTWEAK. During hospital admission, 7 (17%) patients died. Patients whom died during ICU stay had significantly lower levels of sTWEAK when comparing with patients whom survived (Median [IQR]; 509.35 [357.49, 953.92] Vs 1103.03 [716.93, 1663.16]; p=0.015). In contrast, patients that developed shock did not have different concentrations of sTWEAK (Median [IQR]; 1008.04 [531.87, 1390.80] Vs 1062.29 [575.24, 1598.83], p=0.84).
CONCLUSION. To our knowledge, this is the first study to show a role for sTWEAK in the morbidity and mortality of CAP patients. Here we show that CAP patients with lower systemic sTWEAK had increased mortality rate, suggesting a beneficial role for sTWEAK in the host response against infection. This biomarker may identify patients at risk of developing severe CAP and subsequently died in the ICU. However, further studies are needed to confirm these findings.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000703

INTRODUCTION. Although the role of automatic alerts for early detection of sepsis remains unclear, it is true that majority of electronic alerts for early detection of sepsis are based on sepsis 2 definitions. No data about alerts based on sepsis 3 definition has been provided.
OBJECTIVES. The aims of this study were to describe SEPSIS SAVER, a new electronic alert based on sepsis 3 definition; to compare it with an electronic alert based on sepsis 2 and to know its sensiblity, specificity, negative predictive value (NPV) and positive predictive value (PPV).
METHODS. SEPSIS SAVER is a new electronic tool designed by a multidisciplinary group composed by members of three sepsis units of three teaching hospitals based on sepsis 3 definition.
During a month period (March 2018) it has been implemented as a pilot in one of the hospitals and has been prospectively evaluated. This unique center has been working with a previous electronic sepsis alert based in sepsis 2.0 six years ago.
Clinical and microbiological variables were recorded. Any patient admitted at Emergency room was potentially eligible using the two sistems simultaneously. Sensibility, specificity, NPV and PPV were calculated for both alerts using sepsis team criteria as Gold standard.
RESULTS. Among 1378 electronic activations, 58 (4,2%) were confirmed as a sepsis severe/ septic shock (sepsis 2) or sepsis (sepsis 3) by the members of sepsis team. It means a rate of 22,8 episodes/ 100.000 inhabitants a month . The most frequent sources of infections were the respiratory focus (39%) following by urinary (26.6%) and abdominal (18.5%). Only 18.9% of patients were admitted to ICU. Global mortality was 18.9%. The majority of episodes were community adquired (85%). Forty episodes were detected by the two alerts. SEPSIS SAVER detected 46 true episodes with 12 false negative results compared with the tool based on sepsis 2 definitions which detected at the same time 52 episodes with 6 false negative results. Sensibility, Specificity, NPV and PPV of SEPSIS SAVER were 79,3%; 50,6%; 3,3% and 99,1% respectively. Sensibility, Specificity, NPV and

PPV of sepsis 2.0 alert were 89.6%; 49.1%; 3.7% and 99.5% respectively
CONCLUSION. SEPSIS SAVER showed an adequate capability to detect sepsis as well as did alert based on sepsis 2 definition. Both tools need to be modified in order to improve their specificity with new definitions

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000706

INTRODUCTION. Sepsis is a major health issue in Brazil and, is increasing death rate in recent years[1]. A comparison between our country and England showed that crude hospital mortality in sepsis has no difference[2]. The incidence of septic shock (SS) in a French study was 13.7% and the 28 day mortality rate was 42%[3], characterizing a high-risk death population.
OBJECTIVES. To identify the epidemiological profile, resource utilization and mortality in SS patients admitted to a single center ICU, in Southern Brazil.
METHODS. All patients that presented SS criteria (need of vasopressor therapy despite adequate fluid resuscitation to maintain MAP ≥ 65 mmHg) during ICU stay were enrolled in the study. Data collected prospectively were: age, gender, comorbidities [diabetes mellitus (DM), hypertension, cancer and chronic renal disease (CRD)], site of infection, SAPS 3 and SOFA at admission. Resource utilization was considered mechanical ventilation (MV), invasive hemodynamic monitoring (IHM) and renal replacement therapy (RRT). ICU and hospital mortality were reported. Continuous variables were presented as mean±SD, using Student t test for comparison and categorical variables presented as percent. Mortality prediction was done using the receving characteristic curve (ROC).
RESULTS. Between February 2012 and December 2018, 2707 patients were ICU admitted in ICU and 315 (11.6%) presented SS. Mean age was 63,2±15,6 yrs and 56,8% were male. DM, hypertension, cancer and CRD were present in 21.3%, 42.5%, 15.2% and 6.3%, respectively. Average SAPS 3 and SOFA were 66.3±13.7 and 8.4±3.0. The use of MV, IHM and RRT was 93.7%, 7.6% and 15.9%, respectively. Mortality in ICU was 43.5% and in hospital 55.6%. Factors associated with ICU mortality were cancer (OR 1.429; CI 95% 1.081-1.889), CRD (OR 1.546; CI 95% 1.091-2.191), MV (OR 4.576; CI 95% 1.222-17.142) and RRT (OR 1.55; CI 95% 1.192-2.015).
CONCLUSION. In Southern Brazil, SS incidence and mortality is similar to the recent published data. The presence of comorbidities and severity of organ dysfunction increase the mortality risk in a similar rate of observational studies. These patients demand an important resource use, mainly MV and RRT.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000710

INTRODUCTION. Emergence of multidrug-resistant bacteria (MDR) are facilitated by the abusive use of antibiotics. Multiple clinical trials have evaluated the usefulness of procalcitonin (PCT) to guide the initiation and completion of antibiotic therapy. However, they included mainly patients with sepsis of the community, with few MDR isolates.
OBJECTIVES. Investigate the kinetic of PCT and the time necessary to decrease it in MDR infections.
METHODS. Retrospective observational study, PCT curves of all bacterial rescues of ventilation associated pneumonia (VAP) and catheter-related bloodstream infections (CRBSI) were analyzed during the period from November of 2016 to May of 2018 in the intensive care unit of the Hospital Italiano de Buenos Aires, Argentina. Patients with an infectious intercurrence during the antibiotic course were excluded from the study together with those dead before the expected decrease in PCT or with chronic infections.
RESULTS. During the period analyzed, 73 bacterial rescues were recovered. 47 patients were excluded from the analysis due to the exclusion criteria. 12 patients with sensitive bacteria (SB) and 14 patients with MDR were selected for the final analysis, without significant differences between population. Patients with CRBSI generated by MDR showed significantly higher maximum values of PCT: MDR mean 39 ug/l (SD+/-30) vs. SB mean 10.7 ug/l (SD+/-11), (p= 0.02). The time elapsed from the detection of the bacteria to the decrease of 80% or values lower than 0.5 ug/l, with effective antibiotic treatment, was in MDR 7.2 (SD+/-2.9) days vs. 5 (SD+/-1.8) days in SB with a significant difference (p=0.03). The PCT decrease was exponential in both groups, with quicker decrease in SB than in MDR (Figure 1).
CONCLUSION. The inflammatory response measured by PCT in MDR was greater and longer, even with an effective antibiotic treatment, which could be due to greater virulence. However, the decline occurs before conventional antibiotic schemes are completed. In this sense it is necessary to study the potential application of antibiotic protocols guided by PCT to this population.

Immunomonitoring of monocytic HLA-DR and neutrophilic CD64 expression and Sepsis Index as predictive biomarkers of infection and sepsis

A. Herraiz,[1], B. Quirant[2], E. Lucas[2], EM. Martínez-Cáceres[2], O. Plans[1], E. Argudo[1], V. Philibert[1], F. Arméstar[1]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000727

INTRODUCTION. Sepsis is characterized by a simultaneous imbalance of hyperinflammation and immunosuppression. The decreased expression of HLA-DR molecules on circulating monocytes (mHLA-DR) has been associated with anti-inflammatory immune response, referred to as "immunoparalysis" status. On the other hand, in a proinflammatory scenario, neutrophils can increase the expression of CD64 molecules (nCD64), emerging as a potential biomarker in the diagnosis of sepsis. Sepsis Index (SI), which is defined as the ratio between nCD64 and mHLA-DR, is considered a novel parameter in prognostication of sepsis.
OBJECTIVES. This study aims to evaluate the behavior of the nCD64, mHLA-DR and SI biomarkers in critically ill patients and their association with the development of infection and sepsis.
METHODS. A total of 77 critically ill neurological patients were recruited for two years (2015-2016) from the Intensive Care Unit (ICU) of Germans Trias i Pujol Hospital, Spain. Infection was ruled out in all patients enrolled in the study at the time of admission. Patients under 18 years of age or with an ICU stay of less than 24 hours were excluded of the present study. The nCD64, mHLA-DR and SI biomarkers were analyzed in a standardized flow cytometry protocol at different times after admission. The study was previously approved by the Hospital Ethics Committee.
RESULTS. A total of 55 patients developed infection (infected group); the other 22 patients did not develop infection (non-infected group). No significant differences were detected in mortality between groups (p=ns). Nevertheless, SOFA score, days of mechanical ventilation and stay in ICU were higher in infected patients (p<0'05). In the first 24 hours after admission, no differences were observed in the percentage of mHLA-DR and nCD64 between groups. On the third day after admission, however, infected patients showed lower percentage of mHLA-DR, higher expression of nCD64 and an increased Sepsis Index (p<0'05).
CONCLUSION. Patients who become infected are in a state of immunosuppression, since they express lower levels of mHLA-DR. These results suggest that nCD64, mHLA-DR and SI could be considered useful biomarkers to evaluate the susceptibility to develop infection in critically ill patients.

INTRODUCTION. The retina is a window where the microvascular profile can be imaged directly and non-invasively at the bedside. Sepsis is associated with a decrease in microvascular density and its severity is related to mortality [1]. However, features of retinal vessels calibers and density during sepsis are not fully characterized.
OBJECTIVES. To compare the retinal vasculature between septic patients and age matched healthy volunteers.
METHODS. Prospective observational study from January 2018 to April 2019 in a third-level ICU. We performed a single fundus imaging using a hand-held digital fundus camera (Aurora, Optomed Oy, Finland) in patients with sepsis or septic shock (n=37) during first 24 hours after ICU admission and compared these data with age-matched healthy controls (n = 20). Image analysis was performed using ARIA software. The average retinal arteriolar and venular caliber were calculated and summarized as the central retinal arteriolar equivalent (CRAE) and central retinal venular equivalent (CRVE). Arteriole–venular ratio (AVR) defined as the ratio of CRAE to CRVE. The density of manually segmentated retinal vessels was calculated using ImageJ software: vascular length density = skeletonized vessel area/ total area * 100%. Data are reported as medians with 25th and 75th percentiles.
RESULTS. Out of 37 patients, 35 (95%) were in septic shock, 37 (100%) required mechanical ventilation. Median APACHE II and SOFA scores were 16 (12-20) and 9 (7-11), respectively. Mean arterial pressure (MAP) and cardiac index (CI) were 74 (64-81) mmHg and 2.9 (2.1-4.1) L/min/m2, respectively, and the median norepinephrine (NE) dose was 0.24 (0.10-0.33) mcg/kg/min. Patients with sepsis had a median CRAE of 161.8(146.6-183.2) μm compared with 146.3(141.9-157.7) μm in healthy subjects (p = 0.008). Their median CRVE was 257.6(225.0-286.7) μm compared with 243.7(215.1-272.2)μm in healthy subjects (p = 0.221) and AVR was 0.6(0.6-0.7) compared with 0.6(0.5-0.7) in healthy subjects (p=0.508). We found significant correlation between CRAE and diastolic blood preesure (r=0.35, p=0.047), between arterial tortuosity and systolic blood pressure (r=-0.36, p= 0.042). Patients with sepsis showed a significant decrease in retinal vascular lenght density compared with healthy subjects (p=0.001).
CONCLUSION. We found retinal signs of arteriolar vasodilation and decreased retinal vascular density in septic patients.

INTRODUCTION. The retina is a unique site where the microcirculation can be imaged directly at the bedside and non-invasively, providing an opportunity to study changes in the microvasculature relating to the development of hemodynamic state. Altered microcirculation is cornerstone of sepsis and its severity is related to mortality [1]. However, changes of retinal vessels during course of sepsis and their relationship to hemodynamics and outcomes are not fully characterized.
OBJECTIVES. To evaluate changes in retinal microvasculature during 24 hours period of time and compare it with hemodynamic profile and outcomes in patients with sepsis or septic shock.
METHODS. Prospective observational study from January 2018 to April 2019 in a third-level ICU. We performed retinal imaging using a hand-held digital fundus camera (Aurora, Optomed Oy, Finland) and systemic hemodynamic measurements at three time points: at

baseline (earlier than 24 hours after arrival to ICU), 6 hours and 24 hours later. Retinal image analysis was performed using ARIA software. The average retinal arteriolar and venular caliber were calculated and summarized as the central retinal arteriolar equivalent (CRAE) and central retinal venular equivalent (CRVE). Arteriole–venular ratio (AVR) defined as the ratio of CRAE to CRVE. The density of manually segmentated retinal vessels was calculated using ImageJ software: vascular density = vessel area/total area * 100% and vascular length density = skeletonized vessel area/total area * 100%. Data are reported as medians with 25th and 75th percentiles.

RESULTS. Thirty seven patients with median age of 66(54-77) were included. 35 (95%) were in septic shock, 37 (100%) required mechanical ventilation. Median APACHE II and SOFA scores were 16 (12-20) and 9 (7-11), respectively. We compared data between survivors (n= 17) and non-survivors (n=20). We found significant difference in AVR between survivors and non-survivors during first measurement 0.6(0.5-0.6) vs 0.7(0.6-0.8),(p=0.008) as after 6 hours (p=0.041) and 24 hours (p=0.029). We detected significant difference in retinal vessel density (p=0.015) and vessel length density (p=0.05) during second measurement (6 hours after first measurement). We didn't find the difference in mean arterial pressure between survivors and non-survivors during all three measurements.

CONCLUSION. We found an association between retinal arteriole-venular ratio, retinal vascular density and mortality in sepsis and septic shock.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000747

INTRODUCTION. The cardiovascular system is affected by sepsis and is associated with high mortality in seriously ill patients (1). Myocardial dysfunction occurs in half of septic shock patients despite normal or high cardiac output. Echocardiography and cardiac biomarkers are useful to evaluate cardiac dysfunction (2, 3).

OBJECTIVES. To identify if cardiac dysfunctions and cardiac markers are associated with ICU mortality in septic patients.

METHODS. This is the first phase of a larger study to evaluate the predictive value of bedside echocardiography at ICU setting. We assessed a cohort of septic and septic shock patients. Systolic and diastolic dysfunction were defined as ejection fraction function: normal >55%, mild deterioration 45-54%, moderate 30-44% and severe <30%. Sepsis and septic shock were defined according to Sepsis 3 criteria (4). SOFA and APACHE-II scores were calculated on the day of admission with the diagnosis of sepsis.

RESULTS. 59 patients were included. Mean age was 67.3±16.6 years, 27(45.8%) were women. Median time in ICU was 8 (range, 2-49) days. ICU mortality was 22.0% (n=13). Thirty-three (56%) had septic shock. Thirty-eight (66.7%) patients showed diastolic dysfunction (DD), 13 (22%) showed moderate systolic dysfunction (SD) and 1(1.7%) patient had severe SD. SOFA score at admission and maximum SOFA were significantly higher in non-survivors than in survivors: 8.6±4.0 vs. 5.7± 2.1, P=0.0009, respectively and 12.1±4.6 *vs.* 7.0±2.6, P=0.000, respectively. Apache was 21.3±7.9 vs. 15.9±14.2 in non-survivors vs. survivors, respectively, P<0.05. Fifty-one (86.4%) patients received vasopressors and 40(60.8%) were mechanically ventilated. Of 41 patients who had systolic or diastolic dysfunction, 9(19.5%) patients died. Comparing markers in those patients with any dysfunction vs. patients with no dysfunction, ProBNP was 111.8±223.1 ng/ml *vs.* 188.2±336.4 ng/ml (P>0.05), troponin-T was 91.9±121.5 *vs.* 117.9± 197.4 ng/ml (P>0.05), and procalcitonin was 25.1±41.7 *vs.* 22.6±34.5 ng/ml (P>0.05).

CONCLUSION. In our preliminary analysis of a small cohort, dysfunction was not associated with mortality. SOFA score was associated with mortality. Research of a larger sample and robust analysis is necessary to assess the predictive value of echocardiographic tools.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000750

INTRODUCTION. Patients with sepsis have a high risk of developing new onset arrhythmias, such as atrial fibrillation (AF). Previous reports have shown that AF is associated with adverse clinical outcomes in these patients.

OBJECTIVES. To assess echocardiographic and clinical variables of patients with sepsis and new onset AF, admitted to a surgical medical intensive care unit.

METHODS. We prospectively assessed a cohort of septic and septic shock patients with bedside echocardiography. Atrial depolarization speed was measured in all patients by tissue Doppler echocardiography (TDE). Sepsis and septic shock were defined according to Sepsis 3 criteria. SOFA and APACHE-II scores were calculated on the day of admission with the diagnosis of sepsis.

RESULTS. A cohort of 27 patients was evaluated. Five (18.5%) patients presented with AF. SOFA scores at admission were comparable in patients with AF versus patients with no AF (9.2 ± 4.8 vs. 6.5 ± 1.8, p=0.0445). Left atrial area was higher in patients with AF compared to those without AF (21.7 ± 2.0 vs. 18.0 ± 3.5cm2, p=0.029). Left atrial volume was also higher in AF patients (69.4 ± 3.6 vs. 47.8 ± 14.9cm3, p=0.026). Right atrial area was 16.2 ± 1.1cm2in AF patients and 16.1 ± 3.3cm2in patients without AF (p=0.982). Right atrial volume was also similar between both groups (45.3 ± 21.7cm3vs. 38.2 ± 15.5cm3, p=0.44). Atrial depolarization speed was 127 ± 29.1ms in patients with AF and 141.9±37.9ms in patients without AF (p=0.42). Mortality during ICU stay was 2/5 (40%) in patients with AF and 2/22(9.1%) in patients without ICU (p=0.144).

CONCLUSION. Atrial fibrillation is a relatively common complication in septic patients. Although septic patients with AF showed unique echocardiographic features, mortality was not significantly higher as compared to thosewithout AF. Larger studies are needed to assess the clinical impact of AF in septic patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001747

INTRODUCTION. Recent advances in oncology have led to better long-term survival and therefore the benefit of admitting patients with advanced cancer to the intensive care unit (ICU) may be increasing. A leading cause of admission of cancer patients to the ICU is sepsis, so it is important to understand its outcomes.
OBJECTIVES. To describe the incidence, aetiology and outcomes of cancer patients admitted to ICUs with sepsis.
METHODS. All adult admissions to all Icelandic intensive care units (ICU) during six whole calendar years (2006, 2008, 2010, 2012, 2014 and 2016) were screened for severe sepsis or septic shock using the ACCP/SCCM criteria. Demographics and clinical course of sepsis patients with cancer were compared with data from 731 sepsis patients without cancer.
RESULTS. During the study period 240 cancer patients were admitted to the ICUs with severe sepsis or septic shock (25% of all sepsis patients). Their mean age was higher (67 vs. 64 years, $p = 0.005$) and they were more likely to be male (62% vs 55%, $p = 0.045$) compared with sepsis patients without cancer. Of the patients with cancer, 104 patients had solid tumours, 71 solid tumours with metastases, 34 leukaemia and 31 lymphoma. The most frequent source of infection in patients with solid tumours with or without metastases was abdominal, but the lungs were the most common infection site in patients with lymphoma and leukaemia. Infections were more likely to be hospital-acquired in cancer patients compared with other sepsis patients (51% vs. 18%, $p < 0.001$) and the incidence of resistant pathogens was higher (11% vs 7%, $p = 0.03$). Patients with metastases and leukaemia were less likely to receive invasive ventilation (32% and 35% respectively) than other sepsis patients (51%, $p < 0.001$) and their length of stay in the ICU was shorter (median 2 days vs 4 days, $p < 0.001$). Treatment limitations were more commonly applied in cancer patients than other sepsis patients (35% vs 20%, $p < 0.001$). Both ICU (24% vs. 13%, $p < 0.001$), hospital (45% vs. 25%, $p < 0.001$), and one-year (66% vs. 32%, $p < 0.001$) mortality was higher in cancer patients compared with other sepsis patients.
CONCLUSION. Cancer is a common co-morbidity in patients admitted to ICUs with sepsis. The length of stay in the ICU for cancer patients is short, limitations of treatment common and both short- and long-term mortality is high. This suggests that a trial of ICU admission is commonly applied with a change towards palliation for patients that do not respond to treatment. The survival rates in this study are similar as in recent studies.

POIC - Perioperative journey, from delirium to infections

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001306

INTRODUCTION. Platelet functionality test are being ingreasingly used in critically ill patients. However local reference values has been poorly investigated.
OBJECTIVES. To establish local reference range in the use of the platelet functionality aggregometry test ROTEM®-platelet, and to compare them with the reference values provided by manufacturer.
METHODS. Prospective study (ABCD study, NCT:026552897) funded by Carlos III Institute (PI15/00512). Forty consecutive healthy volunteers selected from the Blood and Tissue Bank of the hospital, after obtaining their informed consent, were included. Subjects with known coagulopathy and/or on antiagregant/anticoagulant therapy were excluded. Blood samples were taken for standard coagulation tests, ROTEM® and platelet function tests (ROTEM®-platelet and PFA®-100 Col-Epi).
The following ROTEM®-platelet tests were performed: ARATEM (activation with arachidonic acid), ADPTEM (activation of the ADP receptor) and TRAPTEM (activation with thrombin activating peptide). The parameters determined in each test were the area under the curve (AUC, ohm*min), maximum amplitude at 6 minutes (A6, ohm) and the maximum slope (MS, ohm/min). The reference ranges were expressed by 2.5-97.5% percentiles, according to the recommendations of the Clinical and Laboratory Standards Institute, NCCLS-Guidelines.
RESULTS. Forty subjects [men 19 (47.5%), age 58.5 (56.25-60)] were included. Table depicts the local tests values outside of manufacturer´s range.
CONCLUSION. The local values of the impedance aggregometry ROTEM®-platelet differ significantly from the manufacturer's reference range, underlining the need to establish local reference values. This could have important consequences related to platelet transfusion and antiplatelet drug management.

Single-dose Ketamine Has Long-lasting Effects on EEG

V. Moll[1], M. Kreuzer[2], P. Garcia[3]
[1]Department of anesthesiology, Emory University Hospital Midtown, Atlanta, United States of America; [2]Department of anesthesiology and critical care, Technische Universität München, München, Germany; [3]Department of anesthesiology, Columbia University, New York, United States of America
Correspondence: V. Moll
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001347

INTRODUCTION. As a WHO essential medication, ketamine remains clinically significant for sedation, anesthesia, and analgesia. Although ketamine has shown promise in treating psychiatric illness, and for

acute treatment of delirium 1–4 its utility for preventing postoperative delirium is controversial. It has been shown in one small RCT in cardiac surgery patients to reduce the incidents of delirium5; a larger RCT in a heterogeneous group of surgical patients failed to reproduce this effect6. Spectral features of the electroencephalogram, EEG have recently been associated with delirium7 yet, the effects of ketamine on these features remain largely unexplored.

OBJECTIVES. We present an initial characterization of the neurophysiologic effects of single-dose ketamine in patients undergoing extensive surgery with general anesthesia for treatment of head/neck cancer. This is the initial exploration of preliminary EEG results from a larger study intended to investigate postoperative delirium in these patients.

METHODS. We prospectively randomized patients into a placebo, 0.5mg/kg (low) and 1mg/kg (high) ketamine group. Patients received the study drug after induction. 5-channel EEG was recorded using a SEDLine monitor (Masimo, Irvine, CA) from frontal positions at a sample rate of 250 Hz. In order to evaluate the influence of single dose ketamine we only analyzed the EEG from 4h after the start of EEG recording at induction until 15 minutes before the end of the EEG recording at the end of the procedure.

RESULTS. Out of 29 enrolled patients, 8 were excluded due to persistent EEG signal distortion. The analysis included 3 groups: placebo-10, low-ketamine (LK)- 6 and high-ketamine (HK) 5 patients. We found a significant effect of the HK on spectral EEG features for up to 4h. Alpha and beta band total power were significantly higher in the HK group compared to the placebo group (alpha KW: p=0.014, Chi-Sq=8.53; beta KW: p=0.031, Chi-Sq=7.01, Fig1A-B) Examination of relative band power (normalized to total power) showed a significant difference for the relative alpha power (KW: p=0.0259; Chi-sq: 7.31), but not for the relative beta-band (KW: p=0.0852; Chi-sq: 4.39) (Fig1C-D). The power spectral density (PSD) and normalized power spectral density (nPSD) plots in Fig2A-B show the difference in the spectral power (PSD, A) and composition (nPSD, B) between the placebo and the HK group. AUC graph presents the AUC (o) and the 95% confidence interval (x). Black dots indicate a significant effect, defined by a 95% Ci not containing 0.5. Grey dots indicate a (non-significant) AUC<0.3, but an AUC <0.3 may indicate a clinically relevant effect8.

CONCLUSION. Our preliminary results of a prospective randomized study investigating the effects of ketamine on EEG and delirium reveal that a single dose of subanesthetic ketamine has lasting effects on the EEG (240 min). As enrollment progresses the effects of these spectral features on delirium risk will be determined.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001380

INTRODUCTION. Delirium is associated with poor outcomes and is an independent predictor of mortality in intensive care patients. Early recognition and management of delirium may improve prognosis of delirious patients.

OBJECTIVES. to describe our experience in the management of delirious patients.

METHODS. A prospective cohort observational study conducted over nine months duration from October 2017 to June 2018 including all patients admitted in a 9-bed medical ICU for more than 24 hours. Patients who were deaf or unable to speak or understand were excluded. All included patients were screened by psychiatrist for delirium using DSM-V (Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition) criteria.

RESULTS. During the study period, 137 patients were included. Patients' characteristics were : median age, 60[49-68] years ; female, 29(27.9%) ; median Charlson comorbidity index, 3[2-5] ; median SAPSII, 27[22-33.5] ; invasive mechanical ventilation (IMV), 57(41.6%), remifentanil use, 67(51.1%) ; midazolam use, 24(17.5%) and vasopressors use, 52(38%).

Using DSM-V criteria, 46(33.6%) had delirium. The most common subtype of delirium seen was hypoactive type, 27(58.6%), followed by hyperactive subtype, 15(32.6%) and few patients had mixed subtype of delirium, 4(8.87%).

Management in all delirious patients included non-pharmacologic procedures when appropriate to decrease or treat the modifiable risk factors : Assess patient for common causes of delirium (hypoxia, hypercapnia, electrolyte imbalance, nicotine withdrawal, medications or infection) ; early ambulation ; encourage family to stay with patient during day as much as possible to improve orientation ; encourage social interaction and family visits during visiting hours and try to maintain sleep-wake cycle by limiting unnecessary awakenings. All these interventions were systematic. When insufficient, pharmacologic and other procedures were performed : antipsychotic medication (haloperidol), 17 (36.9%) ; antidepressants medication, 7(15.22%) ; sedation, 9(18.8%) and physical restraint, 6(15.22%). For 6 patients, neither pharmacologic nor physical restraint were performed.

CONCLUSION. The first-line of management of delirium was non-pharmacological. Haloperidol seems to be overused as a result to some physicians'beliefs.

Efficacy of prothrombin complex concentrate (PCC) for the treatment of bleeding: A systematic review and meta-analysis

D. van den Brink[1], M. Wirtz[2], A. Serpa Neto[3], V. Viersen[4], J. Binnekade[1], NP. Juffermans[1]
[1]Department of intensive care medicine, Amsterdam UMC, locatie AMC, Amsterdam, Netherlands; [2]Deparment of trauma surgery/intensive care medicine, Amsterdam UMC, locatie AMC, Amsterdam, Netherlands; [3]Department of critical care medicine, Hospital Israelita Albert Einstein, São Paulo, Brazil; [4]Department of anesthesiology, Amsterdam UMC, locatie AMC, Amsterdam, Netherlands
Correspondence: D. van den Brink
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001383

INTRODUCTION. Bleeding often results in coagulopathy through several mechanisms, including consumption of clotting factors. Prothrombin complex concentrate (PCC) contains either three or four of the vitamin K-dependent coagulation factors and is increasingly being used to correct coagulopathy in bleeding patients. However, a summary of the efficacy of PCC to treat bleeding is lacking.
OBJECTIVES. The aim of this systematic review and meta-analysis is to evaluate the efficacy of PCC administration in bleeding patients.
METHODS. PubMed, EMBASE and CINAHL were searched for studies investigating the efficacy of PCC to treat bleeding in adult patients and providing data on either mortality, red blood cell (RBC) utilization, blood loss or thromboembolic (TE) events. Data were pooled using Mantel-Haenszel random effects meta-analysis or inverse variance random effects meta-analysis.
RESULTS. From 3944 identified studies, 14 observational studies were included (with a total of 2187 patients). Of these, 7 studies included patients undergoing cardiac surgery, 4 included trauma patients, 2 included patients undergoing liver surgery and 1 study included bleeding patients due to various causes. In all patient groups taken together, PCC administration was not associated with reduced mortality (odds ratio = 0.95; CI = 0.71 – 1.28; p = 0.75; I2 = 0%). Patients receiving PCC required significantly less RBC units (mean difference = -1.80; CI = -3.22 - -0.38; p = 0.01; I2 = 92%) compared to patients not receiving PCC. Cardiac surgery patients had significantly lower volumes of blood loss (mean difference = -384; CI = -640 - -128, p = 0.003, I2 = 81%) when receiving PCC. In all patient groups together, PCC administration was not associated with TE event rate (odds ratio = 1.13; CI 0.80 -1.60; p = 0.48, I2 = 0%).
CONCLUSION. PCC was associated with a reduction in blood loss in cardiac surgery patients and with a decreased RBC transfusion rate across a wide range of bleeding patients, without effecting mortality.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001394

INTRODUCTION. Hemorrhage is the most common cause of shock in trauma patients, and the volume replacement, including the transfusion of blood and blood products, is an important part of treatment to maintain tissue perfusion and oxygenation. We present a descriptive study that analyzes the use of blood products in these patients.
OBJECTIVES. To describe the use of blood products in trauma patients as well as their correlation with severity scores, intensive care unit (ICU) stay and mortality and incidence of multiple organ dysfunction syndrome (MODS).
METHODS. Data include all trauma patients admitted at intensive care unit from January 2018 to March 2019, who were followed until hospital discharge or death.
Descriptive statistics, quantitative variables were presented as mean values including standard deviation, or median values including interquartile range as was appropriate. Categorical variables were presented as counts and percentages. Bivariate statistics are analyzed with Student's t test for independent variables with normal distribution, U Mann-Whitney if non-normal distribution and Chi-squared test for qualitative variables association.
RESULTS. 157 trauma patients were included during the period under review. Within the study population, 11 (7%) and 9 (5.7%) patients were previously under antiaggregant and anticoagulant treatment respectively. 44% presented hemodynamic instability and 21.7% coagulopathy associated with trauma. 4 (2'5%) patients developed massive hemorrhage and 5 (3'2%) required arteriography and endovascular embolization.
48 patients (30.6%) needed transfusion of blood products: 42 patients required red blood cells concentrate transfusion during the first day [3.5 (2, 5.3)], 22 patients were administered fresh frozen plasma [950 (595, 1275)]cc and 23 patients were transfused with platelets [2 (1, 2)] pool. Twenty-five patients received prothrombin complex [1300 (700, 1650)]U, 29 patients received fibrinogen [2 (2, 3)]grams, and tranexamic acid was used in 34 patients.
The mean stay at ICU was 5'04 (2.4, 12.05) days. 13.4% of patients died during ICU stay and 16.2% of patients during hospital stay. 21 patients developed MODS; 20 of them during the first three days (12.7%). In our sample, there is statistically significant association between transfused patients and severity according injury indicators (ISS and NISS) and APACHE II. In addition, the incidence of MODS, mortality in the ICU and hospital mortality were also higher in transfused patients. On the other hand, no statistically significant differences were found in gender, age, previous coagulopathy, incidence of nosocomial infection, ICU stay or hospital stay.
CONCLUSION. According to our experience, there is a statistically significant association between the need of transfusions and severity according to the injury indicators; as well as an increase in mortality and the development of MODS in the transfused patients.

Thyroid function in adults patients undergoing cardiac surgery: a pilot study

D. Berbel-Franco[1], G. Muñoz-Del Rio[1], JC. Lopez-Delgado[1], P. Alia-Ramos[2], A. Padro-Miquel[2], M. Dastis-Arias[2], PA. Revelo-Esquibel[1], RE. Avila-Espinoza[1], P. Berbel-Navarro[3], R. Mañez-Mendiluce[1], M. Potocnik[4]
[1]Intensive care, Hospital Universitari de Bellvitge, Barcelona, Spain; [2]Laboratory dpt., Hospital Universitari de Bellvitge, Barcelona, Spain; [3]Medicine school, Universidad Miguel Hernández, Alicante, Spain; [4]Cardiac surgery dpt., Hospital Universitari de Bellvitge, Barcelona, Spain
Correspondence: J.C. Lopez-Delgado
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001427

INTRODUCTION. There is an interaction between thyroid hormones, the immune and inflammatory response and illness severity, leading to lower levels in the setting of critical illness. Cardiac surgery represents an important surgical injury associated with non-thyroidal Illness syndrome (NTIS). However, little is know about NTIS in this scenario.
OBJECTIVES. Evaluate thyroid function in adult patients undergoing cardiac surgery. We also correlated thyroid function with parameters related with inflammatory response.
METHODS. Demographical and surgical characteristics, laboratory results and outcomes were registered. Blood samples were collected before surgery, during first 24h ICU admission,and at day 3 and 5. A serum thyroid profile, including thyroid-stimulating hormone(TSH), free(fT4) and total(tT4) thyroxine, free(fT3) and tota(tT3) triiodothyronine and reverse triiodothyronine (rT3), was analyzed. Drugs potentially having an effect on thyroid function were collected. An statistical analysis was performed to evaluate thyroid function over time.
RESULTS. 10 patients aged 66.7±4.5years were included, mean BMI:29.9±5.6Kg·m-2 and APACHE II:15.8±4 were included. 6 patients underwent valve procedures(VP) and 4 coronary artery bypass graft(-CABG), with a mean CBP time 102±23min. 1 patient died during ICU stay and 3 required vasopressor and inotrope support for over 24h. Statistically significant changes (P<0.001) were observed during the

first 24h of ICU admission on TSH, fT3, tT3 and rT3 levels. TSH levels dropped in the first 24h, returning to baseline afterwards, whereas fT3 and tT3 levels remained low. tT4 levels were normal, resulting on a tT4/tT3 drop of 39.4±10.0% in the first 24h. On the other hand, rT3 levels increased 46.6±15.5% above baseline levels and remained high during the observation period. No statistical correlations with inflammation or tissue hypoperfusion markers (leukocytes, lymphocytes, lactate and C-reactive protein were observed.

CONCLUSION. Our pilot study showed that NTIS may develop soon after cardiac surgery with a lasting effect over T3 levels. The effect of this phenophenon and their influence over outcomes should be evaluated when increasing our sample of patients.

INTRODUCTION. Cardiac surgery is one of the most frequently performed surgical procedures in the world. Regardless of the procedure performed, the final results depend to a great extent on an optimal postoperative care.

OBJECTIVES. Describe the immediate postoperative complications in cardiac surgery patients during their ICU stay.

METHODS. Prospective and observationaly, all patients undergoing cardiac surgery in the year 2018 in Fundación Jiménez Díaz and Rey Juan Carlos Hospitals in Madrid were recruited.

Demographic variables (age, sex), baseline data (heart rate, EuroSCORE II, NYHA), surgery data (type of intervention, CPB and ischemia times) and immediate postoperative data (heart rithm, time of mechanical ventilation, time of ICU stay and re-intervention) were collected.

RESULTS. 293 patients were recruited (61.4% males) with a mean age of 65.6 ± 11 years and EuroSCORE II mean of 5.07 ± 9.39.

The type of intervention was: valve replacement 47.3%, coronary revascularization surgery (CRC) 31.4%, CRC + valvuloplasty 3.4% and other 7.8%. 8.2% of the interventions were emergent or urgent, 26.1% preferred and 65.7% scheduled.

The most frequent complications were cardiac conduction disorders (18.6%): 3º atrio-ventricular block, 2.4% and *de novo* atrial fibrillation 15.5%; with a need for a permanent pacemaker (MP) in 2% of the total. Only 1% (3 patients) presented postoperative acute coronary syndrome.

There was an acute renal failure rate of 8.5% with need for renal replacement therapy of 48% (4.1% of the total) and none required chronic dialysis.

We only found 6.5% of neurological complications: 73.7% diffuse (42.3% encephalopathy, 15.8% seizures, 15.8% delirium) and 26.3% focal. In 10.4% of them there was permanent neurological deficit (0.7% of the total).

6.1% of the total patients required prolonged MV (>96 hours) of which 38.9% ended in tracheostomy (2.4% of the total).

There were infectious complications in 4.1% of the patients (50% pneumonia, 16.7% urinary, 16.7% surgical wound, 8.3% mediastinitis and 8.3% catheter bacteremia).

3.4% of the patients presented pleural effusion requiring drainage, 0.7% pneumothorax, and 0.3% hemopneumothorax.

The average stay in the ICU was 86 hours, the overall mortality was 3.6% and the reoperation rate was 3.4%.

CONCLUSION. The results of cardiac surgery postoperatory in our sample are excellent with a mortality rate below what was expected (according to EuroSCORE II). The complications are diverse and expected, but most are resolved in the immediate postoperative period without sequelae.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001450

INTRODUCTION. ECMO post-cardiac surgery is a rescue therapy in the low cardiac output and in the postcardiotomy refractory shock. Nowadays, it exists controversy about what is the best approach for nutritional support in these patients.

OBJECTIVES. The objective of our study was to evaluate how we perform enteral nutrition (EN) in this group of patients.

METHODS. Prospective observational study from November 2016 to March 2018. Preoperative, intraoperative variables, prognosis scores, postoperative complications and in-hospital and long-term mortality were collected, as well as the NE administered during the first week of admission to the ICU.

RESULTS. 16 patients were included with a mean age 61.1±10.3 years; 62.5%(10) were male; BMI:27.6 ± 4.1Kg•m-2; APACHE II: 18±8; SOFA: 9.3±3.4. 56.25%(9) were coronary revascularization and 31.25%(5) were valvular surgeries. Hospital mortality was 37.5% (6) and 1-year mortality was 43% (7). The ECMO was initiated during the first 72h after admission to the ICU post-surgery with a duration of 6±3.2 days. The complications were: bleeding 37.5%(6), re-exploration 31.25%(5) and sepsis 50%(8). None thrombosis was observed. The EN was started in 12 patients, starting early (<24h) in 50%. They received an average of 11.75±5.1 Kcal/Kg/d and 0.62±0.26 g/Kg/d. In 50% of patients EN was interrupted >24h during ICU stay due to complications from their cardiovascular status. In those patients were EN was interrupted a lower caloric (15.48±3.6 vs. 8.02±3.2 Kcal/Kg/d; *P=0.004*) and protein (0.81±0.16 vs. 0.43±0.18 g/Kg/d; *P=0.004*) nutritional intake was shown. Lactate on the 3rd day in patients in whom the EN was interrupted was higher (1.8±0.4 vs. 1.9± 0.9 mmol/L, *P=0.012*).

CONCLUSION. Patients with post-cardiotomy ECMO receive inadequate nutritional support in our study. Strategies to improve nutritional support, such as supplementary parenteral nutrition among others, may be evaluated in future studies.

INTRODUCTION. Nutritional status influences outcomes in critically ill and new guidelines do not recommend surgery in patients with malnutrition.
OBJECTIVES. To evaluate the influence of nutritional risk on the results and prognosis of patients undergoing cardiac surgery.
METHODS. Prospective observational study from 2011 to 2015. Postoperative nutritional risk was evaluated through the Nutrition Risk in the Critically Ill (NUTRIC) Score. Likewise, preoperative, intraoperative variables, prognostic scores, postoperative complications and in-hospital and long-term mortality were collected.
RESULTS. 2809 patients were included: mean age of 64.6±11.5 years, 63.9% (n=1796) were men, BMI: 27.9±4.2Kg·m-2, APACHE II:12.9± 5.3.The 51.7% were valvular surgeries, 32.3% were coronary, 6.8% were mixed and 9.2% were another type of cardiac surgery. In-hospital mortality was 5.8% (163). According to the NUTRIC Score, 72.3% (2032) of the patients had a low nutritional risk, while 27.7% (777) had a high nutritional risk. The univariate analysis between subgroups identified greater postoperative complications and mortality in the subgroup with greater nutritional risk. The multivariate analysis showed that a high nutritional risk was associated with an older age (OR: 1.107; 95% CI:1.080-1.134;P <0.001), to a higher creatinine before surgery (OR:1.009; 95% CI:1006-1.013; P <0.001), in the presence of atrial fibrillation pre-surgery (OR: 1.614; 95% CI: 1.085-2.399; P = 0.018) and smoking (OR: 1.777; 95% CI: 1.076-2.934; P=0.025), while higher preoperative cholesterol (OR: 0.827, 95% CI: 0.692- 0.987; P < 0.001) and lymphocytes (OR: 0.694; 95% CI: 0.522- 0.924; P <0.001) were both associated with a lower risk. The same analysis revealed that a higher nutritional risk was associated with a greater need for transfusions (OR: 1.092, 95% CI: 1006-1.185, P = 0.036), a higher incidence of low postoperative cardiac output (OR: 3,351; 95 % CI: 2.030-5.531; P<0.001) as well as a longer time in vasoactive drugs (OR: 1002, 95% CI: 1001-1,004, P = 0.008) and worse renal function (OR: 1006, 95% CI : 1.003-1.010; P = 0.008). Long-term mortality was evaluated in 2715 patients: those with higher nutritional risk had worse survival (87.8% vs.70%; P(LogRank) <0.001) and a higher risk in the Long-term mortality (HR: 4.369; 95% CI: 3.075-6.206; P <0.001).
CONCLUSION. A higher nutritional risk evaluated according to the NUTRIC Score was associated with greater postoperative complications after cardiac surgery, as well as a worse long-term survival in our population.

INTRODUCTION. The development of postoperative infectious complications is a major determinant of outcome in pancreaticoduodenectomy (PD) patients.
Patients with preoperative biliary drainage (PBD) are at high risk for positive intraoperative bile cultures, infectious complications and antibiotic resistances.
A short postoperative course of antimicrobial therapy in patients at high risk for biliary contamination has been shown to reduce infectious complications after PD.
PD patients at our institution are admitted in ICU for post-surgical care and monitoring. PBD stents are systematically retrieved during surgery for microbiological culture. Those with PBD are considered high risk patients and undergo a 5-day protocol course of post-surgery empirical antibiotic therapy with piperacillin-tazobactam.
OBJECTIVES. To compare clinical and microbiological results between PBD vs non-PBD PD patients and to analyze antibiotic resistance patterns.
METHODS. Retrospective cohort study of consecutive PD patients admitted at our ICU for post-operative monitoring and care between January 2015 and April 2018.
Median and interquartile (IQR) values are presented and Mann-Whitney and Chi-square tests were used to compare group results.
RESULTS. A total of 313 PD patients were analyzed.
Patient characteristics: median age was 68 years (59-74) and 58,8 % were male. Median Body Mass Index was 24,9 (22,3-27,6), Charlson Comorbidity score was 5 (4-6) and ICU admission-day SOFA was 2 (1-5). Histologic results confirmed malignancy in 81% of patients.
Overall outcomes: median Clavien-Dindo score was 0 (0-2) and 30-day mortality rate was 5,4%.
PBD stent was present in 44,4% (n=139) patients.
When comparing PBD vs. non-PBD groups no differences were found between age (p=0,23), Body Mass Index (p=0,39), Charlson Comorbidiity score (p=0,32), admission-day SOFA score (p=0,20) nor Clavien-Dindo score (p=0,33) or 30-day mortality (p=0,82).
A total of 134 PBD stent cultures revealed 122 microorganisms isolated from 66 (47,4%) patients and 68 (48,9%) had polimicrobian cultures. E. faecalis (22%), E. coli (16%) E. cloacae (13%) and K pneumoniae (12%) were the most frequent bacteria and 7% were ESBL. Antibiotic testing (n=115) reported resistance rates of 21% to piperacillin-tazobactam and 19% to ampicillin plus cefotaxime combination.
CONCLUSION. The presence of PBD in PD high risk patients was not associated with worse outcomes.
E. faecalis was the most frequent bacteria isolated from PBD cultures. Overall antibiotic resistance rates from PDB stent cultures were similar between piperacillin-tazobactam and the combination of ampicillin plus cefotaxime.

Ampicillin plus cefotaxime may be an alternative choice for post-operative empirical antibiotherapy in PD high risk patients with PBD.

INTRODUCTION.
Introduction: Progress in near-infrared spectroscopy (NIRS) technology seem to have improved its accuracy for continuous, non-invasive monitoring of regional tissue oxygenation and may provide clinicians with an additional information to achieve patient safety.
OBJECTIVES. Veno-arterial (VA) extracorporeal membrane oxygenation (ECMO) may result arterial blood mixing and delivery of hypoxic blood to the brain. Additionally, VA-ECMO by femoral artery cannulation may compromise perfusion to the lower limbs. Oxygen saturation measured by near-infrared spectroscopy (NIRS) can be used to monitor brain and lower limb oxygenation in the patients treated by VA-ECMO.
METHODS. We retrospectively analyzed prospectively collected data of the patients, who treated by veno-arterial ECMO, using femoral vessels approach, between 01.2015 and 12.2018 in large tertiary center. All patients were continuously monitored using the (INVOS™ 5100C Cerebral/Somatic Oximeter) tissue oximeter. Sensors were placed on the patients' foreheads and on the lower limbs. NIRS tracings were recorded, analyzed, and correlated with clinical events.
RESULTS. Ninety-five patients (age 22-78) were monitored with NIRS, and 83 patients (87.4%) has distal lower limb perfusion. Eight patients (8.4%), 2 with distal limb perfusion and 6 without, had unilateral persistent decreasing lower limb oximetry (StO2) below 40% and clinical presentation of lower-limb ischemia: cold limb, mottled skin and pulseless Doppler ultrasound. In 7 patients were performed surgical placement a distal perfusion cannula and in one patients surgical placement and trombectomy from lower limb. Eleven patients (11.6%) had a significant, below 40% and longer than 30 minutes drop in cerebral oximetry (StO2). In 9 patients (9.5%) interventions, which involved increasing pressure, oxygenation, and/or ECMO flow corrected the underlying ischemia. Two patients (2.2%) required further diagnostic intervention and were found to have a cerebrovascular accident (CVA).
CONCLUSION. Use of near-infrared spectroscopy (NIRS) in the patients treated by ECMO is important in detecting, prevention and treatment ischemic cerebral and peripheral vascular events.

Infection in Toxic Epidermal Necrolysis: A 13-year trial from a Burn Unit

JF. Martins[1], I. Coutinho[2], R. Meireles[3], C. Silva[1], E. Sousa[1], L. Cabral[3], P. Martins[1]
[1]Intensive care unit, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal; [2]Immunoallergology department, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal; [3]Burn unit, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001511

INTRODUCTION. Toxic Epidermal Necrolysis (TEN) is a rare drug-related life-threatening acute dermatological condition. The devitalization of epidermis and immunosuppression predispose patients to secondary infection that are the major cause of morbidity and mortality. The mortality rate is higher mainly in those requiring intensive care admission (REF).
OBJECTIVES. Characterization of the rates and types of infection-microbials in TEN patients, aged >18 years, admitted to a Burn Unit (BU) of a tertiary hospital, between 2005 and 2017.
METHODS. Retrospective, descriptive and inferential study, evaluating: age; gender; onset of symptoms to admission on BU; suspected etiologies of TEN; percentage of epidermal detachment (% of Total Body Surface Area, TBSA); severity of TEN assessed by the SCORTEN score, microbial infections identified by culture; nosocomial pneumonia (NP); Systemic therapy (corticosteroids, Plasmapheresis, intravenous immunoglobulin (IVIG)]; invasive procedures - mechanical ventilation (MV) or hemodialysis (HD) and BU length of stay. The primary outcome was in-hospital mortality.
RESULTS. A total of 29 patients were included, 58.6% (n=17) female, with median age of 65.7 years (min: 22.0; max: 91.0). The median SCORTEN score and TBSA were 3.0 and 57.3%, respectively. Alopurinol was the most frequent agent identified (24.1%, n=7) followed by Amoxicilin-Clavulanate, Carbamazepine and Hydantoins with 6.9% (n=2), each one. Etiological agent was not identified in 31.0% of patients. The mucous membranes were involved in 89.7% (n=26) of patients, with the oral mucosa being the most frequent (69.0%, n=20). The incidence of NP was 44.8% (n=13) and the most common agent identified was Methicillin-sensitive *Staphylococcus aureus (MSSA)* with 10.3% (n=3). MSSA was also the most commonly isolated agent in surgical wound infections (17.2%; n=5). Bacteriemia occurred in 58.9% of the patients. 51.7% of patients were under MV (n=15), 65.5% (n=19) of patients were submitted to plasmapheresis, 44.8% (n=13) to IGIV and 10.3% (n=3) to HD. The median BU length of stay was 10.0 days (min: 2, max: 42) and in-hospital mortality was 48.3% (n= 14). There was a statistically significant relationship between age and in-hospital mortality (p=0.02), with a worst prognosis in older patients. The study demonstrated a high variability in the number of infections, and there was no association with regard to mortality (p= 0.275). MV was associated to a higher mortality rate (66.6%, n=10) on this population (p=0.02).
CONCLUSION. Compared with other reported studies of secondary infection in TEN patients, our study had a lower rate of bacteremia. This finding suggests a response regarding the infection control measures applied in the study population. Despite that, the numbers of multi resistant microorganisms in this series corroborates the need for an early diagnosis and timely referral of these patients to specialized units.

The use of HPI (Hypotension probability indicator) during major intracranial surgery; preliminary results of a prospective randomized trial

J. Pouska, V. Cerveny, J. Zatloukal, J. Kletecka, J. Beneš
Department of anaesthesiology, resuscitation and intensive care, University Hospital in Pilsen, Plzeň, Czechia, Czech Republic
Correspondence: J. Pouska
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001525

INTRODUCTION. Based on our current knowledge, intraoperative hypotension is common and may have detrimental effect to patients outcome. HPI (Hypotension probability indicator) is new concept of artificial intelligence application in clinical medicine. It is based on machine learning technique analysis of invasive arterial pressure curve. Development of future hypotensive event (within 5 minutes time) should be predicted with reasonable sensitivity and specificity according to the manufacturer data. To which extent HPI may improve patient care has not been established yet.
OBJECTIVES. Major objective of this study was to assess the use of HPI to avoid hypotension in major intracranial surgery.
METHODS. Randomized prospective study performed in a University hospital approved by its local ethics committee. Patients undergoing major supratentorial tumour resection with ASA physical status 1-3 were enrolled and randomly (1:1 randomization) assigned to interventional (group A) or control group (group B). Anaesthesia was maintained by propofol and remifentanil. Haemodynamic monitor EV 1000 (Edwards Lifesciences Inc., Irvine, CA, USA) was used for goal directed haemodynamic therapy in both groups with predetermined mean arterial pressure (MAP) target of more than 65mmHg; fluids, vasopressors and inotropes were used based on predefined protocol. In the interventional group, HPI value of more than 85% was considered significant for prediction hypotensive event and used to prompt the appropriate treatment. The HPI value was covered for the treating anaesthesiologist in the control group.
The haemodynamic data were collected in 20-seconds intervals; hypotension and severe hypotension were defined as mean arterial pressure below 65 mmHg and 55mmHg. The cardiac index below 2,0l/min/m2 was deemed as hypoperfusion. Number of events and their duration were used as primary indicators. Because the first 30 minutes after induction are extremely turbulent, a separate maintenance phase of anaesthesia was evaluated too.
RESULTS. We enrolled 40 patients in our study, 20 in each group. Analysis of the whole anaesthesia time showed only slight trend towards lower hypotension and severe hypotension related burden without any statistical significance (Table 1). During the maintenance phase the number of patients free of hypotension (10 pts.in Group A vs. 4 pts.in Group B, p=0,047) was significantly lower.
CONCLUSION. Based on our data it seems that the inclusion of HPI into a goal directed treatment strategy could lower the incidence of hypotension within maintenance phase of anaesthesia.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001532

INTRODUCTION. Analgesia and sedation are highly discussed components of critically ill patient treatment, aimed at minimizing patient discomfort and modulating the stress response for the least period of time. ICU admission for post-operative patients can be scheduled preoperatively or a consequence of intra-operative complications. Post-operative sedation is maintained until haemodynamic stability, adequate respiratory exchanges and necessary instrumental investigations.
OBJECTIVES. The aim of this study was the evaluation of the sedative effect of inhaled sevoflurane and intravenous hypnotic agents (propofol and midazolam) in postoperative ICU sedation after major maxillofacial surgery. We related their use to hemodynamic stability, times of awakening and ICU discharge, onset of adverse events
METHODS. Retrospective matched-controlled analysis of prospective, non-randomized data comparing sevoflurane-SEVO group-MIRUS system (courtesy of PALL Medical) and intravenous propofol and midazolam-TIVA group. Inclusion criteria: Postoperative patients of maxillofacial oncologic surgery with vascularized flap, Age> 18 years, Sedation required for> 6 hours. Exclusion criteria: Pregnant Patients, Controindication to the use of halogenates, Neurological and/or psychiatric disorders in chronic pharmacological therapy. Recorded parameters: BIS value, Hemodynamic data, Respiratory parameters, Sedative/analgesic infusions, Inotropic/VP infusion, Hourly administration of fluids, lab and blood gas analysis. We defined: Time of awakening (minutes from the suspension of spontaneous breathing-extubation or breath by tracheostomy), Time of ICU discharge, Onset of adverse events.
RESULTS. 40 consecutive patients were evaluated for the study(20 SEVO and 20 TIVA), 4 were excluded from the analysis for postoperative surgical complications(1 group SEVO and 3 group TIVA). The study population was homogeneous and comparable. All patients were in a medium-high age group (67 ± 12 SD and 64 ± 10 SD years) and were in normal weight. Surgery duration was similar (10h 07 '± 1h 17' DS SEVO and 11h 10 '± 2h 20' DS TIVA). No substantial differences in intraoperative management occurred, as all patients were managed according to our Institution procedural protocol. Postoperative management revealed no statistically significant differences for hemodynamic stability, duration of sedation (12.9 ± 1.6 SEVO and 14.4 ± 2.2 TIVA) and administered post-operative fluids. The times of awakening to the suspension of sedation were significantly lower in SEVO patients (27 '± 16' SD) compared to TIVA ones (105 '± 56'DS) with a statistically significant difference ($p < 0.05$). There was no significant difference in the time of ICU discharge and in the total time from the suspension of sedation to discharge. There were no significant differences for complications during sedation and on awakening.
CONCLUSION. Sevofluorane can be effective in guaranteeing the sedation depth required for post-operative complex maxillofacial surgery patients, allowing faster recovery and extubation times than intravenous sedation, maintaining adequate hemodynamic stability without relevant adverse events.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001541

INTRODUCTION. Recent studies suggests the use of restrictive fluid regimen in major abdominal surgeries to aviod postoperative complications such as acute kidney injury (AKI) or prolonged length of hospital stay (LOS Hospital) (1). Its known that intraoperative fluid management impacts outcome in living donor related liver transplant (LDLT) patients (2).
OBJECTIVES. The aim of this study is to evaluate the effects of restrictive versus liberal fluid regimens on outcome in LDLT recipients.
METHODS. We retrospectively evaluated the adult patients who underwent LDLT surgery between january 2015 and january 2017. Restricted group has consisted of patients who received <8ml/kg/h fluid, while liberal group has consisted of patients who received ≥8ml/kg/h fluid. Demographic data, surgery time, clamping time, diuresis, noradrenalin requirement, total administered fluid, operation fluid balance, central venous pressure (CVP), blood loss, erithrocyte suspension (ES) requirement, pre and postoperative lactate levels, pre and postoperative serum creatinin levels, delta creatinin, length of intensive care unit stay (LOS ICU), LOS-hospital, renal replacement therapy (RRT) requirement, readmission to ICU, reoperation, ICU and first year mortality rates were recorded.
RESULTS. The baseline demographic and clinic characteristics were similar in both groups. The operation fluid balance, postoperative CVP, intraoperative diüresis, intraoperative blood loss, ES requirement, noradrenalin requirement, postoperative serum lactate level and LOS-hospital were signifcantly higher in liberal group ($P<0.05$ for all). Postoperative 1st day serum creatinin was higher in restricted group ($P<0.05$), whereas need for RRT, increase in postoperative 7th day serum creatinin levels, ICU and first year mortality rates were similar between two groups.
CONCLUSION. Intraoperative restricted fluid regimen seems to decrease the LOS-hospital and ES requirement without negative effect on outcome compared to liberal fluid regimen in LDLT recipients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001546

INTRODUCTION. Patients with systemic autoimmune diseases pose a particular challenge for clinicians involved in critical care due to involvement of multiple organs and severe side effects of immunosuppressive drugs. Diffuse alveolar haemorrhage (DAH) is one of the most serious and life-threatening manifestations, typically present in patients with autoimmune diseases. Available data concerning clinical profile of patients with DAH treated in intensive care units remains scarce.
OBJECTIVES. We aimed to describe patients with systemic autoimmune disease who developed DAH and were treated in the intensive care unit in terms of baseline demographic and clinical features as well as mortality.
METHODS. In this retrospective cohort study performed in the Intensive Care Unit of University Hospital in Krakow (Poland) we included 21 patients treated for the first time in the ICU due to autoimmune diseases with diagnosis of DAH. For each patient APACHE II, APACHE III, SAPS II and SOFA scores were calculated on the admission. Mortality was assessed during ICU stay and during 5-year follow-up based on telephone calls and available data from national health provider registry.
RESULTS. Median age of the patients accounted to 53 (18-78) years. Majority (15/21; 71.4%) of patients were females. The most common diagnoses were granulomatosis with polyangiitis (38.1%), systemic lupus erythematosus (23.8%) and microscopic polyangiitis (14.3%). Most of the patients required mechanical ventilation (85.7%), renal replacement therapy (57.1%) and blood products transfusions (71.4%). Mortality in the ICU was 52.4%, while in both 1-year and 5-year follow-up it accounted to 76.2%.
CONCLUSION. Our study shows that among patients with systemic autoimmune diseases, DAH is diagnosed most typically in patients with primary systemic vasculitides such as granulomatosis with polyangiitis and microscopic polyangiitis. These patients often require advanced therapeutic measures and are characterized by high short- and long-term mortality.

Comparison of preoperative levels of coagulation & fibrinolysis markers between patients undergoing vascular surgeries due to peripheral artery disease and abdominal aortic aneurysm

K. Polok, J. Górka, J. Fronczek,, W. Szczeklik
Intensive care and perioperative medicine, Jagiellonian University Medical College, Kraków, Poland
Correspondence: K. Polok
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001555

INTRODUCTION. Myocardial injury after noncardiac surgery (MINS) is common and significantly affects patients` outcomes. Its etiology is uncertain, however available studies suggest association between activity of hemostatic and fibrinolytic systems and incidence of MINS.
OBJECTIVES. We aimed to compare patients undergoing vascular surgeries due to peripheral artery disease (PAD) and abdominal aortic aneurysm (AAA) in terms of preoperative levels of coagulation and fibrinolysis markers.
METHODS. Patients at the age of 45 years or older, who received general or regional anesthesia for vascular surgery and stayed overnight in the hospital. We gathered demographic and clinical data on the patients. Coagulation (fibrinogen, factor VIII [FVIII], von Willebrand Factor:CoR [vWF:CoR], antithrombin III [ATIII]), fibrinolysis (D-dimer, plasmin-antiplasmin complexes [PAP], tissue plasminogen activator [tPA]) and inflammation (soluble CD40 ligand [sCD40L]) markers` levels were measured before surgery.
RESULTS. The study group consisted of 131 patients at the mean age of 68.3 years. History of smoking and diabetes were more common in the PAD group. Platelet count (209.5 vs. 250.5, $p=0.001$) as well as level of fibrinogen (4.1 vs. 5.4, $p<0.001$), FVIII (141.9 vs. 176.9, $p<0.001$), vWF:CoR (152.3 vs. 188.9, $p=0.009$) and sCD40L (7936.6 vs. 9016.0, $p=0.005$) were higher in the PAD group. The d-dimer level was higher (2590.5 vs. 808.0, $p<0.001$) in the AAA group. We did not observe statistically significant differences in ATIII, tPA and PAP levels
CONCLUSION. Our results suggest more pronounced activation of coagulation in patients undergoing surgeries for PAD compared to those with AAA. Together with relative hypofibrinolysis, it may put this group of patients at higher risk for cardiovascular complications. However, differences in baseline clinical characteristics may partially explain these differences. Further studies, performed on larger study groups, utilizing dynamic assessment of coagulation and fibrinolysis, are warranted.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001684

INTRODUCTION. Because of high rates of prevalence and related mortality, Klebsiella species and their resistance need to be addressed in many rural hospitals of Egypt. Antimicrobial stewardship program (ASP) based on clinical pharmacy services is required to optimize antibiotics use especially broad spectrum ones.
OBJECTIVES. to measure the impact of ASP on rational antibiotics use and bacterial resistance
METHODS. Carbapenems consumption in intensive care units (ICUs) was recorded by defined daily dose (DDD) per 1000 patients prospectively from April 2017 to January 2019. Klebsiella species isolates and their antimicrobial susceptibility were recorded from October 2017 to November 2018. The ASP started on the first of March 2018 and the effects of the program on the following were measured and compared with the data collected before: (1) carbapenems-resistant Klebsiella prevalence, (2) carbapenems consumption in ICUs, and (3) probability of Klebsiella to be in a lower or a higher category of resistance based on classification of Klebsiella resistance into three categories; carbapenems resistant, carbapenems only sensitive and cephalosporins sensitive . The effect of the program was measured in ICUs of El-Araby hospital.
RESULTS. SPSS 25 software was used. Carbapenems consumption after starting the ASP was significantly lower than that consumed before (0.98 vs. 1.51 DDD per 1000 patients respectively, P-value=0.02). The prevalence of carbapenems-resistant Klebsiella was significantly lower than the prevalence before the program (48.6% vs. 85.25% respectively, P-value=.000) with odds ratio (OR) =0.164 (.075-.357). The probability of being in a higher category of Klebsiella resistance was significantly decreased after implementation of the program with OR = 6.3 (2.88 – 13.73). The probability of being in a higher category of Klebsiella resistance was also decreased with the decrease in carbapenems consumption with OR = 3.17 (1.367 – 7.345).
CONCLUSION. The antimicrobial stewardship program aiming to reduce unnecessary carbapenems use is extremely important to reduce prevalence of highly resistant strains of Klebsiella in similar hospitals.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000790

INTRODUCTION. Central line (central venous catheter) associated bloodstream infections (CLA-BSI) which are one of the healthcare-associated infections pose a great threat to patient safety. Patients followed in intensive care units (ICU) can be colonized with resistant microorganisms during their ICU stay and as a result, they have an increased risk of hospital acquired infections including CLA-BSI. In this reason, ICU needs to be monitored for nosocomial infections.
OBJECTIVES. The aim of this study was to evaluate the CLA-BSI rate, invasive device use rate and causative microorganisms isolated in these infections, between 2014 and 2018.
METHODS. This study was conducted in an Anesthesiology and Reanimation Intensive Care Unit. Five year's surveillance data was evaluated in this study. CLA-BSI rate per 1000 central venous catheter-days and device utilization ratios are retrospectively evaluated (CLA-BSI rate = CLA-BSI number / central venous catheter-days x 1000). Microbiological culture results of invasive device associated infections were also evaluated. Hospital acquired infection definitions are made according to the US Centers for Disease Control and Prevention (*CDC*) criteria.
RESULTS. A total of 2944 patients were enrolled. Central venous catheter usage ratio was 74.8% in the ICU for 28.721 catheter days. The mean rate of central venous catheter associated bloodstream infection was 6.38. Between 2014 and 2018, the number of central venous catheter-associated bloodstream infections was 21, 17, 48, 48, and 57, respectively. When compared with 2014, the CLA-BSI rate was slightly increased in 2018 (6.1 and 7.8 respectively). Candida spp. (25.6%) was the most frequently detected agent between the years of 2014-2016, while it was Klebsiella spp. (21.5%) in 2017-2018.Generally, Klebsiella spp. (20.1%), Candida spp. (19.6%) and Enterococcus spp. (16.6%) were mostly detected in the five-year evaluation.
CONCLUSION. Use of central venous catheter, increases the incidence of invasive device associated infection rate in ICU. The high mortality rates in patients with invasive device could be related to high infection rates and inappropriate antibiotic use. Incidence of infections can be reduced by education of health care givers and use of barrier preventive methods.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000808

INTRODUCTION. Insertion and management of peripheral intravenous catheters (PIVCs) is a daily routine for nurses. However, PIVCs can pose serious threats to patient safety and can cause catheter associated blood stream infections if not cared for properly (1). Thus, hospitals have guidelines for PIVC care, but do the nurses follow them?
METHODS. We aimed to measure if the nurses followed procedure for good PIVC care.
RESULTS. At baseline all PIVCs had at least one deviation from procedure, whilst at first follow-up 8 PIVCs an 6 at second follow-up were perfect. At baseline the average PIVC had median 4 deviations from procedure (95%CI 3.7-5.1%) whilst the average PIVC score fell to 2 deviations (95% CI 1.1-2.2) on first and 1 deviation after second measurement after intervention, p<0.001. At second measurement 1 PVK had a score of 7, and this patient and the PVK had just arrived from another hospital.
CONCLUSION. Nurses do not automatically follow PIVC guidelines. Improvement processes to improve PIVC care are needed. A 30 minutes training session gave good effect, which points to a high motivation for good PIVC care among the nurses. Since we developed the PIVC quality instrument and only one nurse had the measurement responsibility, the instrument needs testing in different settings, and the interrater reliability needs to be established, as LH Høvik et al recently have done (2).

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001492

INTRODUCTION. Risk factors related to CSF infection in patients with CSF drains include drain days, drain insertion conditions, opening and manipulation, diabetes mellitus and CSF leak (1). In most of these studies and with one exception known to us (2) the role of pre-existing extracranial infection has not been addressed.
OBJECTIVES. To identify risk factors related to the emergence of cerebrospinal fluid drain (CSFD) infections and to describe the microorganisms cultured in the CSF compared to those cultured in other specimens.
METHODS. We designed a retrospective single center cohort study. We reviewed the electronic hospital records of all ICU admissions to identify the eligible neurosurgical cases admitted between January 1st 2011 and December 31st 2018. Eligibility criteria for the study participants were: presence of a CSF drain during ICU stay, time lapsed from drain insertion to ICU admission < 24 hours, no previous diagnosis of CSF or any other infection either hospital or community acquired, and length of ICU stay > 24 hours. Patients' demographic and clinical characteristics were recorded, as was microbiology laboratory data. We used non-parametric statistical methods to identify possible risk factors for CSFD infection.
RESULTS. We identified 799 neurosurgical admissions of which 70 fulfilled the inclusion criteria. The figure shows the relative frequencies of different pathogens in the form of comparative pie charts [A: CSF (inner disc) vs blood (annulus); B: CSF vs bronchial; C: CSF vs anywhere else, including bronchial, blood, urine, and wound swab samples]. Acinetobacter baumannii was the most frequent single pathogen isolated in the CSF. The relative frequencies of pathogens in the CSF did not differ significantly from those of pathogens in other specimens (p = 0.3699). The presence of previous bacteraemia was the only statistically significant risk factor for CSFD infection in our population OR = 3.274, CI: (1.082-10.71), p = 0.0274
CONCLUSION. Our data suggests that, in an ICU population, the distribution of pathogens causing CSFD infections is similar to the overall distribution of pathogens cultured in other specimens. The most frequently isolated pathogens were Gram negative Enterobacteriaceae. Among them, the most frequent one was A. Baumannii. In our population, previous bakcteraemia was the only risk factor for CSFD infection. This finding warrants further investigation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000554

INTRODUCTION. The incidence of *Pneumocystis* pneumonia (PCP) in non-HIV individuals is increasing. These patients typically present with severe disease and may require admission to the Intensive Care Unit (ICU). Modern diagnostic techniques are not widely available and prompt administration of appropriate treatment is essential.
OBJECTIVES. To examine the underlying diseases in non-HIV patients with PCP and the diagnostic yield of direct immunofluorescence (DFA).
METHODS. From June 2016 to March 2019 all cases with confirmed PCP pneumonia admitted to ICU of Saint Savvas Hospital were identified. Inclusion criteria were: diffuse pneumonia requiring intubation, absence of HIV antibodies and detection of PCP morphological structures with DFA. Bronchial samples were obtained via aspiration and examined with DFA by the same experienced microbiologist. Patients' demographic data, their underlying diseases-risk factors for PCP, their inflammatory markers as well as co-infection with bacterial strains were recorded. The number of bronchial samples required to make the diagnosis and their short-term prognosis- ICU discharge or death were also recorded. All patients received trimethoprim-sulfamethoxazole (TMP/SMX) and steroids, initiated when PCP pneumonia was suspected.
RESULTS. Overall, 9 cases with documented PCP pneumonia were recorded aged from 36 to 72, 3 males. Nobody was receiving TMP/SMX prophylaxis. Due to severe hypoxemia none of the patients underwent bronchoscopy to obtain bronchoalveolar lavage. In 4 patients (44,4 %) the first bronchial sample was diagnostic for PCP, in 3 patients (33.3%) PCP was detected in the second sample and in 2 cases (22.2%) only the third sample confirmed the diagnosis. The sensitivity of the method on bronchial aspirates was only 44.4%. Seven patients had solid tumors but only one was receiving concurrent chemotherapy. One had multiple myeloma with recent autologous bone marrow transplantation and one had scleroderma on 5 mg prednisolone daily. Five patients had concurrent blood stream or respiratory infection with gram negative bacteria. 7/9 patients survived, and were discharged from ICU (77.7% survival).
CONCLUSION. As the accuracy of staining methods is highly dependent on the quality of respiratory specimen, when bronchial aspirates are examined especially in non-HIV-patients who have lower burden of PCP, more than one bronchial samples may be required to increase the diagnostic yield of DFA.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001548

INTRODUCTION. In order to improve the selection of antibiotics, doses and infusion strategies, we wanted to describe the value of the Accelerate PhenoTest kit, approved by the Food and Drug Administration (FDA) as a method that can be useful to speed up microbial identification and to predict antimicrobial susceptibility in patients with bacteraemia compared to the reference standard that continues being the blood culture.
METHODS. observational, descriptive study. We included the patients admitted to the Intensive Care Unit and Infectious Diseases Unit, with clinical suspicion of bloodstream infection, from January to June 2018. Antimicrobial susceptibility testing (AST) results were analysed for essential agreement and for categorical agreement. Results based on EUCAST 2016 breakpoints.
RESULTS. 31 samples were evaluated, being excluded two of them. About the identification performance, 15 of them were gram- positive bacteria, 13 gram-negative bacteria (achieving a sensitivity and specificity of 100%) and one of the microorganisms was outside the PhenoTest panel, so the kit coverage was finally 96.6%. We also found an essential and categorical agreement of 93.5% and 92.9%, respectively, compared with the routine methods and we found the AST discrepancies in gram-negative bacteria. The potential on-average hours saved to AST was 23,4h compared to current techniques.
CONCLUSION. The coverage panel of the Accelerate PhenoTest kit was 96.6%. The essential and categorical agreement were above 90% and the results were obtained with a saved time of 23,4 hours compared to routine methods.

A Review of Adherence to Endotracheal Cuff Pressure Guidelines

L. Hill
Intensive Care unit, East Surrey Hospital, Redhill, United Kingdom
Correspondence: L. Hill
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000692

INTRODUCTION. Ventilator associated pneumonia (VAP) is the leading cause of death amongst hospital acquired infections (4,). Guidelines for the Provision of Intensive Care Services (GPICS) (2015) states its prevention as an important and cost-effective healthcare goal. Studies recommend several components should be adhered to help prevent VAP; including maintaining endotracheal tube cuff pressure to reduce micro aspiration.As part of the local Intensive care unit's ventilator care bundle it prompts Nursing staff to check cuff pressure 4 hourly, as per Department of Health (2011). GPICS (2015) recommend cuff pressure is kept above 20 cmH20, however over inflation of the cuff can cause ulceration or fistulation (2).
OBJECTIVES. To audit cuff pressure monitoring for endotracheal tubes in patients who are mechanically ventilated.
METHODS. A retrospective audit was conducted between the 22/6/18 and 1/8/18. 256 recordings of cuff pressures were analysed in total. 15 Patients were included with a total of 44.5 ventilated days, with stays ranging from 0.5-6 days. Each day was split into 2 x 12-hour shifts. Cuff pressures were recorded into time zones per shift 2-4 hourly, 4-6 hourly, 6-8 hourly, 8-10 hourly, once per shift and never on shift, with a total of 89 recordings taken. Cuff pressure was also

recorded and split into groups of <20cmH20, 20-30cmH20 and >30cmH20.
RESULTS. 68.5% of the time recommendations were met and cuff pressures checked 2-4 hourly. 31.5% of the time the standards expected were not being met related to timely recordings. 10.11% of the time cuff pressure was never checked on shift. 96.25 % of recorded cuff pressures were between the recommended pressures of 20-30 cmH20. However 3.75% of the time pressure was >30 cmH20 and never recorded <20 cmH20.
CONCLUSION. Despite 68.5% of the time standards being met relating to timing of cuff pressure measurement, the aim should be 100% to ensure the best quality care is being provided. Improvements to education of staff surrounding good cuff pressure maintenance and monitoring has now been introduced. Highlighting of the cuff pressure box every four hours has been introduced on the nursing observations charts to act as a visual prompt to staff to check the cuff pressure. These changes are now in place and there is a plan to re-audit in 6 months to see if improvement has been made.

Rapid Response Teams and hospital/ICU mortality rate in Oncology patients

CM. Park[1], J. Lee[2]
[1]The Catholic University of Korea Seoul St Mary's Hospital, Seoul, Republic of Korea; [2]Division of pulmonary, allergy and critical care, seoul st. mary's hospital, college of medicine, The Catholic University of Korea Songeui Campus, Seoul, Republic of Korea
Correspondence: C.M. Park
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000720

INTRODUCTION. Although rapid response teams (RRTs) are widely used at many hospitals, their effectiveness in reducing hospital mortality is uncertain. Improving the understanding of RRTs and their utilization in specific patient populations, such as cancer patients, might be helpful to improve the outcome and optimize RRT utilization
METHODS. A retrospective cohort study of hospitalized patients requiring RRT activation over 3-year period from January 2016 to December 2018 in a single academic medical center in Seoul, Republic of Korea.
RESULTS. Of the 274 patients, 104 were cancer patients. Cancer patients had a significantly higher Charlson Comorbidity Score (5.0 vs 8.0. $p < 0.001$). Also, cancer patients had significantly higher APACHEII (14.0 vs. 17.5, $p < 0.001$) and MEWS (6.0 vs. 7.0, $p < 0.001$). Proportion of patients requiring ICU transfer was significantly higher in cancer patients (52.9% vs. 38.2%, $p = 0.001$). Cancer patients had a significantly higher in-hospital mortality compared with other patients (44.2% vs. 11.8%, $p < 0.001$). The survival rate was 75.9% and survival was associated with cancer and Charlson Comorbidity Score. The utilization of RRT resources during the study period was also much higher for cancer patients with 2.34 activations per 1,000 patient discharges compared with 0.78 per 1,000 patient discharges for the other patients.
CONCLUSION. Oncology patients requiring rapid response team activation have a significantly higher in-hospital mortality and ICU mortality rate. Presence of cancer was the most important factor related to survival. In addition, cancer patients also utilize RRT resources at a much higher rate.

Serial C-Reactive Protein (CRP) levels do not correlate with antibiotic efficacy in critically ill patients with bacteremia

J. Inglez[1], S. Branco Ribeiro[2], J. Lage[1], J. Monteiro[1], C. Granja[2], A. Binnie,[2]
[1]Department of biomedical sciences and medicine, University of Algarve, Faro, Portugal; [2]Emergency and intensive care medicine department, Algarve University Hospital Centre, Faro, Portugal
Correspondence: S. Branco Ribeiro
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001545

INTRODUCTION. Antibiotic resistance is an increasing problem in intensive care units and inadequate empiric antibiotic therapy is associated with increased mortality. Biomarkers of treatment efficacy can theoretically be used to determine adequacy of antibiotic therapy prior to culture results being available. The aim of this study was to investigate the relationship between C-Reactive Protein (CRP) levels and (a) appropriateness of antibiotic therapy and (b) the presence of an untreated infectious focus in ICU patients with culture-confirmed bacteremia.
OBJECTIVES. To investigate the relationship between CRP levels and (a) appropriateness of antibiotic therapy and (b) the presence of an untreated infectious focus in ICU patients with culture-confirmed bacteremia.
METHODS. This retrospective observational study included all critically ill patients with culture-confirmed bacteremia admitted to the intensive care of the Algarve University Hospital Centre in Faro, Portugal from January to December 2018. Patients who did not receive antibiotic therapy were excluded from the study. Appropriateness of empiric antibiotic therapy was determined based on final culture and sensitivity results. Bacteremia episodes were designated as "complicated" or "simple" based on the presence or absence of an untreated or untreatable source (eg intra-abdominal abscess, infected hardware). CRP levels and standard clinical and biological variables were collected for 12 days, starting from the day prior to blood culture draw until 10 days afterwards.
RESULTS. A total of 59 culture-confirmed bacteremia episodes were identified. CRP concentrations on the day of positive culture varied widely from 9 mg/L to 480 mg/L. Out of the 59 patients in the cohort, a total of 38 (64.4%) patients received adequate empiric antibiotic therapy (as determined by final culture results) on the day of positive blood culture. CRP levels showed an overall negative trend from Day 0 (day of positive culture) to Day 10 irrespective of the adequacy of empiric antibiotic therapy. The presence of a "complicated" infection also had no significant impact on CRP trend. However, in multivariate regression analysis time to adequate antibiotic therapy was an important determinant of patient mortality, reinforcing the need for early appropriate antibiotics.
CONCLUSION. Although some studies have suggested that CRP is a useful marker of antibiotic adequacy, our results do not support this conclusion. Instead, we find that CRP levels show a similar downward trend from Day 0 to Day 10 in bacteremic patients, irrespective of the adequacy of empiric antibiotics. Further studies are needed to determine whether other biomarkers show greater utility than CRP in determining the efficacy of antibiotic therapy in this population.

Gastrointestinal motility disorders as a risk factor for sepsis in patients with major trauma

J. Schäper[1], F. Semper[1], M. Quintel[1]
[1]Department of anesthesiology, emergency and intensive care medicine, University Hospital Göttingen - University Medical Center Göttingen, Göttingen, Germany
Correspondence: J. Schäper
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001551

INTRODUCTION. The gut as a motor of sepsis hypothesis is an accepted hypothesis for the pathogenesis of systemic inflammation in critically ill patients. Impaired gastrointestinal motility may be a surrogate parameter for intestinal failure including gut barrier failure.
OBJECTIVES. This retrospective analysis in patients with major trauma tested different clinical variables of gastrointestinal motility as independent risk factors for sepsis and death on ICU.
METHODS. Retrospective data analysis of clinical variables from a patient data management system (IntelliSpace Critical Care & Anesthesia, ICCA™). Identification of 424 patients with major trauma (ISS>16) treated on the ICU in the timespan of Jan 2010 - Oct 2014 using the search items polytrauma and PTR. Chronologic analysis of 100 patients with respect to clinical variables of gastrointestinal motility (time until 50% of nutritional needs were achieved, gastric residual volume, time until first defecation) were analysed on days 0, 1, 2, 3, 5, 7, 10, and 14 as well as outcome parameters (sepsis, death on ICU). Statistics: multivariate analysis of prior evaluated variable-candidates for dichotomous outcome measures sepsis and death on ICU. Comparison of variables of patients with gastrointestinal motility disorders with and without sepsis. Group comparison with Mann-Whitney U test. Significance level at $p<0.05$.
RESULTS. Patients with a long duration to achieve 50% of nutritional needs were at a higher risk of developing sepsis (odds ratio 0.94; CI 0.89/0.99; p=0.03). This also applied for severe sepsis and septic shock. As risk factors for death on ICU old age (odds ratio 0.92; CI 0.86/0.98; p=0.01) and presence of brain trauma (odds ratio 38.47; CI 1.73/854; p=0.02) could be determined. Patients with sepsis needed more time until first defecation (173 ± 78 vs. 126 ± 77 h (mean ± SD) p=0.009) and until 50% of nutritional needs were achieved (146 ± 87 vs. 98 ± 51 h (mean ± SD), p=0.012)
CONCLUSION. In this ICU-cohort of patients with major trauma variables of gastrointestinal motility served as risk factors for sepsis, severe sepsis and septic shock. Gastrointestinal motility disorders were more pronounced in patients with sepsis compared to patients without sepsis.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001564

INTRODUCTION. Hemodynamic status of critically ill patients typically declines during sepsis and requires vasopressor support. Machine learning models have been recently implemented for a variety of ICU tasks with considerable success. A model capable of forecasting hemodynamic changes of septic patients could be critical in stratifying clinical intervention. Along this rationale, we hypothesize that the most predictive features would be those related to heart rate and blood pressure measurements, i.e. systolic (SP), diastolic (DP), mean (MP), or pulse pressure (PP).
OBJECTIVES. The purpose of the analysis was to create a prediction model for worsening of hemodynamic status in septic patients by using data from the first 6 hours after ICU admission.
METHODS. Data was pooled from the Medical Information Mart for Intensive Care III (MIMIC-III)(1) database. Patients in the 18-89 age range fulfilling the international consensus sepsis-3 criteria(2,3) were included. An increment of vasopressor equivalents (VPE) above 0.2 mcg/kg/min over the following 6 hours was chosen as indication of worsening of hemodynamic status. Firstly, a "null" logistic regression model using clinical data relative to the first 6 hours of ICU stay was trained to formulate predictions. Secondly, SP, DP, MP and PP were each integrated in the model and assessed for performance. Finally, a model with all pressure measurements was built and a feature selection process (LASSO) was run to yield only the most indicative. Performance was evaluated using the area under the receiver operator characteristic curve (AUC), recall and F1 score.
RESULTS. 5778 ICU stays were evaluated, of which 4370 (76%) do not receive vasopressors in the first 6 hours. The described increment in VPE was observed in 402 (6.9%) patients. Despite thelow prevalence, the models achieved moderate performance. The addition of any pressure measurement only slightly improved the AUC of the null model (0.84 vs 0.82) while it did improve recall, especially when using MP (0.83 vs 0.75). In all models, Glasgow coma scale and peripheral oxygen saturation were the the highest graded features; SP was also particularly highly ranked in its model, and MP and PP in an intermediate fashion. Likewise, the LASSO model selected SP as the most predictive feature.
CONCLUSION. Increment of vasopressor dose, as a marker of worsening of hemodynamic status, could be predicted 6 hours in advance using clinical data with moderate accuracy. SP was revealed as the most predictive of all pressure measurements, although it did not markedly improve accuracy of the model itself.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001565

INTRODUCTION. Sepsis is the most preventable cause of death worldwide,whichis estimated between six to nine million deaths every year [1]. Experimental studies are useful for a better understanding of this pathology, but require to follow new guidelines of animal modeling to fit with a clinical relevance.
OBJECTIVES. We aimed to explore (A) what is realized in articles published in 2018 using a cecal ligation puncture (CLP) model in rat, (B) if the instructions about antimicrobial therapy fit with microbiology in a peritonitis model based on CLP.
METHODS. (A) The review was performed on Pubmed using as keywords "CLP" and "RAT"for the year 2018, and selected English-written papers. We checked if animals received antibiotics and if bacteriological documentation was available before treatment. (B) We explored bacteria involved in the sepsis, using peritoneal fluid and blood cultures, at least 16 hours between CLP and sacrifice.
RESULTS. (A) Ninety-five studies were found. Among them 9 were excluded as they had a different meaning for CLP. Only in 11 cases (12%) antibiotics were used and mainly ceftriaxone at the dosage of 30mg/kg. None of the studies identified the pathogen before treatment.(B) In our series of eleven rats, we found mainly *Escherichia coli, Enterococcus faecalis, Lactobacillus murinus* in peritoneal fluid (fig. 1) and *Escherichia coli, Enterobacter cloacae, Enterococcus faecalis* in blood (fig. 2). All the bacteria exhibit a wild type phenotype for antimicrobial agent susceptibility.
CONCLUSION. These new recommendations provide a better match between experimental and clinical approaches, and improve translation of pre-clinical findings. Our findings suggest a better adequacy of antimicrobial treatment to pathogens and to the animal. More specific investigations are required to explore the bacterial diversity in peritoneal fluid and blood culture.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001597

INTRODUCTION. Optimal drug dosing is crucial in the therapeutic process. It plays a particularly important role in critically ill patients, especially those with severe sepsis, when proper antibiotics dosing is essential. The influence of renal replacement therapy on meropenem concentration in septic patients is largely unknown.
OBJECTIVES. The aim of this study was to determine the effect of continuous veno-venous hemodialysis (CVVHD) with regional citrate anticoagulation on meropenem concentrations in patients with acute kidney injury due to sepsis.
METHODS. 15 patients with acute kidney injury in the course of severe sepsis with clinical necessity for CVVHD according to KDIGO guidelines were enrolled in a prospective observational trial. Meropenem was administered by a continuous infusion, 2g every 8 hours. Meropenem concentrations were measured in blood plasma using high performance liquid chromatography coupled with tandem mass spectrometry. Blood samples were obtained prior and then 6 times after introducing CVVHD with regional citrate anticoagulation (RCA-CVVHD).
RESULTS. Median APACHE IV score was 118 points (IQR 97-134) and the median SOFA score on the day of admission was 19.5 (18-21). There were no significant differences in plasma meropenem concentrations measured directly prior to RCA-CVVHD and in the first 450 minutes of the procedure. Drug concentration reached its peak 2 hours after start of the infusion and then steadily declined.
CONCLUSION. Continuing high dose meropenem (2g every 8 hours) after introducing RCA-CVVHD ensures similar concentrations of meropenem both prior and after introducing RCA-CVVHD.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001598

INTRODUCTION. The course and outcome of infections is a dynamic interplay between the host and the pathogen. Central to this interplay is the struggle for iron, a micronutrient essential to both the mammalian host and virtually all microbes.(1,2)
OBJECTIVES. The aim of this study is to test whether markers of iron metabolism predict patient outcome in a cohort of sepsis patients.
METHODS. Patients admitted with sepsis to the ICU were consecutively enrolled from January 2018 to March 2019. Sepsis was defined as fulfilment of Sepsis-3 criteria, patients were enrolled within 24 hours after admission or diagnosis of sepsis respectively. Patients with haemato-oncologic disorders and patients with prior transfusions were excluded from analysis. Serum ferritin, transferrin and iron, as well as interleukin-6, procalcitonin, c-reactive protein and SOFA scores were obtained at the day of study inclusion. Patient outcome was defined as ICU mortality or discharge. Predictor variables were tested for a significant difference between survivors and non-survivors and imputed into a multiple logistic regression model. Predictors were tested for correlation with markers of inflammation. Statistical analyses were performed in R, results are presented as mean ±standard deviation. A p-value of >0.05 was considered as statistically significant.
RESULTS. Of 31 included patients, 4 were excluded due to prior transfusion of blood products. Of the remaining 27 patients, four were excluded due to presence of an active haematologic disorder and one due to missing iron parameters. 27% of patients were female, mean age was 65 ±14 years with a mean SOFA score of 12 ±3. 64% of patients survived. Iron levels of survivors vs. non survivors differed significantly (4.87 ±2.47 vs. 7 ±5mmol/L; $p = 0.01$), as did levels of ferritin (median 700 vs. 302µg/L; $p < 0.0001$) and transferrin (121.64 ±46.67 vs. 87.75 ±58.86 mg/dL; $p < 0.0001$) between surviving and deceased patients. Multiple logistic regression analysis of these parameters against ICU mortality did select transferrin as best predictor with an AUC of 0.66. Correlation analysis of transferrin and markers of inflammation did not reveal significant associations.
CONCLUSION. Parameters of iron metabolism differ significantly between survivors and non-survivors of sepsis in our cohort. Transferrin levels are inversely correlated with ICU mortality, but no statistical significant correlation could be shown with parameters of inflammation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001608

INTRODUCTION. The increase of antibiotic resistance is a serious threat to public health throughout the world that enhances the costs of health care the rate of treatment failure and mortality. The main objective of the "Resistencia Zero" (RZ) program is to reduce by 20% the rate of patients in whom one or more multiresistant bacteria of nosocomial origin are identified during ICU stay
OBJECTIVES. To describe, according to the origin, the trend in the pattern of multiresistant germs in a medical ICU based on the results of the RZ.
METHODS. Descriptive study of the quantity of multiresistant germs acquired in our ICU with regards to the total of multiresistant germs acquired during ICU stay and out of ICU from 2008 to 2018, in a medical ICU of 26 beds. Data collected from the ENVIN-HELICS study and expressed as a percentage.
RESULTS. During the period under review, a total of 81 multiresistant germs were registered. The following results are described: 14 MRSA (8 of them were adquired at ICU); 2 Enterococcus resistant to Vancomycin (1 was adquired at ICU); 13 Pseudomonas multiresistant (7 were adquired at ICU); 19 Acinetobacter resistant to Imipenem (12 were adquired at ICU); 21 Enterobacteria-ESBL (9 were adquired at ICU); 12 BGN producers of Carbapenemase (6 were adquired at ICU).
According to whether the isolation of the germ was prior to admission to the ICU or during ICU stay, we obtain the following annual results.
CONCLUSION. We observe a change in the trend of MR isolations during the last decade. At first, most isolates were originated at ICU but during the last years the origin of the majority of isolations is out of ICU. These data are consistent with those of the RZ program nationwide. Antibiotic policies at ICU and the Zero Projects play a key role in the decrease of MR isolates within the ICUs.

Table 1 (abstract 001608). See text for description

Year	Total Multiresistant	Upon Admission to the ICU	Acquired in ICU
2008	6	0 (0%)	6 (100%)
2009	4	0 (0%)	4 (100%)
2010	2	1 (50%)	1 (50%)
2011	15	3 (20%)	12 (80%)
2012	5	1 (20%)	4 (80%)
2013	5	2 (40%)	3 (60%)
2014	8	7 (87,5%)	1 (12,5%)
2015	6	3 (50%)	3 (50%)
2016	6	3 (50%)	3 (50%)
2017	10	7 (70%)	3 (30%)
2018	14	11 (78,57%)	3 (21,43%)

Preadmission Use of Beta Blockers Is Associated With Improved Mortality in Patients With Sepsis and Septic shock

M. Harazim, M. Nalos, M. Matejovic
1st medical department, University Hospital in Pilsen, Pilsen, Czech Republic
Correspondence: M. Harazim
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001639

INTRODUCTION. The beta-adrenergic system is a powerful modulator of the immune and cardiovascular response to sepsis and inflammatory cytokine production. Recent data suggest a potential beneficial role of prior β-blockers use in patients with sepsis. The benefit from beta-blockers in sepsis may not be only derived from a class-specific effect. We sought to assess impact of premorbid β-blocker use on mortality within 28 days of ICU admission.

METHODS. We conducted a retrospective cohort study of patients with sepsis and septic shock admitted to the medical ICU from January 1, 2014, to December 31, 2018. Chronic beta-blockers use was defined to have a previous prescription for β-blocking agent for 3 or more months prior to ICU admission. Demographics, initial vital signs, the source of infection, 28-day mortality, SOFA and APACHE II were obtained from the electronic database. Adjustment for age, gender, and severity of illness was performed.
RESULTS. We identified 784 patients with sepsis and septic shock, 290 (37%) of whom had a previous prescription for β -blockers before hospital admission. Common medications used by patients were metoprolol (54 %) and bisoprolol (22 %). The median age was 67 years (IQR 57- 76), 456 (58%) of patients were males. Patients who were on chronic β-blockers had lower 28-day mortality (20,8%) compared to patients who were not (31,5%), *(p=0.05)*. After adjusting for age, gender, and severity of illness using SOFA and APACHE II scores, the mortality was significantly lower in those on β-blockers *(p<0.05)*. There were no statistically significant association in admission heart rate in both groups.
CONCLUSION. Long-term β-blocker therapy decreases 28-day mortality of ICU patients with sepsis and septic shock.

Correspondence: S. Nseir
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001652

INTRODUCTION. SEPSIS-3 was recently reported and validated in patients admitted to the ICU with sepsis. No study to date has evaluated the usefulness of this definition in patients with ICU-acquired infections.
OBJECTIVES. The aim of this study is to determine the accuracy of SEPSIS-3 in diagnosing and predicting mortality of ventilator-associated lower respiratory tract infections (VA-LRTI).
METHODS. Prospective observational study, conducted in a single mixed ICU during a 2-year period. All consecutive patients with VA-LRTI were included. SEPSIS-3 criteria were considered as present if an increase of total SOFA score ³2, between 48h before and the day of VA-LRTI diagnosis, was observed. VA-LRTI were defined as ventilator-associated pneumonia (VAP), and ventilator-associated tracheobronchitis (VAT). Only first episodes of VAP or VAT with quantitative microbiological confirmation were analyzed. Sensitivity (Se), specificity (Sp), positive predictive value (PPV), and negative predictive value (NPV) for accuracy of SEPSIS-3 in diagnosing or predicting mortality of VA-LRTI were calculated.
RESULTS. 206 patients with VA-LRTI (136 VAP, and 70 VAT) were included. SEPSIS-3 criteria were present in 53 (39%), and 6 (8.5%) patients with VAP, and VAT; respectively (p<0.001, OR 6.8 [95%CI 2.8-16.8]). No significant difference was found in ICU-mortality between patients who presented the criteria of SEPSIS-3, and those who did not (24 of 59 (41%) vs 40 of 147 (27%), p=0.059).
CONCLUSION. Accuracy of SEPSIS-3 was moderate in diagnosing VAP, and low in predicting mortality among patients with VA-LRTI. The high positive predictive value of SEPSIS-3 in diagnosing VAP might be helpful in differentiating VAP from VAT.

Table 1 (abstract 001652). Accuracy of SEPSIS-3 in diagnosing and predicting mortality of VA-LRTI

	Se	Sp	NPV	PPV

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001653

INTRODUCTION. Intravenous vasoactive agents are key component in management of persistant hypotension in septic shock after adequete fluid resusitation ,yet they carry risk of many complications related to the drug complication and acsess etc..(1) The use of oral Midodrine is hypotheised to decresase the duration of vasoactive infusion and help their weaning.
OBJECTIVES. Evaluation of the role of midodrine in weaning of vasopressor infusions in patients admitted to the ICU with septic shock and its impact on outcome.
METHODS. This was a prospective randomized control study performed in a medical intensive care unit (ICU). All study subjects had a diagnosis of septic shock requiring at least 24 hours of IV vasopressors and demonstrated clinical stability with stable or decreasing doses of IV vasopressors. The two groups compared were those who received IV vasopressors only(30 patients) and those who received IV vasopressors with adjunctive midodrine 10 mg every eight hours(30 patients).Research and Ethics comittee approval was taken prior to performing the study and a written consent from each patient and or his next of kin before participating in the study.
RESULTS. There was no difference between both groups regarding demographics ,baseline charechteristics and source of sepsis (age, gender, APACHE 2 score and SOFA score on admission etc..).
Study findings showed that the IV vasopressor duration (hours) and IV vasopressor weaning duration (hours) were lower in the midodrine group when compared to IV vasopressor only group but the difference is statistically insignificant (139.03±46.95 VS 141.90±79.77 and 62.37±14.94 VS 74.20±36.78 p value 0.4.0.11 respectively).
Regarding the effect of midodrine on MAP, we found that despite the decrease of vasopressor dose in the midodrine group, the MAP in this group had significantly improved from 84.50 mmHg at the time of midodrine initiation to 88.03 mmHg after 24hours of midodrine initiation (p=0.04), this was statiscally higher than group A not using Midodrine.
Concerning the effect of midodrine on the outcome of septic patients, our study showed that there was no significant difference between both groups regarding the ICU length of stay and ICU mortality, reinstitution of an IV vasopressor after successful discontinuation and survival rate.
CONCLUSION.

- Using midodrine in septic shock patients doesn't reduce duration of IV vasopressor infusion and weaning during the recovery phase of septic shock.
- Using midodrine as an adjunct to vasoactive agents has no impact on overall survival, length of ICU stay and ICU mortality.
- Administration of midodrine improved mean arterial blood pressure MAP.

The impact of antibiotics on mitochondrial function in immune cells

M. Khpal, N. Arulkumaran, M. Singer
Bloomsbury institute of intensive care medicine, University College London, London, United Kingdom
Correspondence: M. Khpal
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001670

INTRODUCTION. Sepsis is associated with both mitochondrial and immune cell dysfunction (1-3). Antibiotics are known to impair mitochondrial function in non-immune cells (4-7). We hypothesise that antibiotics impair immune cell mitochondrial function, contributing to immune cell dysfunction in sepsis.
OBJECTIVES. To investigate the impact of antibiotics on mitochondrial function in immune cells *ex vivo*.
METHODS. Healthy volunteer immune cells were incubated in Hanks buffered saline solution (37oC, 21% O2, 5% CO2) with one of five antibiotics (amoxicillin, ciprofloxacin, gentamicin, meropenem and teicoplanin) at 5mcg/mL for 5 hours. Cells were subsequently incubated with fluorochromes (Thermo Fisher Scientific, UK) for flow cytometric assessment of mitochondrial membrane potential (Dψm) (using TMRM at 25nM), mitochondrial reactive oxygen species (Mitosox Red at 2mM), and cell death (far red cell viability stain at 1mM) using the LSR Fortessa flow cytometer (BD Biosciences). The two main cell populations, granulocytes and peripheral blood mononuclear cells (PBMCs) were identified by gating on characteristic forward and side scatter profiles. All data were collected from 3–5 individual experiments expressed as mean ± standard error of mean (SEM) compared to untreated cells. Flow cytometric data were analysed using FlowJo version 10.0 (Tree Star Inc, USA). Statistical data analysed using a non-parametric Kruskal Wallis with post-hoc Dunn's test using GraphPad Prism v5 (San Diego, USA).
RESULTS. At 5mcg/ml, gentamicin and teicoplanin increased granulocyte mitochondrial ROS production by 22% (p=0.026) and 44% (p=0.012) respectively, compared to untreated cells. At 15mcg/ml, teicoplanin increased granulocyte mitochondrial ROS production by 43% (p=0.041). In PBMC population, ciprofloxacin, gentamicin and meropenem increased mitochondrial ROS production at 5mcg/ml by 13% (p=0.0014), 21% (p=0.0148) and 9% (p=0.0296) respectively. At 15mcg/ml, ciprofloxacin, gentamicin and meropenem further increased mitochondrial ROS production by 75% (p=0.0014), 31% (p=0.026) and 61% (p=0.0369) respectively, compared to untreated cells.Mitochondrial membrane potential (MMP) in granulocytes was not altered when treated with 5mcg/ml antibiotic concentrations (p=0.1585). At 15mcg/ml, teicoplanin induced a reduction in MMP (p=0.006). However, in PBMCs, MMP was unaffected by antibiotics at both 5 and 15mcg/ml (p=0.1722 and p = 0.1436, respectively.Cell viability was unaffected by antibiotic exposure (p=0.98 for granulocytes, p=0.87 for PBMCs compared to untreated cells).
CONCLUSION. A number of antibiotics cause direct mitochondrial dysfunction in immune cells *ex-vivo*. This may explain, in part, the immune dysfunction seen in septic patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001685

INTRODUCTION. The Surviving Sepsis Campaign [1] recommends to administer 30 ml/kg of fluid within 3 hours following the onset of hypotension, before introducing vasopressors. However, evidence supporting this recommendation is lacking.
OBJECTIVES. Determine i) the optimal timing and ii) the optimal fluid volume before vasopressor introduction in septic shock.
METHODS. We used the data from the MIMIC II dataset. (2) To be included, patients had to present an acute hypotensive episode of septic origin and a lactate level > 2 mmol/l. The primary outcome measure was hospital mortality. We used a machine learning approach accounting for time-varying confounders called longitudinal targeted maximum likelihood estimation. (3)
RESULTS. 933 patients were included: SOFA 7; arterial lactate 3.3 mmol/L, average hospital mortality rate 11.5%. Hospital mortality was significantly minimized when vasopressors where introduced by hour 3 following the onset of hypotension. When compared to 30 ml/kg, switching to vasopressors after 5 or 10 ml/kg was associated with reduced mortality (Fig. 1).
CONCLUSION. In septic shock, administering 5-10 ml / kg within 3 hours after the onset of hypotension appears to maximize the chance of survival.

Pentraxin 3: which role in sepsis?

G. Scarpati, I. Russo, E. Della Rocca, L. Ferrara, O. Piazza
Anaesthesia and intensive care, University of Salerno, Baronissi, Italy
Correspondence: G. Scarpati
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001692

INTRODUCTION. Pentraxin-3 (PTX3) is a molecule of the humoral pattern recognition arm of the innate immune system, as complement components, collectins, and ficolins [1]. PTX-3 has been appreciated for its diagnostic value for sepsis and septic shock.
OBJECTIVES. This study evaluated the accuracy of PTX3, Endocan, Nitric Oxide (NO) and Presepsin as biomarkers of severity and prognosis in patients with sepsis/septic shock.
METHODS. We enrolled 12 sepsis patients admitted to our ICU. Blood samples for measuring PTX3, NO, Endocan, and Presepsin were taken within 12 hours from diagnosis and repeted for the next three days. A group of patients admitted in ER with hip fracture was used as controls. Mortality at 28-day was considered as outcome.
RESULTS.
Serum levels of NO, Endocan, and Presepsin in septic patients were higher than control group, but PTX3, which was higher in the hip fracture group. Endocan and Presepsin day 1 concentrations in non survivors were higher than the concentrations measured in survivors. At day 1, NO and PTX3 concentrations were higher in surviving patients.
CONCLUSION. Sepsis patients had higher concentrations of Nitric Oxide, Endocan and Presepsin than those with hip fracture. Beyond its role as the first line of resistance against pathogens, innate immunity is involved in initiating the process of tissue repair. PTX3 appears to be more closely related to endothelial damage, prevalent in patients with femur fractures. Furthermore, some authors suggest a protective role of PTX3 and NO [2].
Models based on the combination of several biomarkers provide a novel and useful strategy to overcome the limited performance of one parameter for a given outcome. Hopefully, a new mortality prediction model could improve the prediction of sepsis related mortality by combining PTX3, NO, endocan and presepsin.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001719

INTRODUCTION. Sepsis is responsible of both an immune hyperactivity damage from inflammation and immune suppression and paralysis. A few studies support the role of IgM enriched immunoglobulins G as adjunctive of antimicrobial treatment
OBJECTIVES. To assess the efficacy of IgM enriched IgG as adjuvant therapy in treating sepsis in the critically ill.
METHODS. A PCRT was set and performed, since 12/2016 to 01/04/2019; patients experiencing a septic shock - admitted with a first 24h SAPS II > 25, associated with a SOFA-score > 4 were randomised in two group: (A) undergoing treatment with IgM-e-IG, given for three days at the total dosage of 500 mg/kg plus conventional antimicrobial therapy; (B) undergoing conventional antimicrobial therapy. The therapy response was based on clinical, microbiological and rheological data.
RESULTS. During the study period 23 and 22 patients were respectively recruited in the two groups; no differences were found in median age [61 (55-78) vs. 63 (58-77) p=0.662], ICU length of stay [14 (5-19) vs. 15 (6-18) p=0.462]; duration of mechanical ventilation [7 (5-8) vs. 8 (5-9) p=0.348] and antimicrobial treatment [9 (8-11) vs. 11 (12-14) p=0.552]. PCT, CRP, WBC, Lactates and SOFA score were daily measured and computed the differences between day of stopping and starting IM-enriched IgG (For the patients of group B, such parameters ware considered over the same 72 hrs period. No differences were found in the trend of all parameters but SOFA [3.7 (2-5) vs. 0.8 (0-2) p=0.025], indicating a quicker and more timely recovery from sepis related organ failure in the group A. The VLAD computed on the basis of SMR in the two group showed a higher number of saved lives in the treatment group (4.7 vs. 0.8, p=0.002). No differences in survival was found by Kaplan Meier analysis although at 28 days all patients of the treatment group were still alive.
CONCLUSION. IgM enriched immunoglobulins G as adjunctive of antimicrobial treatment may have a role in improving patient outcome, however PRCT should be prosecuted up to proper determined sample size.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001746

INTRODUCTION. Polymyxin B hemoperfusion (PMX-HP) is one of a new blood purification therapy for sepsis. PMX-HP can remove circulating endotoxin particularly in gram-negative infection which potentiates improving clinical outcomes.
OBJECTIVES. To evaluate the efficacy of polymyxin-B hemoperfusion therapy over conventional treatment for sepsis.
METHODS. An ambi-directional cohort was conducted. PMX-HP arm was collected prospectively in septic patients during 2017-2018 from 5 ICUs in Thailand. PMX-HP treatment was performed 2 hours for 2 consecutive days. South East Asia-Acute Kidney Injury (SEA-AKI) Study dataset was used as a historical control arm (collected during 2013-2015 from 17 ICU-centers in Thailand, n=5,476). Propensity score match and survival analyses were used to identify 28-day mortality between patient with and without PMXB-HP therapy.
RESULTS. A total of 1,358 septic cases were enrolled (PMX-HP, n=30 and SEA-AKI Study, n=1,328). Comparing patients who treated with vs without PMX-HP therapy, 28-day mortality was 14/30 (46.7%) vs 318/1,328 (24.0), respectively, HR = 0.971; 95%CI, 0.567-1.663, p = 0.916. However, there were multiple differences in patient baseline characteristics, including pre-existing diseases (diabetes mellitus, hypertension, and coronary heart disease); severity of illness (APACHE-II and SOFA score); and usage of organ support (ventilatory support, vasopressor, and renal replacement therapy). Although all baseline variables were similar after matching by propensity score, 28-day mortality remained no significant difference (11/21 (52.4%) vs 8/21 (38.1%), HR=0.938; 95%CI, 0.377-2.334, p = 0.891).
CONCLUSION. In septic patients treated with PMX-HP matched to conventional therapy, no significant differences in 28-day mortality were found.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000899

INTRODUCTION. Prone positioning (PP) decreases mortality of moderate to severe acute respiratory distress syndrome (ARDS) [1]. This benefit may be related to the prevention of ventilation-induced lung injury (VILI) by PP. More precisely, it remains unclear whether PP

modulates the deleterious inflammatory response associated with VILI, namely *biotrauma*. [11C]-PK11195 is a positron emission tomography (PET) radiotracer that allows the non-invasive quantification of lung macrophage recruitment in the lungs, in combination with lung computed tomography (CT) evaluation.
OBJECTIVES. To evaluate the effects of PP on VILI surrogates and macrophage lung recruitment quantified by [11C]-PK11195 lung uptake in PET/CT, in an experimental model of ARDS.
METHODS. Experimental ARDS was performed in 9 pigs (weight, 27 [interquartile range, 25–29] kg) in supine position (SP), by means of tracheal instillation of hydrochloric acid. Animals were under general anesthesia, neuromuscular blockade, and protective ventilation (tidal volume 6 ml/kg, positive end-expiratory pressure 5 cmH2O) [2]. Respiratory mechanics, including esophageal pressures, were recorded. Ventilation settings were not modified thereafter. Immediately after completion of experimental ARDS, animals were randomized to be prone positioned or to remain in SP, during 4 hours. Coupled PET/CT acquisitions were performed immediately before (T1), and after 4 hours of experimental ARDS (T2). Non-invasive measurements in PET/CT were performed on the whole lungs, and by dividing the lungs into 2 regions-of-interest (ROI) defined equally along the ventrodorsal axis. [11C]-PK11195 was quantified using the standardized uptake value (SUV), corrected for tissue density in the corresponding CT ROI. Collapsed lung volume corresponded to the non-aerated volume of gas fraction in a given ROI.
RESULTS. PP was performed in 5 animals, and SP in 4. The PaO2/FiO2 ratio was 143 [90–169] at 30 minutes of ARDS onset. Experimental ARDS increased the elastance-derived transpulmonary pressure (ΔPL) between T1 and T2 (8 [7–10] to 15 [13–18] cmH2O, $P<0.01$), and CT-derived lung weight (427 [409–508] to 608 [572–642] g, $P<0.01$). At T2, PP animals had lower ΔPL compared to SP animals (13 [12–14] vs. 20 [17–23] cmH2O, $P=0.03$). PP decreased collapsed lung volume in the dorsal region at T2, compared to SP (12 [9–22] vs. 262 [204–275] ml, $P=0.02$), by redistributing it to ventral regions (144 [140–169] vs. 13 [9–24] ml, $P=0.02$). At T2, [11C]-PK11195 SUV of the whole lung of PP animals was 1.3 [1.2–1.3], and 1.4 [1.2–1.7] in SP animals ($P=0.73$). However, we observed a lower [11C]-PK11195 SUV at T2 in the ventral region of PP animals, compared to the ventral region of SP animals (1.3 [1.2–1.4] vs. 1.6 [1.4–1.9], $P=0.03$). No difference existed in dorsal regions (1.4 [1.2–1.5] vs. 1.4 [1.2–1.6], $P=0.55$).
CONCLUSION. PP improved respiratory mechanics, redistributed collapsed lung volume, and decreased [11C]-PK11195 lung uptake (and presumably macrophage lung recruitment) in the ventral lung regions of animals with experimental ARDS.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000902

INTRODUCTION. Severe community acquired pneumonia (sCAP) frequently requires admission to the intensive care unit (ICU) admission and is associated with significant morbidity and mortality1. The use of non-invasive ventilation (NIV) in this setting is controversial and may be associated with worse outcomes2. Characterisation of parameters predictive of NIV failure may be of value in risk stratification to minimise increased risk of subsequent mechanical ventilation, or death3.
OBJECTIVES. Clarify the role and impact of NIV in sCAP cohort and identify factors that might allow earlier detection of NIV failure.
METHODS. Retrospective, observational study of consecutive admissions to ICU with sCAP from January 2016 to May 2017. sCAP defined as CAP requiring critical care management. Adequate NIV trial classified as minimum of two hours. NIV cohort was sub-divided into three sub-sets for analysis; NIV as ceiling of care, NIV failure requiring invasive mechanical ventilation (IMV) and NIV success so avoiding intubation. Student t-test utilised in statistical analysis.
RESULTS. Total of 201 sCAP patients identified over the study period. NIV was utilised in 121 (60%) cases with immediate IMV required in 54 (27%) cases and no NIV support required in 26 (13%) cases. Successful NIV use was associated with reduced length of ICU (4 days)and hospital (14 days) stay and reduced long-term (6 month) mortality. In the NIV group, partial pressure of oxygen to fraction of inspired oxygen (Pa02/Fi02) ratio improvement in 2 hours of ICU admission was associated with increased hospital and long-term survival. NIV failure cohort had a reduced Pa02/Fi02ratio 2-hour improvement (50% versus 69% in NIV success cohort). Daily sequential organ failure assessment (SOFA) scores over initial 72 hours of admission highlighted daily improvement in the whole cohort. However, worsening SOFA scores at 24-hours were identified in the NIV failure cohort (7.84.4 versus 3.52.0, p-value <0.0001). Average time to intubation in this failed NIV cohort was 25 hours (30 hours).
CONCLUSION. Utilisation of NIV in sCAP patients can be successfully employed with good clinical outcomes in selective patients. Failure of NIV is associated with poor short- and long-term outcomes. Worsening Pa02/Fi02ratios within 2 hours of ICU admission and deteriorating SOFA scores are associated with NIV failure. Further large, prospective studies are required to validate clinical indicators of NIV failure.

INTRODUCTION. Tracheotomy is a usual technique in patients with invasive mechanical ventilation in intensive care units (ICU)
OBJECTIVES. To analyze the variables related to 30-day mortality of patients who underwent tracheotomy during ICU stay, and create a predictor model of mortality.
METHODS. Observational and retrospective study conducted between may-2014 and October-2018 that included all patients who underwent tracheotomy in ICU. Exclusion criteria: tracheotomy before the admission and re-admitted patients. There were collected demographic (age, gender) data, clinical (co-morbidity) data and severity scores, related to invasive mechanical ventilation (IMV) and tracheotomy, and to ICU and hospital stay.

Fragility before the hospital admission was evaluated by the Clinical Frailty Scale (CFS) (Fragile CFS ≥ 5). We describe categorical variables as frequency and percentages; and numerical variables as median and interquartile range (IR). We compared percentages using chi-square or Fisher exact test, and continuous variables with t-Student or U Mann-Whitney tests. Multivariate analysis conducted by cox regression model.

RESULTS. Of the 2630 patients admitted to ICU, 105 were analyzed. 30-d mortality was 32.4%. There were no significant differences comparing by sex or co-morbidities. Age, severity scores, fragility (CFS) and limitations of life support techniques (LLST) were significantly higher among dead patients. Reintubation, days with IMV, days in spontaneous ventilation (SV), % of time with tracheotomy in SV, ICU and hospital stay were significantly lower among dead patients. Dead patients underwent tracheotomy earlier (table 1). Multivariate analysis showed that age, fragility, day of tracheotomy, disconnection from IMV and % of time with tracheotomy in SV, were independent predictive factors of 30-d mortality (table 2), creating a mortality predictive normogram (Figure 1).

CONCLUSION. Age, severity scores and fragility were mortality associated factors in patients with tracheotomy, who also died before. Fragility, day of tracheotomy, disconnection from IMV and % of time without IMV were 30-d mortality independent predictive factors since de ICU admission. Our predictive model could be useful to decide the LLST.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000918

INTRODUCTION. Extracorporeal membrane oxygenation (ECMO) has increasingly found its place in the treatment of severe acute respiratory failure, as well as severe circulatory collapse. Mechanical ventilation and ECMO are both technologies interacting on gas exchange. Nevertheless, besides a consensus paper [1], no evidence-based guidelines regarding protective lung ventilation on ECMO exist to date. Mechanical Ventilation with Intellivent-ASV, an algorithm driven, closed loop system, provides an opportunity to standardize ventilation on ECMO.

OBJECTIVES. To propose and validate lung protective ventilation with a closed loop ventilation mode in patients with ECMO due to ARDS or cardiogenic shock.

METHODS. We retrospectively analyzed mechanically ventilated patients on ECMO for cardiogenic shock or ARDS admitted to the medical ICU of the University Hospital Zurich from March 2016 on until May 2018. All patients were initially ventilated with the dual positive airway pressure (DuoPAP) mode and were then switched to Intellivent-ASV+®. Every eight hours ECMO settings, ventilation parameters and blood gas analyses were collected. Driving pressure was calculated as the difference between peak pressure and PEEP.

RESULTS. 62 patients were included into the study, of which 43 had a cardiogenic shock and 19 had an ARDS, the ICU mortality for both groups was 27.4%, population characteristics were homogeneous. Patients of both groups were on average on ECMO for 11.6 days and ventilated for 9.9 days on Intellivent-ASV+®. After switch to Intellivent ASV, during the first 72 hours, at constant blood flow on ECMO, ASV-Intellivent mode decreased mean FiO2 by 25% while keeping PEEP constant. Regarding ventilation, keeping airflow on ECMO constant over time, Intellivent-ASV+® led to a significant decrease in mean peak (7%) and driving pressure (14%) ($p < 0.0001$), while tidal volumes stayed below 6 in both groups and pCO2 remained constant. On steady state after switch to Intellivent-ASV+® the driving pressure was 13.12±0.67 kPa, despite significant differences in lung compliance 37.28±3.75 ml/mbar (cardiogenic shock) versus 28.46±5.26 ml/mbar (ARDS).

CONCLUSION. In this retrospective analysis we, for the first time, show that the automated mechanical ventilation algorithm Intellivent-ASV+® can safely ventilate patients with either ARDS or Cardiogenic Shock on ECMO.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000925

INTRODUCTION. Optimal anticoagulation monitoring in patients with extracorporeal membrane oxygenation (ECMO) is controversial, but fundamental to avoid haemorrhagic and thromboembolic complications. In addition to conventional coagulation tests (ACT, aPTT), there is growing interest in the use of viscoelastic haemostatic assays (VHA) for management of anticoagulation, in particular of tromboelastography (TEG) [1,2]. However, evidence on the use of rotational tromboelastometry (ROTEM) for this purpose is lacking.

OBJECTIVES. The aim of our study is to evaluate ROTEM compared to TEG and conventional coagulation assays to monitor anticoagulation with unfractionated heparin (UFH) during ECMO.

METHODS. We conducted a prospective, observational, monocentric study. We included patients admitted to intensive care unit at ASST Monza in ECMO support for either respiratory (Veno-Venous) or cardiac failure (Veno-Arterial), anticoagulated with UFH. Conventional coagulation tests and viscoelastic assays were performed daily, as per clinical practice. We focused our statistical analysis on reaction time parameter (R, min) for Kaolin TEG, and clotting time (CT, sec) INTEM for ROTEM. Test results were correlated with UFH infusion rate (UI/die) and conventional coagulation test results at the time of sampling.

RESULTS. We included twelve patients in ECMO support; 41 data points were available for the analysis. CT INTEM parameter showed a moderate correlation with both UFH dosing and standard coagulation tests (see Figure 1), while correlation coefficients for R-TEG K with other variables were poor.

CONCLUSION. CT INTEM parameter shows moderate correlation with UFH infusion rate and other coagulation tests. Further studies are needed to identify an appropriate anticoagulation target for ROTEM during ECMO support.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000929

INTRODUCTION. Muscle paralysis during mechanical ventilation (MV) treatment decreases the lung injury through better synchrony and improves survival ultimately. However, some patients have a progress toward development of severe respiratory acidosis and sometimes encounter hemodynamically instability. Contrary to a well-known knowledge of intensive care unit (ICU)-acquired weakness induced by prolonged use of neuromuscular blocking agents (NMBA), respiratory acidosis immediately after infusion of NMBA has not been reported.

OBJECTIVES. We investigated to reveal the risk factors for post-NMBA respiratory acidosis in patients under mechanical ventilation who started cisatracurium just before the event.

METHODS. Following a retrospective review of the medical records of patients admitted to the ICU of our medical center from January to October 2017, we included adults who received cisatracurium during MV. Data of vital signs, arterial blood gas analysis (ABGA), and parameters of the ventilator before and after NMBA infusion were recruited. Respiratory acidosis developed after cisatracurium infusion was defined discretionally as decreased arterial pH more than 0.2.

RESULTS. The mean age of the patients was 64 years and 67% (n = 172) was male. Of total 256 Patients, 24 patients (9.4%) showed a progression of acidosis. Among them, seven patients' blood pressure dropped immediately after NMBA infusion and vasopressor was needed. In univariate analysis, a higher pH, lower arterial partial pressure of carbon dioxide ($PaCO_2$), and higher pulse rate (PR) measured before NMBA infusion were associated with progression of respiratory acidosis. Emphysema was more common in patients with respiratory acidosis. On the other hand, disease severity presented by APACHE II score and pre-NMBA tidal volume based on patients' efforts are not related with a progression of respiratory acidosis. In multiple logistic regression model including variables of age, sex, emphysema, pre-NMBA pH, pre-NMBA $PaCO_2$, and pre-NMBA PR, emphysema (OR, 4.11; 95% CI 1.21–13.96), higher pH (OR, 3.10 per 0.1; 95% CI 1.67–

5.75), lower PaCO2 (OR, 0.90; 95% CI 0.83–0.98) and higher PR (OR, 1.03; 95% CI 1.01–1.05) are associated with progression of respiratory acidosis after NMBA infusion.
CONCLUSION. Emphysema, higher pH, lower PaCO2 and higher PR are risk factors for post-NMBA respiratory acidosis. It suggested patients with respiratory failure who showed active cardiopulmonary compensation especially in those with emphysema might have a risk for a progression of respiratory acidosis after muscle paralysis.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000931

INTRODUCTION. Electrical impedance tomography (EIT) can assess alveolar overdistension and collapse during a decremental positive end-expiratory pressure (PEEP) trial in mechanically ventilated patients [1]. Using this approach, it is possible to identify the "best compromise" PEEP at which overdistension and collapse are minimized as shown in patients with acute respiratory distress syndrome (ARDS) [2] and in patients during general surgery [3]. However, even with the "best compromise" PEEP, a variable amount of simultaneous overdistension and collapse remains. We hypothesized that the sum of overdistension and collapse detected by EIT at the "best compromise" PEEP is higher in patients with ARDS than in lung-healthy control patients during general surgery and might be a marker of disease severity.
OBJECTIVES. To investigate whether the sum of residual overdistension and collapse at the "best compromise" PEEP is higher in patients with ARDS than in patients without pulmonary pathology.
METHODS. We compared EIT data sets of 12 patients with ARDS (5 female, age: 67±11 years, height: 174±9 cm, weight: 79±22 kg, PaO2/FiO2 at baseline: 151±38 mmHg) to 8 patients without pulmonary pathology (all female, age: 38±19 years, height: 169±5 cm, weight: 77±21 kg) undergoing general anesthesia for laparoscopic gynecological surgery. Decremental PEEP trials were carried out in all patients during pressure-controlled ventilation with constant driving pressure. In control patients, one PEEP trial was performed after induction of general anesthesia in the supine position and another one during capnoperitoneum in the Trendelenburg position. All PEEP trials were analyzed as described in [1] and "best compromise" PEEP was defined as the value associated with equally balanced overdistension and alveolar collapse. Residual overdistension and collapse was calculated as the sum of overdistension and collapse at the "best compromise PEEP". Data sets were compared by one-way analysis of variance with Bonferroni post test. Written informed consent was obtained from control patients and from the legal representatives of ARDS patients. Numerical values are presented as mean±SD.
RESULTS. In ARDS patients, we identified 14.5±7.1% of residual overdistension and collapse at the "best compromise" PEEP of 13.3±2.4 mbar. In control patients, the sum of residual overdistension and collapse was 6.3±3.8% at the "best compromise" PEEP of 7.3±2.4 mbar in supine position and 3.4±3.5% at 18.0±2.1 mbar in the Trendelenburg position with capnoperitoneum. The difference between ARDS and lung-healthy patients was statistically significant both for supine ($p<0.01$) and Trendelenburg positions ($p<0.001$).
CONCLUSION. Our preliminary results imply that the sum of residual alveolar overdistension and collapse at the "best compromise" PEEP level is higher in patients with ARDS than in control patients both during ventilation in the supine and in the Trendelenburg position with capnoperitoneum. This supports the hypothesis that this measure might serve as a marker of disease severity in mechanically ventilated patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000933

INTRODUCTION. Acute Respiratory Distress Syndrome (ARDS) still remains a serious pulmonary condition with substantial mortality and without specific therapeutic options. Retrospective analysis of randomized controlled trials have identified the presence of two distinct phenotypes, based on clinical and biological variables (1–3), namely a hypo-inflammatory (P1) and a hyper-inflammatory (P2) endotype. The development of clinically relevant models to replicate these endotypes, will likely enable better understanding of these endotypes.
OBJECTIVES. We aimed to develop an ovine model of P1 and P2 ARDS endotypes and to characterize clinical and biological features, opening the pathway for further prospective evaluation of endotype-specific treatment options.
METHODS. We studied 20 anesthetized sheep on mechanical ventilation up to 6 hours, and randomized into three distinct groups: 1) the oleic acid (OA) only group received an intravenous infusion of OA to achieve a PaO2/FiO2 ratio <100 mmHg (n=8); 2) the OA-IV-LPS group received an OA infusion and intravenous infusion of lipopolysaccharide (n=5) and; 3) the OA-IP-LPS group received an OA infusion and intrapulmonary infusion of LPS (n=7). Pulmonary, hemodynamic and laboratory parameters were assessed hourly. In addition, interleukin (IL) -6, -8 and -10 were quantified in serum and bronchoalveolar lavage (BAL).
RESULTS. Severe impairment in PaO2/FiO2 ratio was found in all study groups (Figure 1). We found a) more hemodynamic and pulmonary impairment b) decreased albumin and platelets levels and c) upregulation of inflammatory (IL-6 and IL-8) and anti-inflammatory cytokines (IL-10) in serum and BAL only in OA-IV-LPS in comparison with the other two groups. Therefore, the OA-IV-LPS model may mimic a pattern closest to the human P2 endotype and the OA only model the P1 endotype.
CONCLUSION. We developed innovative models of ARDS that mimic clinical and inflammatory status of human P1-P2 endotypes, while characterized by similar severity of pulmonary dysfunction. These animal models could be applied to explore in detail mechanical and biological differences between ARDS subphenotypes and identify endotype-specific treatment options.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000946

INTRODUCTION. Systemic inflammation and metabolic acidosis, which characterize patients with sepsis and septic shock, can increase the spontaneous respiratory drive and effort and the risk of patient self-inflicted lung injury, with potentially detrimental effects on outcome[1]. A retrospective study reported that septic shock patients intubated during their intensive care unit (ICU) stay had fewer 28-day alive without organ support, as compared to patients already intubated upon admission[2].
OBJECTIVES. To compare ICU mortality in a large cohort of patients with sepsis/septic shock classified as: already intubated upon admission (early intubation) vs. intubated during ICU stay (late intubation) vs. never intubated (no intubation). To identify early factors associated with risk for late intubation.
METHODS. We included 1425 patients with sepsis (824) and septic shock (601), consecutively admitted to three tertiary level general ICUs in Italy between 2014-2018. Patients data and outcomes were prospectively collected in a centralized clinical registry (PROSAFE Giviti electronic case report form). Categorical variables are expressed as counts (%) and compared with Chi-square or Fisher's exact test. Median (IQR) was used for continuous variables and differences in distributions were assessed by ANOVA on ranks with Dunn's post-hoc test.

RESULTS. Patients with late intubation were 339 (24%), early intubation 878 (61%), no intubation 208 (15%). Patients in the late intubation group had significantly higher hospital mortality than patients in the other two groups (47% late vs. 31% early vs. 10% no, p<0.0001). Table 1 shows differences between groups at ICU admission: patients with late intubation presented more organ failures, lower GCS, higher SOFA and SAPS II scores in comparison to no intubation

In patients with late intubation, upon admission, we also observed significantly lower oxygenation, more severe acute kidney injury, higher bilirubinemia, lower systolic pressure, higher imbalance of acid-base status vs. no intubation (p<0.01 for all). Interestingly, early clinical and physiologic derangements were similar between late vs. early intubation groups.
CONCLUSION. Mortality of ICU patients with sepsis and septic shock is significantly higher when intubation occurs after ICU admission. Comparable baseline severity with patients already intubated at admission might suggest a specific role for injurious spontaneous breathing. Early identification of patients at risk for late intubation might prompt prophylactic interventions.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000952

INTRODUCTION. Mechanical ventilation in prone position has demonstrated to decrease mortality in patients with severe Acute Respiratory Distress Syndrome (ARDS). It is scarcely documented in the literature clinical experience about use of fiberoptic bronchoscopy (FOB) in prone position , only 9 patients, (1,2). Bronchoalveolar lavage in these conditions are exceptional.
OBJECTIVES. The aim of the present study are: to describe the clinical experience in the realization of FOB in critically ill patients ventilated in prone position and to analyze the complications related to the procedure.
METHODS. Retrospective study performed in an medical-surgical ICU. Time of study was five years. Inclusion criteria were patients with ARDS and indication of FOB. Informed consent was requested for the performance of the procedure. The following variables were collected: Demographic data, heart rate and arterial pressure during the FOB, ICU lenght of stay, level of positive end-expiratory pressure (PEEP) and categories of ARDS according Berlin classification criteria, complications and mortality. The statistical analysis was performed using SPSS program, the quantitative variables are shown in mean ± standard deviation.
RESULTS.
11 FOB were performed during the time of study. Most of patients (81.8%) were indicated for microbiological study performing bronchoalveolar lavage. In one case it was indicated due to complete atelectasis and another case due to pulmonary hemorrhage. The procedure was performed with control pressure ventilator mode with FiO2 of 100% without modifying the previous PEEP. Table 1 shows clinical characteristics. Mean PaO2/FiO2 was 185,1 ± 52,05, resulting between 200 and 300 in 5 patients, between 100 and 200 in 5 cases and < of 100 in one. In most patients (72.7%) no complications related to FOB were observed. 18.2% developed self-limiting supraventricular tachycardia without hemodynamic impact nor needing to increase vasoactives and we observed in 9% transient hypoxemia that was corrected by removing the FOB.
CONCLUSION. In our experience the realization of FOB in patients with ARDS ventilated in prone position is a safe procedure and does not need to decrease or to withdraw the previous PEEP.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000958

INTRODUCTION. Intensive care acquired skeletal muscle atrophy (SkMA) during acute respiratory distress syndrome (ARDS) is associated with long-term functional restriction **(1).** Veno-venous extracorporeal membrane oxygenation (vvECMO) represents the management of extreme cases of ARDS **(2,3)** but the degree of SkMA and the relationship between lung parenchyma recovery in this cohort has not been described.

OBJECTIVES. In patients rapidly deteriorating within 24-hours due to ARDS, we will: (i) describe the degree of SkMA and (ii) evaluate relationships between lung parenchyma change and SkMA.

METHODS. Patients with ARDS who presented to hospital, received mechanical ventilation (MV) and vvECMO and underwent thoracic and abdominal computed tomography (CT) imaging within 24-hours were included to ensure an initial measurement of muscle mass as close to pre-morbid baseline . A second CT (at variable intervals) whilst receiving vvECMO was also required. 18 patients met the criteria. Images were assessed for proportions of normal lung, ground-glass opacity (TLGG) and lung consolidation (TLCo) with the sum of the scores giving a total lung parenchyma score (TLS) as previously described **(4)**. Skeletal muscle cross-sectional area (SkMCSA) was calculated at the level of the third lumbar vertebrae **(5,6)** and sarcopenia was determined by the muscle index (=SkMCSA/height2; <55.4cm2/m2 for males, < 38.9cm2/m2 for females). Raters were blinded to all identifiable data and high observer reliability was ensured (intra-class correlation coefficients of >0.9).

RESULTS. The interval between images ranged from 3 to 25 days. The mean decline in SkMCSA was 14.7±11.1% (p<0.001) - equating to a mean daily decline of 2.2±2.4%. All who were sarcopenic at admission (9/18, 50%) were male. Males also had a mean decline in MI of 9.2±6.4% (p<0.001). SkMA (10% over 7 days, or 1.4%/day **(7)**) was more common in men (58% vs. 33%) but not statistically significant. SkMA was associated with lower TV (r=-0.711, p=0.007), higher BMI (r=-0.603, p<0.01) and admission lactate (r=0.535, p=0.02). Patients who were sarcopenic at admission had a longer ICU length of stay (LoS) and greater duration of mechanical ventilation and vvECMO (Table 1). The median change per day in TLCo and TLS was -1.65 points/day (-0.43 to -3.30) and -0.75 points/day (-1.33 to -2.40) respectively – favouring resolution. The median change in TLGG was +0.45 points/day (0.00 to 1.73) indicating increased GG. There was no significant association between SkMCSA decline and parenchymal changes per day, nor between the absolute/daily change of TLCO, TLGG and TLS and ventilator/vvECMO parameters or ICU length of stay.

CONCLUSION. Underlying sarcopenia was significant in those who required vvECMO for severe ARDS within 24-hours of presentation. This led to significant SkMA, with an average decline of 14% over an interval of 3-25 days. Those with sarcopenia had considerably longer ICU LoS and MV and vvECMO duration. The lung parenchyma score needs further validation over longer time periods to understand its utility and its relationship to muscle atrophy and functional restriction in the post-critical illness period.

INTRODUCTION. Recruited lung volume (Vrec) elicited by positive end expiratory pressure (PEEP) can be measured by using either CT scan or pressure-volume (P-V) curve method.
OBJECTIVES. The purpose of this study was to perform a systematic review and meta-analysis of Vrec measured by the P-V curve in patients suffered from Acute Respiratory Distress Syndrome (ARDS). Primary aim was prevalence of recruiters (R). The secondary aims were to compare physiologic data and ICU outcome in R and non-recruiters (NR).
METHODS. We conducted a search on PubMed, including all papers published from inception to 30/11/2018 containing the key words: lung recruitment, alveolar recruitment, volume pressure curve, ARDS, PEEP, humans and adult. Two reviewers independently screened all articles. Articles concerning animals, children, case reports and reviews were excluded. We also excluded studies that didn't measure Vrec by PV curve or in which Vrec was not elicited by PEEP. Disagreements were resolved by discussion. Subsequently, same both reviewers extracted data into a predefined case record form. The data of Vrec was obtained directly from the studies or from reported graphs using the GetData Gaph Digitizer software to retrieve values or by contacting directly the authors. Extracted data also included the baseline value of anthropometric variable, ARDS cause, physiologic characteristic of patients, ventilator settings, respiratory mechanics. Patient outcome at ICU discharge was also recorded. We used the threshold of Vrec > 150 ml to define R patients. Data are expressed as mean±SD. The meta-analysis was performed using R (meta package). For the continuous variables we used the mean difference and for the binary variable the relative risk (RR) with their confidence intervals (C.I.) between R and NR. A random effects model was applied for pooling the data.
RESULTS. From a total of 650 studies, 26 were potentially eligible. After full-text evaluation, 16 articles were kept for the present study and included 316 patients. Vrec was measured between PEEP 5 and 15 cmH2O in 6 papers, from 0 to 15 in 4, from 0 to 10 in 3 and from other range in 3. Vrec averaged 373±146 ml in R and 81±33 ml in NR (P<0.001). The prevalence of R was 71% (0.57; 0.82). The pooled data analysis showed no significant difference between R and NR groups for baseline anthropometric variables, PEEP, tidal volume, PaO2/FIO2, FIO2, Simplified Acute Physiology score 2, ARDS cause, and for days in ARDS before the start of the investigation. However, we found a significantly higher compliance (mean difference 9.40 (C.I. 2.26; 16.53) ml/cmH2O) and significantly lower plateau pressure (mean difference 2.41 (4.11; 0.72) cmH2O) in R than in NR. Finally, mortality at ICU discharge was similar in R and NR: 40.7 (40.0; 41.0) vs: 47.8% (41.0; 55.0) (P=0.40, Fisher exact test), RR 1.11 (0.85-1.45).
CONCLUSION. Most of ARDS patients exhibited lung recruitment after increase in PEEP. However, this recruitement did not correlate with any difference in mortality.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000974

INTRODUCTION. Multiple studies have shown the potential of electrical impedance tomography (EIT) as a tool for monitoring of regional lung function in neonates and infants with respiratory failure. In this high-risk population, EIT can detect one-sided intubation [1], pneumothorax [2, 3] and identify recruitable atelectasis and overdistension [4]. As all previous studies have used EIT for analyzing short and specific episodes, the feasibility and safety of long-term monitoring with EIT has not yet been established.
OBJECTIVES. To assess the feasibility and safety of continuous EIT monitoring for up to 72 hours in neonates and preterm infants at risk for respiratory failure.
METHODS. In the ´**C**ontinuous **R**egional **A**nalysis **D**evice for neonate **L**ungs´ (CRADL) study (clinicaltrials.gov NCT02962505), we determined the feasibility and safety of continuous EIT monitoring for up to 72 hours in critically ill neonates and infants. We included patients needing supplemental oxygen, non-invasive or invasive respiratory support who were treated in neonatal or pediatric intensive care units. After obtaining written informed consent from the parents or legal representatives, a 32-electrode EIT belt was placed around the patient's chest and connected to an EIT image acquisition system (Sentec BB2, Landquart, Switzerland). At the bedside, investigators were blinded to the EIT findings but were prompted by the device to reattach the EIT belt if a loss in electrode contact occurred. The maximum duration of EIT examinations was 72 hours, but examinations could be terminated earlier, e.g. if the patients were discharged or transferred to another unit.
The study was conducted between November 2016 and March 2019 at four European university hospitals. As a primary outcome parameter, we assessed the overall percentage of EIT examination time with at least 26 out of 32 electrodes exhibiting sufficient skin contact impedance, the minimum required for reliable EIT image reconstruction with the Sentec BB2 system. Numerical results are presented as mean±SD unless otherwise specified.
RESULTS. 200 patients were included in the study. For our preliminary analysis, we included the first 194 data sets of 117 male and 77 female patients with a gestational age of 31±5 (range: 24-42) weeks and postnatal age of 5±15 (range: 0-122) weeks. The most frequent diagnoses explaining the need for respiratory support included

prematurity, respiratory distress syndrome, meconium aspiration and bronchopulmonary dysplasia.
The average duration of EIT measurements was 54±21 hours. The percentage of EIT examination time suitable for analyzing as defined in the primary outcome parameter was 84.7±17.6%. No moderate or severe study-related adverse events were recorded. Minor study-related adverse events included reversible redness of skin or imprint of EIT belt on the patient´s skin.
CONCLUSION. In the CRADL observational study, continuous EIT measurement for up to 72 hours was feasible and safe in a mixed population of neonatal and pediatric critically ill patients with respiratory failure.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000977

INTRODUCTION. ARDS remains a major cause of morbidity and mortality and standard of care involves the treatment of the underlying cause and supportive care [1]. The Phase III clinical study of a new potential treatment - Interferon beta-1a [2] - yielded disappointing mortality outcomes, in part thought to be related to the concomitant corticosteroid use. Steroids are commonly used for septic shock (SS) and for several indications associated with ARDS. They have been used in ARDS to improve oxygenation and airway pressures, however the effectiveness on ARDS mortality is debatable [3].
OBJECTIVES. We aimed to identify the current ICU practice around steroid use at UCLH in relation to the severity of ARDS as per the international definition and SS.
METHODS. Demographic data, physiologic scores and outcomes, from January 2017 to January 2018 of our 45 bed ICUs, were accessed via the Unit's electronic record system Philips Intellivue. ARDS patients were defined as: mechanical ventilation requirement >48h, ARDS diagnosis stated in medical notes and ARDS severity according to the Berlin definition. SS patients were defined as a noradrenaline requirement.
RESULTS. 56 patients were documented as having ARDS, with 44 (79%) receiving steroids (28-day mortality - 64% on steroids and 25% no steroids). 28 (50%) of all patients had concomitant SS diagnosis (Table 1).
Of those without SS, only 3 (16%) received steroids for ARDS and 1 (5%) for PCP; 15 (79%) did not have a clear indication but the majority were haematological malignancy patients (HMP). Of those with SS, 10 (40%) received steroids per SS protocol, 2 (8%) per ARDS protocol, 1 (4%) for PCP and 13 (52%) did not have a clear indication but again were commonly HMP.
CONCLUSION. Septic shock-related ARDS patients had a higher overall disease severity, mortality and ventilatory support requirement. 79% of patients with ARDS were treated with steroids, mainly not for ARDS indications and appeared to have a higher mortality rate. This high level of steroid use may have implications for trials in ARDS.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001018

INTRODUCTION. Left ventricular diastolic dysfunction (LVDD) is quite common in critically ill patients. Echocardiography plays a vital role in identifying diastolic dysfunction at the bedside. It has been demonstrated to have a strong association with weaning failure, abrupt pulmonary edema and sepsis outcome.
OBJECTIVES. Aim of this study is to investigate the prevalence of LVDD during the early phase of acute respiratory distress syndrome (ARDS) and its relationship with lung mechanical properties.
METHODS. We enrolled mechanically ventilated patients within 48 hours after ARDS diagnosis. Demographic characteristics and partitioned respiratory mechanics variables were recorded; CT scan quantitative analysis was performed at two levels of airways pressure for the evaluation of recruitability; functional residual capacity (FRC) was measured by helium technique. Transthoracic echocardiography, including Pulse wave doppler and Tissue doppler imaging, was performed to measure during early left ventricular diastolic phase the velocity of intracardiac blood flow at the tip of mitral valve (E') and the longitudinal excursion of the septal mitral annulus (e'). LVDD diagnosis was made when septal e' < 8 cm/sec.
RESULTS. 10 of 16 patients presented a normal LV function [ND], 6 patients (37.5%) had a LVDD diagnosed [DD], 4 patients had a grade II dysfunction. No significantly differences were reported in terms of demographic, hemodynamics, respiratory variables and CT parameters between groups. DD group presented a significantly higher FRC (756 [450 – 878] mL vs. 403 [116 – 490] mL, P = 0.038) but a higher dead space compared to ND. DD patients demonstrated significantly higher 28 days mortality compared with ND (5/6 = 83% vs. 2/10 = 20%, p = 0.035).

CONCLUSION. We did not find any relationship between ARDS severity and the LVDD development. The higher FRC and dead space in DD patients could be due to the presence of emphysema in lung parenchyma. The higher 28-day mortality in DD patients should be further investigated.

INTRODUCTION. In patients with acute respiratory failure, changes affecting respiratory mechanical property (compliance and resistance) and the applied ventilatory setting can generate an incomplete deflation of the respiratory system at end-expiration, promoting a dynamic hyperinflation and intrinsic PEEP (iPEEP).
OBJECTIVES. Aim of this study was to evaluate in a large population of ARDS patients mechanically ventilated, the presence and the amount of iPEEP, the possible associated factors (patients characteristics and ventilator setting) and the effect of two levels of external PEEP on iPEEP.
METHODS. A secondary analysis of patients previously enrolled in 6 published studies. Patients were divided according to the presence of iPEEP. The iPEEP was computed as the difference between total PEEP measured at the end of an expiratory pause and external PEEP measured at end-expiration of a regular breath. 5 and 15 cmH2O of PEEP were applied. Lung CT scan was performed at 5 and 45 cmH2O of PEEP.
RESULTS. 217 sedated and paralyzed patients were enrolled. iPEEP was detected in 87 patients. Eighty-seven patients (40%) had iPEEP with a median value of 1.1 [1.0-2.3] cmH2O at 5 cmH2O of PEEP.
Patients with intrinsic PEEP had a significantly higher body mass index and arterial carbon dioxide partial pressure.
Both at 5 and 15 cmH2O of PEEP the applied tidal volume was significantly lower (480 [430-540] vs 520 [445-600] mL at 5 cmH2O of PEEP; 480 [430-540] vs 510 [430-590] at 15 cmH2O of PEEP) in patients with intrinsic PEEP while respiratory rate was significantly higher (18 [15-20] vs 15 [13-19] bpm at 5 cmH2O of PEEP; 18 [15-20] vs 15 [13-19] bpm at 15 cmH2O of PEEP).
At both PEEP levels, total airway resistance and compliance of the respiratory system were not different among patients with and without iPEEP.
The total lung gas volume and the lung recruitability were not different among patients with and without iPEEP (961 [701-1535]vs 973 [659-1433] mL; 15 [0-32] % vs 22 [0-36] % respectively).
CONCLUSION. In our population iPEEP was detected in 40% of ARDS patients. In sedated and paralyzed ARDS patients the amount of intrinsic PEEP during lung protective ventilation is of negligible entity and does not influence gas exchange and respiratory mechanics properties.

Effects of super-nasal high flow (S-NHF) on lung volumes and comfort in critically ill hypoxemic patients: preliminary results

G. Montanari[1], F. Dalla Corte[1], G. Grasselli[2], A. Galazzi[2], F. Migliavacca[2], E. Spinelli[2], T. Mauri[2], A. Pesenti[2]

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001026

INTRODUCTION. Nasal high flow (NHF) in hypoxemic patients is usually delivered at flows of 30-50L/min and recent studies [1] showed that higher flow rates may improve the benefit of NHF. However, only one study in healthy volunteers showed that NHF delivered at flows >60 L/min (super-nasal high flow (S-NHF)) is associated with physiologic advantages [2].
OBJECTIVES. Aim of this study was to compare differences in oxygenation, end-expiratory lung volume, minute ventilation and patient's comfort by NHF delivered at three different gas flow rates: 0.5 L/min/Kg PBW, 1 L/min/Kg PBW; and 1.5 L/min/Kg PBW (S-NHF).
METHODS. we performed a prospective, interventional, randomized cross-over trial in patients with hypoxemia (PaO2/FiO2≤300 mmHg) admitted to the Intensive Care Unit of Ospedale Maggiore Policlinico in Milan. We delivered stable air/oxygen mix to obtain saturation of 90%-96% during all phases. Flow was set as detailed above for 20 minutes. At the end of each phase, data on lung volumes were recorded by EIT (Dräger Medical GmbH, Lubeck, Germany), ABG was performed and comfort was collected by visual numeric scale (0-10). Statistics were performed by one-way repeated measures ANOVA. Normally distributed variables are represented by means and SD, while median [IQR] have been used for non-normal.
RESULTS. We enrolled 7 patients (73±11) years old, 4 females,baseline PaO2/FiO2(166±47). During S-NHF, End Expiratory Lung Impedance (DEELI) significantly increased in comparison to lower gas flow rates (p=0.017), indicating larger PEEP effect, and Global Inhomogeneity (GI) of ventilation distribution was reduced. PaO2/FiO2, respiratory rate and corrected minute ventilation (MVcorr), instead, remained stable. Finally, S-NHF was associated with significantly poorer patient's comfort.
CONCLUSION. S-NHF might be associated with partial improvement of the physiologic effects of NHF at the expense of lower patient's comfort.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000567

INTRODUCTION. Cardiac surgery with cardiopulmonary bypass (CPB) is associated with significant microcirculatory impairment that may impact patient outcomes.1 Post-operative resuscitation routinely targets normalized systemic hemodynamic goals to achieve adequate tissue perfusion. Functional microcirculatory derangements are well described in sepsis, but poorly understood after cardiac surgery. Incident dark field videomicroscopy (IDF) allows for high resolution, real-time functional assessment of human microcirculation.
OBJECTIVES. To evaluate changes in microcirculatory function after resuscitation from cardiac surgery compared to baseline measurements when targeting normalization of systemic hemodynamic indices and identify phenotypes of microcirculatory dysfunction when compared with arterial lactate levels.
METHODS. These are preliminary results from an ongoing prospective, observational, single center study of elective CABG or valvular surgery patients. Sublingual microcirculation measurements (CytoCam, Braedius Medical BG, the Netherlands) were obtained in the pre-operative ward and in ICU 2-4 hours post-op once hemodynamic indices were normalized. Measurements were required to have a quality score < 10. Microcirculation videos were analyzed manually, measuring criteria based on ESICM 2nd consensus recommendations.3
RESULTS. We enrolled 20 subjects, median (IQR) age 63 years (55-71), 85% male, cardiopulmonary bypass time 115 min (82-143). Post-operative macrocirculatory indices were MAP 75 mmHg (70-83), CI 2.3 L/min/m2 (2.0-2.9), CVP 10 (7-12). Post-operative SvO2 was 72% (62-77), and arterial lactate 5.0 mmol/dL (2.1-8.6). Compared to pre-operative measurements, post-operative convective flow was significantly impaired. MFI (AU) 2.9 (±0.1) vs. 2.2 (±0.5), p<0.0001, PPV (%) 93.7 (±3.2) vs. 75.1 (±12.8), p<0.0001, with significant heterogeneity, HI (AU) 0.1 (±0.1) vs. 0.6 (±0.3), p<0.0001. Diffusive capacity was significantly impaired, PVD (mm/mm2) 21.5 (±3.3) vs. 15.8 (±3.9), p< 0.0001, and TVD (mm/mm2) 21.2 (± 4.6) vs. 19.1 (± 3.9) p≤0.05.
CONCLUSION. An elevated lactate level after resuscitation from cardiac surgery is associated with a significant reduction in both microcirculatory convective blood flow and diffusive capacity.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000653

INTRODUCTION. Cardiac surgery in dialysis-dependent patients is associated with high mortality and morbidity (1). Lactate is a well-known marker of ischemia and a prognostic indicator, and kidney and liver play the main role in lactate metabolism (2). Although several studies proved the association between hyperlactatemia and prognosis in cardiac surgery (3), the prognostic relevance of lactate levels in dialysis-dependent patients is not well characterized.
OBJECTIVES. We aimed to evaluate the prognostic value of hyperlactatemia on the mortality and length of intensive care unit (ICU) stay in dialysis-dependent patients who had undergone cardiac surgery.
METHODS. This was a multicenter retrospective study and we included dialysis-dependent patients who underwent cardiac surgery with cardiopulmonary bypass between January 2014 and December 2018 at two mid-size private hospitals. Lactate data were collected at three time-points: at ICU admission (T1); peak level within 24 hours after the operation (T2); and 24 hours after the operation (T3). Lactate clearance was calculated using the following formula: (T2 lactate −T3 lactate)/T2 lactate × 100. We also obtained patient characteristics, hospital mortality, length of ICU stay, and days to return to dry weight after the operation. Prolonged ICU stay was defined as the 70th percentile of subjects. Using ROC curve analysis, we examined which point of lactate predicted hospital mortality and prolonged ICU stay. All statistical analyses were performed using software R (Ver.3.4.2).
RESULTS. We enrolled 122 dialysis-dependent patients. The median age was 73 (IQR 69-78) years, and hyperlactatemia was observed in 97 (79.5%) patients. Hospital mortality was 11.5%, median ICU stay was 7 (IQR 5.0-10.8) days, and the median days to return to dry weight were 8 (IQR 5.0-12.3) days. Prolonged ICU stay was defined as ≧10 days by the 70th percentile of ICU stay. On ROC-AUC analysis, T2 lactate showed the strongest association with hospital mortality (AUC 0.848) and the cutoff level was 10.6 mmol/L; T1 lactate showed the strongest association with prolonged ICU stay (AUC 0.778), and the cutoff level was 2.0 mmol/L.
CONCLUSION. Peak lactate level within 24 hours after the operation was associated with hospital mortality and lactate at the ICU admission was associated with prolonged ICU stay.

INTRODUCTION. Arrhythmias are common clinical events in the intensive care unit (ICU) and its impact on continuum of critical illness is unclear.
OBJECTIVES. To study type of arrhythmias in critically ill patients and its association with diagnoses, duration of ICU stay and clinical outcome.
METHODS. Retrospective study of 360 patients admitted to medical ICU over 3 months period. Socio-demographic data, associated co-morbidities, arrhythmias identified and interpreted, ICU diagnoses and various clinical outcomes [mortality, ICU-length of stay (ICU-LOS)] were studied.
Inclusion criteria: age > 18yrs
Exclusion criteria: Arrhythmias and other waveforms present during ACLS or CPR.
RESULTS. Out of the 360 patients admitted to ICU during study period 50pts (13.88%) had arrhythmias , with 46 pts having 1 event , 2 pts having 2 events and 2 pts having 3 events. Of these 50 pts, 61% patients had supra-ventricular Arrhythmias, 18% patients had ventricular Arrhythmias and 21% patients had premature complexes. The socio-demographic profile and select clinical variables of patients is shown in Table 1. Most Arrhythmias (76% events) occurred in first 3 days of ICU stay, Atrial fibrillation being the most common. Patients with dys-electrolytemia and myocardial infarction upon admission had increased risk of developing Supra-ventricular arrhythmias. Development of Ventricular arrhythmias was not found to be associated with any particular clinical mediator. Patients with Ventricular arrhythmias had increased risk of in-hospital mortality (P<0.05). Patients with Supra-ventricular Arrhythmias were associated with increased duration of ICU stay (5.2days) as compared to patients with premature complexes and ventricular arrhythmias, though not clinically significant (p= 0.06).
CONCLUSION. Arrythmias occurring in critically ill patients increase in-hospital mortality and ICU-LOS.

INTRODUCTION. Primary coronary intervention (PCI) in STEMI has advantage over fibrinolysis in terms of mortality and complications. Hospitals implement its availability during 24 hours for all patients with STEMI.
OBJECTIVES. Evaluate the impact of disponilility of PCI during 24 hours for all STEMI treated in our hospital, Juan Ramón Jiménez Hospital
METHODS. Analytical descriptive study of prospective cohort of regional database of Andalusia (ARIAM) of patients with STEMI admitted to Intensive Care Unit between January 2017 and January 2019. From June 2018 the PCI was available 24 hours, being all patients with STEMI referred to our hospital and indicated by the emergency doctor in charge of patient. Prior to this, the indication of PCI was based on classical criteria, indicated by intensivist in case of cardiogenic shock, contraindication or failed of fibrinolysis in of-time work and like fist election in-time work. We used SPSS statistical software with chi-square for frequency analysis and t student for medians. The significant result was defined as p<0,05.
RESULTS. There are 206 patients, 82,1% males, median age of 62 years. The most frequent presentation was anterior AMI (43,5%), Killip I (62,8%) with LVEF 46,5%. The 53,9% was hypertensive, 48,5% smokers, 44,2% dyslipidemics, 33,5% diabetics and 19,4% chronic ischemic heart disease. The 44% presented complications, and they are cardiorespiratory arrest (10,6%), cardiogenic shock (9,7%), hypotension (7,7%), complete nodeatrial block (4,8%), coronary dissection (3,9%), ventricular tachycardia with pulse (3,9%), stent thrombosis (2,9%) and haemorrhage (0,5%). The 84 patients presented before 24 hours disponilility of PCI and 122 patients after this period. The group of pre-disponilility period, had significantly difference (p<0,05), with predominance of inferior (36,9 vs. 22,1%) and undetermined AMI (3,6 vs 0%) and presented more Killip III (14,3 vs 4,9%).

The other characteristics was similar between the groups. The implementation of PCI 24 hours shown reduction of hypotension (14,3 vs 3,3%, p= 0,003), statistically significant, and, in time from first medical contact to PCI (175 vs 136 minutes, p=0,07) and from first electrocardiogram to PCI (156 vs 118 minutes, p=0,06), in overall mortality (6,0 vs 2,4%, p=0,2) with related to myocardial ischemia (4,8 vs 1,6%, p=0,19) and cardiogenic shock (13,1 vs 7,4%, p=0,17), but non-statistically significant.
CONCLUSION. The availability of PCI 24 hours has significantly affected the reduction of several factors that coan influence in unforable evolution of patients with AMI as hypotension or worse killip. Its implementation has improved time from first medical contact to PCI and reduction of global mortality but in a trend non-statistically significant. Its possible needs more following in time of our population to see more changes in outcomes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000749

INTRODUCTION. Admission for symptomatic bradycardia in the ICU is frequent and the initial therapeutic option, while waiting for permanent pacemaker implantation, depends on the severity of symptoms, the center's infrastructure, and the personnel who perform the care. This study tries to describe the clinical outcome of the three most frequently used therapeutic options before definite pacemaker implantation: temporary transvenous pacemaker (TTVP), chronotropic drugs (C+) and observation (OBS).
OBJECTIVES. To analyze the characteristics and clinical outcomes of three initial therapeutic options (TTVP, C+, and OBS) in patients admitted to the ICU due to symptomatic bradycardia.
METHODS. A retrospective cohort study of patients admitted to the ICU due to symptomatic bradycardia [symptomatic atrioventricular block (sAVB), sinus node dysfunction (SND), hyperkalemia (HK), drug overdose (OD), etc.] from January 2014 to December 2018.
We collected demographic data: age and sex; and clinical variables: APACHE II, diagnosis at admission, low cardiac output, agitation, time from ICU admission to permanent pacemaker implantation (TPPM), length of stay in ICU (LSICU) and in the hospital (LSH); the last three measured in days.
The demographic variables were compared by $\chi 2$ and the quantitative ANOVA or nonparametric test (Kruskal-Wallis).
RESULTS. We analyzed 137 patients divided into 3 groups: TTVP: 86, C+: 19, OBS: 32. Of these 54% were men; median age 80.5 (IQR: 72.5-85.5).
The APACHE II median was 14 (IQR: 10-17) with no significant differences (NSD) between the 3 groups (p = 0.200).
The most frequent diagnosis was sAVB (82.5%), with NSD in the type of bradycardia between the 3 groups (p = 0.146).
There where NSD in low cardiac output between the 3 groups (p = 0.535).
Agitation was more frequent in the TTVP (22.1%) and C+ (26,3%) groups compared with OBS (3.1%), although with NSD (p=0,037).
The TPPM (days) was 0.85 (0.61-1.81) in TTVP; 0.88 (0.73-1.02) in C+; and 0.83 (0.6-1.75) in OBS; with NSD between the 3 groups (p = 0.275).
The LSICU (days) was significantly larger in TTVP: 1.65 (1-2.38) in TTVP; 1.1 (1.03-2.17) in C+; 1.06 (0.9-1.35) in OBS (p = 0.028).
The LSH (days) was 4.8 (3.91 - 5.69) in TTVP; 4.78 (1.96-7.6) in C+; 3.83 (3.03-4.63) in OBS; with NSD between the 3 groups (p = 0.334).
Four patients in the OBS group (12.5%) and two patients in the C+ group (10.53%) required an urgent placement of TTVP.
CONCLUSION. In our series, there were no significant differences between the three groups in any of the studied variables, except for LSICU days, in which case it was significantly larger in TTVP.
There was a higher incidence of agitation in the TTVP and C + group, although with no significant difference.

INTRODUCTION. Peripheral arterial catheters are invasive hemodynamic monitoring devices used in intensive care unit and are considered the gold standard in blood pressure monitoring. Although even if the risk of complication is low, arterial catheters are not harmless and can result in ischemia, infection and thrombosis.
OBJECTIVES. We carried out this prospective analysis to evaluate the hypothesis that non-invasive blood pressure (NIBP) monitoring would be as accurate as invasive blood pressure (IABP) monitoring in certain situations. We also evaluated whether the deviation of pressure transducer would affect the results of IABP.
METHODS. For the NIBP measurements, oscillometric blood pressure measurements were performed; cuff size was selected on the basis of the patient's limb circumference. For the IABP measurements, a 20-G arterial catheter was present in the radial artery. The transducer system was connected to the arterial catheter. The pressure transducer was placed at the level of the heart and zero-calibrated to atmospheric pressure. For the study it was elevated 10cm upward and downward from zero. The correlations between invasive and noninvasive values were assessed using Pearson correlation coefficient. Agreements between invasive and noninvasive blood pressure methods were assessed using Bland–Altman analysis and t-test. All summarized values are presented as mean ± SE. P-value of less than 0,05 was considered statistically significant.

RESULTS. In total, 80 patients were analyzed the study included 3 different groups: control, arrhythmia, vasopressor. The mean age was 59,1±17,0. The mean BMI was 27,4±4,6 kg/m2. The correlation coefficients between invasive and noninvasive devices for systolic, diastolic, and mean arterial pressure were all significantly correlated with P-values of less than 0,0001. The mean biases for IABP and NIBP with brachial cuff SAP were 0,36±11,5 mmHg, DAP −6,25±5,96mmHg, and MAP -5,53±5,5mmHg although with thigh cuff SAP were -6,15±10,2 mmHg, DAP -5,11±6,9mmHg, and MAP -6,4±5,6. The mean biases for mean IABP and NIBP in control group were -5,4±5,48mmHg (brachial), -5,78± 5,77mmHg (thigh), in group with arrhythmias -4,75±6,14mmHg; -6,35± 5,46mmHg, in group with vasopressor dose 0,1-0,2mcg/kg/min were -5,69±4,4mmHg; -6,3±4,1mmHg, and with dose >0,2mcg/kg/min were -8,14±6,17mmHg; -10,29±6,97mmHg. The correlation coefficients between invasive arterial pressure before and after pressure transducer ascending 10cm and descending 10cm from zero were all significantly correlated with P-values of less than 0,001. The mean biases for calibrated IABP and 10cm higher IABP transducer was 7,85±2,6mmHg and for 10cm lower was -7,59±2,56mmHg.
CONCLUSION. NIBP monitoring is not as accurate as IABP monitoring in patients especially with high vasopressor doses. Although NIBP monitoring is more accurate than erroneously calibrated IABP in most cases.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000827

INTRODUCTION. Atrial fibrillation (AF) is a common arrhythmia in Intensive Care Units (ICUs). It is suggested that different mechanisms related to patients previously diagnosed with AF are related to the development of this pathology during ICU stay. Thus, the present study aims to compare the profile of patients and factors associated with new onset and chronic AF.
OBJECTIVES. To assess the incidence and differences of new onset and chronic AF in patients admitted to the general ICU.
METHODS. Retrospective cohort of patients with AF, admitted to an adult general ICU between August/2015 and August/2018. Data was prospectively extracted from patient records. The D'agostino test was used to determine the normality of the studied variables and to evaluate the difference between means and risk, the student`s T-test and Chi-square test were respectively used.
RESULTS. 2401 patients were admitted, of whom 247 (10.29%) presented AF during their hospitalization. Patients with chronic AF represented 61.13% (n = 151) of our population, with a mean age of 77.59 ± 11.10 and mean SAPS3 score 51.94 ± 9.65. The majority were women [n = 131, (86.75%)], and, of these 26.49% (n=40) presented associated with cardiovascular diseases. New onset AF (NoAF) corresponded to 38.86% (n = 96), with female gender predominating 57.29% (n = 55), mean age = 76.53 ± 15.02, BMI 26.24 ± 6.01, SAPS 3 = 51.08 ± 12.57 and of those 39.58% (n = 38) presenting with cardiovascular diseases. There was identified a higher risk for the development of NoAF in patients with cardiovascular diseases [OR (95% CI) 1.8 (1.053-3.139); p = 0.031]. Mean arterial pressure (MAP) was higher in patients with NoAF (95.0 ± 21.8 vs 103.1 ± 22.6, p = 0.01), as well as C-reactive protein (CRP) = 86, 5 ± 68.1 vs 109.1 ± 72.9; p = 0.037. There were no differences between the groups (chronic / NoAF) regarding outcome variables, such as length of hospital stay, use of vasoactive drugs or mechanical ventilation, changes in sodium, potassium and mortality.
CONCLUSION. In this cohort of critically ill patients, the incidence of AF was similar with literature. Demographic characteristics were similar in the new onset and chronic AF groups, but patients with cardiovascular diseases had higher incidence of NoAF. Higher MAP and CRP values was identified in NoAF patients compared with chronic AF patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000857

INTRODUCTION. Little is known about the level of distress experienced by patients hospitalized with Acute Coronary Syndrome (ACS)
OBJECTIVES. To describe levels of physical, psychological and spiritual distress among patients admitted to a hospital with Acute Coronary Syndrome (ACS)
METHODS. Every Israeli patient admitted to a hospital over a 2 month period with ACS (n=1958) was included in a bi-annual, national, two month prevalence study, Acute Coronary Syndrome Israel Study (ACSIS). Clinical medical data were collected for the entire sample. A convenience sub-sample of these patients (n=990) completed the Distress Thermometer. Demographic and clinical data were taken from the patient's medical record.
RESULTS. The mean overall level of distress was 4.6/10 (Median= 5, *S.D.* = 3.5). The most common source of physical distress was discomfort (n=527, 54.7%), followed by fatigue (n=598, 62%). Most were worried (n=506, 53%) with many reporting feelings of depression (n= 139, 15%) or sadness (n=238, 25%). Few reported having spiritual or religious concerns (n=18, 2%).
CONCLUSION. Patients admitted to a coronary care unit with ACS experienced moderate levels of distress, from both physical and psychological sources. While previous reports have described distress after discharge, this study provides evidence that such responses are already present in the immediate, acute phase of illness.

Hydrogen selenide as the 4th gasotransmitter: a metabolic modulator with potential therapeutic utility in acute/critical illness states

K. Samra, M. Singer, A. Dyson
University college london, Bloomsbury Institute of Intensive Care Medicine, London, United Kingdom
Correspondence: A. Dyson

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000883

INTRODUCTION. The endogenous 'gasotransmitters' – nitric oxide (NO), carbon monoxide (CO) and hydrogen sulphide – are anti-inflammatory, directly inhibit oxidative phosphorylation, and depress metabolic activity. They have potential therapeutic utility in hypoxia, ischaemia/reperfusion and circulatory shock [1]. Selenium is an essential micronutrient and an important antioxidant [2]. Its physiological derivative, hydrogen selenide (comprising gaseous H2Se and the anion, HSe-) was recently proposed as the fourth gasotransmitter [3]. It offers potential as a metabolic modulator *and* antioxidant therapy in critical illness.
OBJECTIVES. To characterise the basic salt, sodium hydrogen selenide (NaHSe), and investigate its effects on mitochondrial function.
METHODS. Sodium hydrogen selenide (NaHSe) was synthesized as described [4]. H2Se gas liberated by the salt was measured using a commercially available detector. Chemical reduction of oxygen to water was assessed in closed chambers. Effects of NaHSe on oxidative metabolism *ex vivo* was assessed by oxygen consumption (soleus muscle) and cytochrome C oxidase activity (liver). Sodium hydrogen sulfide (NaHS), K-cyanide (KCN) and the reducing agent, sodium dithionite, acted as positive controls. *In vivo* pharmacology of intravenous NaHSe was assessed in anaesthetised, instrumented rats.
RESULTS. H2Se gas was detectable from vials containing dissolved NaHSe (Fig 1A). Selenide was a powerful reducing agent (Fig 1B) and dose-dependently decreased muscle oxygen consumption (VO2) (Fig 1C), and inhibited cytochrome C oxidase activity (Fig 1D). Hydrogen selenide was less potent than both sulfide and cyanide (Fig 1C, D), and its activity on mitochondrial function was transient (Fig 1D). *In vivo*, hydrogen selenide exhibited a striking effect on heart rate (Fig 1E).
CONCLUSION. Hydrogen selenide caused significant (and, desirably, transient) metabolic effects via inhibition of cytochrome C oxidase (mitochondrial complex IV). In keeping with the known activity of other gaseous mediators (NO, CO, sulfide) as inhibitors of complex IV, hydrogen selenide can indeed be considered the fourth gasotransmitter. The metabolic and antioxidant effects of hydrogen selenide warrant further investigation as a therapeutic agent.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000967

INTRODUCTION. Peripheral veno-arterial extracorporeal membrane oxygenation (pVA-ECMO) has become an accepted treatment option for advanced cardiogenic shock, allowing myocardial recovery as well as limiting or even reversing secondary end-organ damage.[1] Respiratory management of patients on pVA-ECMO-ECMO, in particular extubation and spontaneous breathing without ventilator support, remains controversial.
OBJECTIVES. We therefore developed a prediction model to study the effect of spontaneous breathing without ventilator support (ventilator-free time) during pVA-ECMO on hospital discharge outcome.
METHODS. After IRB approval, we retrospectively analyzed data from 265 patients undergoing pVA-ECMO for cardiogenic shock with or without concomitant acute respiratory failure. We classified hospital discharge outcome as unfavorable (death/hospice), intermediate (skilled nursing facility/other acute care hospital), and favorable (rehabilitation facility/home). We extracted patient demographics, clinical findings, and laboratory results from the electronic medical records. Statistical analyses included Wilcoxon test, chi-square test, Fisher's exact test as well as machine learning based analytics for model development. P <0.05 was considered statistically significant. Data are given as median (interquartile range).
RESULTS. Hospital discharge outcome of all patient was as follows: 41.6% unfavorable, 22.3% intermediate, and 36.2% favorable. Overall hospital length of stay was 21.6 days (12.1-37.9); pVA-ECMO duration was 7.9 days (4.3-16.7). 26.5 % of all patients were ventilator-free during 29.8% (10.9-51.7) of their time on pVA-ECMO. Overall vascular complication rates were low and statistically not significantly different between patients who were extubated and those who were not. After variable selection by means of generalized regression with machine learning validation, we fitted a proportional odds model to predict hospital discharge outcome with the following independent variables: age, race, cardiovascular SOFA scores, respiratory SOFA scores, lactate levels, need for durable mechanical circulatory support after pVA-ECMO, and ventilator-free time (as % of pVA-ECMO duration). In addition to age, need for durable mechanical circulatory support after pVA-ECMO, cardiovascular SOFA score at the end of pVA-ECMO, and respiratory SOFA score at the beginning of pVA-ECMO, ventilator-free time emerged as a significant predictor for hospital discharge outcome [odds ratio 1.18 (95% CI 1.04-1.34) per 10% increase, p=0.011].
CONCLUSION. Analysis of our cohort suggests that patients can be safely extubated during pVA-ECMO without any relevant adverse effects. Moreover, our data allows us to hypothesize that ventilator-free time during pVA-ECMO is an independent predictor of hospital discharge outcome.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000996

INTRODUCTION. In pulmonary arterial hypertension (PAH), abnormal proliferation of vascular smooth muscle cells, inflammation and pulmonary vascular remodeling are prominent features. Severalstudieshave demonstrated that both hypoxia-induced factors-1 (HIF-1) and p21-activated kinase-1 (PAK-1) are involved in the regulation of cell growth, leading to vascular remodeling.Our previous study showed that intraperitoneal administration ofinduced pluripotent stem cells (iPSCs) improves the function of hemodynamics in lung of monorcotaline (MCT) or hypoxia-induced PAH rats. In recent years, therapeutic benefit of iPSCs may be

mediated by a paracrine effect of exosomes.However,the underlying mechanisms mediating these protective effects remain obscured.
OBJECTIVES. To determine whether iPSC-derived exosomes (iPSC-Exos) treatment can improve chronic hypoxia-induced PAH and vascular remodeling in rats, as well as to identify the mechanisms underlying these effects.
METHODS. iPSC-Exos were intraperitoneal injected daily to a chronic hypoxia-induced PAH rat model which under 10% Oxygen concentration for 8 weeks. The protocol of iPSC-Exos were designated as (i) prevention by the provision of iPSC-Exos treatments on same time with under hypoxia condition, or (ii) reversal by administration of iPSC-Exos treatments after hypoxia situation for 4 weeks. The phenomenon of vascular remodelingwere assessed by immunohistochemical and Elastic Van Gieson staining.Hypoxia-induced HIF-1a and PAK1 expression were determined by Western blotting and qPCR.Furthermore, MTT assay and BrdU staining, and TUNEL assay were used to analyze hypoxia-induced pulmonary smooth muscle cells (PASMCs) proliferation and apoptosis, respectively.
RESULTS. The *in vivo* study demonstratedthat administration of iPSC-Exos group decreases the hemodynamic values of RVSP and ameliorates the lumen diameter and wall thickening of pulmonary arterioles in hypoxia-induced PAH.Histological examination of lung tissue showed that the levels of HIF-1a and PAK1 was lower in the iPSC-Exos group than the no-treatment group. Administration ofiPSC-Exossignificantly inhibited hypoxia-induced HIF-1a and PAK1 expression inlung tissue lysates revealed by Western blotting and qPCR.Similar to the results observed in vivo,treatment of PASMCs with iPSC-Exossignificantly inhibitedhypoxia-induced HIF-1a and PAK1 protein and mRNA expression.By MTT assay and BrdU staining, the proliferation of PASMCs induced by hypoxia was significantly inhibited by pretreatment with iPSC-Exos. By TUNEL assay, iPSC-Exos promoted PASMCs apoptosis in response to hypoxia stimulation.
CONCLUSION. Our findings showed that iPSC-Exos exerts a protective effect on pulmonary vascular remodeling in hypoxia-treated PAH model through down-regulation of HIF-1a and PAK1,leading to ameliorate hemodynamic values of RVSP. In PASMCs, iPSC-Exosinhibits hypoxia-induced HIF-1a and PAK1 signaling pathway and blocks excessive cell proliferation. iPSC-Exos also prevents the resistance of PASMCs to apoptosis. These finding may provideuseful information about iPSC-Exos as a new therapeutic strategy for PAH diseases.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001035

INTRODUCTION. Acute circulatory failure is a life-threatening condition. Fluid loading aims to increase cardiac output and restore organ perfusion. Only 50% of patients are fluid responders, while the remainder are at risk of volume overload (peripheral and pulmonary edema).
Electrical impedance tomography (EIT) shows lung impedance as determined by small electrical currents. An increase in intrapulmonary gas volume increases impedance, while an increase in blood or fluid volume, lowers it. In healthy volunteers, saline administration led to a decrease in lung impedance.
OBJECTIVES. Aim of the present study was to assess the effect of a fluid challenge on EIT-derived lung impedance in critically ill patients with acute circulatory failure.
METHODS. Hemodynamic and respiratory variables, blood samples, cardiac ultrasound and EIT measurements were recorded before a 5 ml/kg fluid challenge, and repeated at the end of fluid infusion and 20 minutes after. As a surrogate for stroke volume, the pulsed-wave Doppler examination of the left-ventricular outflow tract velocity-time integral (VTI) was measured; an increase >15% of VTI identified fluid responders. Factorial analysis of variance for repeated measures was used to compare the values obtained during each study phase.
RESULTS. We enrolled 13 patients (8 males, age 70±10 years, BMI 26±4 kg/m2). The average volume of the fluid challenge was 280±90 ml. 5 patients were fluid responders (38.5%).
Systolic blood pressure significantly increased with fluid challenge (105± 13 vs. 119±24 vs. 121±26 mmHg, p=0.005), as did the VTI (19.5±4.2 vs. 22.1±5.6 vs. 21.9±5.4 mm, p=0.002). End-expiratory lung impedance significantly decreased after fluid administration: 1700±814 vs. 431±436 vs. 207±202 arbitrary units, p<0.001. The decrease in lung impedance was associated with worsening oxygenation (R=0.560, p=0.047) (Figure 1).
CONCLUSION. Electrical impedance tomography, thanks to its high temporal resolution, could be a valuable tool to assess the effect of fluid loading on lung water.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001043

INTRODUCTION. Accurately predicting fluid responsiveness in the critically-ill remains a challenge. Point-of-care ultrasound assessment of corrected carotid flow time (cFT) has been proposed as a feasible, non-invasive means of determining fluid responsiveness.1Prior research found a change in cFT of 7ms following a passive leg raise, as measured by expert sonologists, was able to predict fluid responsiveness in patients with undifferentiated shock.2
OBJECTIVES. We aimed to prospectively evaluate the ability of point-of-care ultrasound assessment of cFT performed by novice sonologists enrolled in a medical critical care fellowship, to predict fluid responsiveness in critically-ill intensive care unit patients.
METHODS. Three novice sonologists performed point-of-care ultrasound assessments of cFT in 115 intensive care unit patients with suspected volume depletion admitted at two urban academic medical centers from November 2016 to July 2018. The novice sonologists received a 6-hour training session and were required to demonstrate proficiency in 10 proctored exams. They performed assessments of cFT in study participants

using a Sonosite Edge (Bothell, WA) at baseline and following a 500 mL 0.9% normal saline intravenous bolus. Fluid responsivenesswas defined as a ≥ 10% increase in cardiac index following the fluid bolus, as measured using bioreactance (NICOMTM, Cheetah Medical, Tel Aviv, Israel). The change in cFT was then compared to this fluid responsiveness definition. Novice sonologists were blinded to the NICOM results.
RESULTS. Characteristics of the study participants: median age of 53 years old, APACHE II score of 15, BMI of 27 kg/m3, and 57 (50%) were fluid responders. Diagnosis at hospital discharge included; severe sepsis/septic shock (29%), DKA/HHS (31%), GI hemorrhage (12%) and alcohol withdrawal (5%). The optimum change in cFT of 6ms performed poorly at predicting fluid responsiveness: AUC-ROC of 0.53 (95% CI: 0.41-0.63), sensitivity of 55% (95% CI: 43%-67%), specificity of 54% (95% CI: 42%-67%), and positive and negative likelihood ratios 1.21 (95% CI: 1.19-1.22) and 0.82 (95% CI: 0.81-0.84), respectively.
CONCLUSION. Our study does not support the use of point-of-care ultrasound assessment of cFT to predict fluid responsiveness in intensive care unit patients by novice sonologists. Further research examining the relationship between point-of-care ultrasound proficiency and cFT is warranted.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001048

INTRODUCTION. In critical care patients the positive fluid balance is associated with highly mortality (HR 1.014 ml/kg)1, therefore the fluid administration, despite being an essential treatment for septic shock patients, must be assessed and individualized. Furthermore in the critical care patients with acute respiratory distress syndrome (ARDS), the extravascular lung water index (EVLWi) has been an independent prognostic factor2. In ARDS patients the fluid administration based in EVLWi meditions is safe and lead to a less fluid balance acummulation, mortality, mechanic ventilation days and UCI stay days3.
OBJECTIVES. To determinate the association between fluid balance and ELVWi
METHODS. Retrospective, cohort, analytical study establishing the association between daily fluid balance, changes in EVLWi and mortality in ICU at 24, 48 and 72 hours.
RESULTS. We collected data from 20 patients with EVLWi and fluid balance daily monitoring for the first 3 days, we established an EVLWi cutoff value of >11 ml/kg, and was associated with a higher mortality; on the first 24 hours with an OR 36 (95% IC 2.7210 a 476.2989, p = 0.0065), at 48 hours OR 20 (95% IC 1.4161-282.4627, p = 0.0266) and at 72 hours OR 19.2857 (95% IC 0.7977-466.2641 p = 0.0686). Fluid balance cutoff value was established at ≥ 3.5 L, without association with mortality OR 0.0877 (95% IC 0.0041-466.2647 p = 0.0686) at day 1, OR 0.4667 95% CI 0.0369 – 5.9028 p=0.5561)at day 2 and OR 0.5000 95% CI 0.0374-6.6838 p= 0.6003) at day 3. The association between fluid balance and EVLWi results in a Pearson's R2= 0.01269.
CONCLUSION. EVLWi was associated with an increased mortality, as shown in previous studies3, unlike fluid balance ≥3.5 L, that shows no association with mortality, we believed this results from the management and neutralization of cumulative fluid balance during the UCI stay. We did not find correlation between fluid balance and EVLWi. We believed that lower values of fluid balance and EVLWi maybe correlated with improvement and good response to treatment.

Quality of Life and Survival after Transcatheter Aortic Valve Implantation (Transfemoral TAVI)

CM. Rodríguez Mejías, L. Olivencia Peña, P. Castán Ribas, A. López Fernández, JP. Valencia Quintero, MJ. García Delgado
Medicina Intensiva, Hospital Universitario Virgen de las Nieves, Granada, Spain
Correspondence: C.M. Rodríguez Mejías
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001063

INTRODUCTION. Aortic stenosis is the most frequent valvular disease in adults, its main etiology being degenerative. The gold standard treatment is the surgical valvular replacement. Although there are non-candidates because of the high surgical risk, using less invasive methods such as transfemoral TAVI.
OBJECTIVES. To analyze survival, degree of functionality and quality of life after implantation of transfemoral TAVI.
METHODS. Longitudinal, unicentric study, based on the ARIAM prospective registry of cardiac surgery. Including 77 patients consecutively submitted to transfemoral TAVI from January 2015 to December 2016. Follow-up time from 1.5 to 3.5 years, made by telephone. Descriptive analysis of baseline demographic variables: age, sex, comorbidities, surgical risk (EuroSCORE) and NYHA grade. Survival by the Kaplan-Meier method, quality of life with the SF-12 Health Survey questionnaire and post-TAVI functional assessment according to NYHA. We used non-parametric Wilcoxon test for NYHA pre and post, Cox regression for factors associated with survival and multivariate logistic regression model for factors associated with quality of life.
RESULTS. The mean age was 78.51 ± 8.70 years, with 53.2% women, NYHA of 2.48 ± 0.66, EuroSCORE of 15.23 ± 9.20 and EuroSCORE 2 of 3.64 ± 2.96. The survival within the first month was 98.70% (95% CI: 96-100%), 90.90% at 6 months (95% CI: 85-96%), 80.52% (95% CI : 72-88%) after one year, 72.0% (95% CI: 63-80%) at two years and 60.30% (95% CI: 50-69%) after three years. Twenty five patients died, being the most frequent cause heart failure for 16% of them and cerebral hemorrhage for 16%. Forty seven patients answered to the quality of life questionnaire. Our SF-12 scores were below those for the Spanish population above ≥75 year. There was a small difference in the physical summary component and a large difference in the mental summary component. Functional capacity results show recovery (NYHA I) in only 17% of patients, with no association in the explored variables associated with survival after TAVI (age, sex and NYHA).
CONCLUSION. The implantation of transfemoral TAVI in our center shows very good results in terms of survival in the short and medium terms. Our results for gain in quality of life and functional recovery are comparable to previously reported results.

The impact of atrial fibrillation on the cardio-circulatory performance in critically ill: An analysis of a prospectively maintained database on transpulmonary thermodilution and pulse contour analysis

W. Huber, F. Weikl, G. Batres-Baires, U. Mayr, A. Herner, S. Schreiber, R. Schmid, T. Lahmer
Medizinische klinik und poliklinik ii, Klinikum rechts der Isar; Technische Universität München, Munich, Germany
Correspondence: W. Huber
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001066

INTRODUCTION. Atrial fibrillation (AF) is one of the most frequent arrhythmias in the ICU. The prevalence in non-cardiac ICUs is given with up to 10%. While the incidence of new-onset AF and the risk of neurological sequelae is well investigated, little is known about the impact of AF „per se" on the cardio-circulatory performance in critically ill patients.
METHODS. Therefore, we analysed a prospectively maintained database on advanced haemodynamic monitoring with transpulmonary thermodilution (TPTD) and pulse contour analysis (PCA) (PiCCO; Pulsion; Germany). Primary endpoint: Comparison of haemodynamic parameters between patients with SR and AF. The final analysis was restricted to patients with jugular/subclavian CVC, since femoral CVC indicator injection might result in overestimation of global end-diastolic volume index GEDVI. Statistics: Wilcoxon-test for unpaired samples. ROC-analysis and multiple regression analysis regarding CI≤2.5L/min/m^2. IBM SPSS 25.
RESULTS. The database included 19,025 TPTDs in 1,067 patients. AF and sinus rhythm (SR) were documented in 2925 (15.4%) and 15,653 (84%) of the TPTDs, respectively. Among the 11,297 TPTDs in patients with jugular or subclavian CVC, 1,771 (15.7%) TPTDs were performed under AF and 9,306 (82.7%) under SR. 61% of the patients were male, 39% female. The underlying diseases were sepsis (30%), liver cirrhosis (26%), GI-bleeding (7%), ARDS/pneumonia (10%), cardiogenic (7%), pancreatitis (3%), various (17%). Biometrics: Measurements under AF were more frequent among women compared to men (44% vs. 38%; p<0.001). Patients with AF were older (69±9 vs. 61±13 years; p< 0.001), smaller (171±10 vs. 173±8cm; p<0,001) and had higher weight (91±28 vs. 80±25kg; p<0.001) and BMI (33±13 vs. 26±7kg/m^2; p<0.001). Patients with AF had a higher heart rate (100±21 vs. 91± 18/min; p<0.001) and CVP (17±6 vs. 15±7 mmHg; p<0.001), but slightly lower MAP (82±14 vs. 83±15mmHg; p=0.039). Global end-diastolic volume index GEDVI was substantially higher in patients with AF (914±210 vs. 816±188mL/m^2; p<0.001). As expected, stroke volume variation SVV was markedly higher in patients with AF (21±7 vs. 13±7%; p<0.001). Contractility was moderately impaired under AF: CI (3.3±1.2 vs. 4.4±1.4/min/m^2; p<0.001), stroke volume index SVI (35±13 vs. 49±16mL/m^2; p<0.001) and dPmax (1392±523 vs. 1446± 596mmHg/s; p=0.007) were lower under AF compared to SR. General cardiac performance as measured by cardiac power index CPI was lower for patients with AF (0.60±0.23 vs. 0.81±0.30W/m^2; p=0.331). Extravascular lung water was slightly higher under AF (12±5 vs. 11± 5mL/kg; p<0.001). By contrast, pulmonary vascular permeability index

PVPI (2.1±0.9 vs. 2.1±1.1; p=0.987) was comparable for measurements with AF and SR.
AF (ROC-AUC=0.639; p<0.001), low GEDVI (AUC=0.621; p<0.001) and low heart rate (AUC=0.532; p=0.002), but not CVP (AUC=0.515; p=0.149) predicted a CI≤2.5L/min/m^2. In multivariate analysis AF, low HR and low GEDVI were independently associated with a CI≤2.5L/min/m^2.
CONCLUSION. AF resulted in a moderate reduction of SVI and CI. Heart rate and GEDVI were slightly elevated. General cardiac performance with AF measured by CPI was reduced by 26%.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001071

INTRODUCTION. dPmax is defined as the maximum increase in arterial pressure per time and can be measured invasively by catheterization or noninvasively by Doppler-technique. Left ventricular and aortic dPmax have been suggested as an index of cardiac performance. However, the usefulness of dPmax is controversely discussed, since it might also depend on preload, afterload, heart rate and myocardial hypertrophy.
Several haemodynamic monitoring devices provide continuous dPmax. Surprisingly, there is a lack of systematic data on the association with other haemodynamic parameters as well as with biometric data. Therefore, we analyzed a large prospectively maintained database on transpulmonary thermodilution and pulse contour analysis (PiCCO; Pulsion; Germany).
METHODS. Analysis of a database including 19,025 triplicate measurements in 1067 patients. Statistics: Spearman correlation, Wilcoxon test, multivariate regression, ROC-analysis. IBM SPSS 25.
RESULTS. 61% of the patients were male, 39% female. Age 63±13 years, height 172±8cm, weight 80±23kg. The underlying diseases were sepsis (30%), liver cirrhosis (26%), GI-bleeding (7%), ARDS/pneumonia (10%), cardiogenic (7%), pancreatitis (3%), various (17%).
Among biometric parameters, dPmax had a slight, but significant association with low weight (r=-0.099; p<0.001), small height (r=-0-095; p<0.001) and lower age (r=-0.015; p=0.043). Women had significantly higher dPmax (1473±593 vs. 1381±555 mmHg/s; p<0.001). In multivariate analysis (R^2=0.019), dPmax was independently associated with low weight (T=-11.3), small height (T=-10.0) and young age (T=-6.1; all p<0.001).
Preload: dPmax correlated with low GEDVI (r=-0.195, p<0.001), low CVP (r=-0.018; p=0.039) and high SVV (r=0.195; p<0.001). In multivariate analysis (R^2=0.047), dPmax was independently associated with low GEDVI (T=-2.22) and high SVV (T=6.1; all p<0.001).
With regard to parameters of afterload, dPmax was associated with low SVRI (r=-0.154; p<0.001) but not with MAP (r=0.010; p=0.282).
With regard to contractility, dPmax significantly correlated with CI (r=0.194; p<0.001) and SVI (r=0.082; p<0.001). The strongest univariate association of dPmax was found with pulse pressure PP (r=0.601; p<0.001).
Finally, dPmax was associated with heart rate (r=0.161; p<0.001) and sinus rhythm (vs. atrial fibrillation; r=0.020; p=0.006), but not with extravascular lung water index EVLWI (r=0.001; p=0.891).
In a combined regression analysis (R^2=0.673), dPmax was independently associated with pulse pressure (T=38.5), low SVRI (T=-6.1), low preload (GEDVI: T=-5.0); SVV: (T=4.3), high heart rate (T=5.1) and high weight (T=3.1; p=0.002; all other p-values <0.001).
In ROC-analysis, low dPmax (AUC=0.637; p<0.001) provided the largest AUC to predict CI≤2.5L/min*m^2 compared with low GEDVI (AUC=0.618; p<0.001), low PP (AUC=0.602; p<0.001) and low heart rate (AUC=0.538; p=0.001), whereas CVP was not predictive.
CONCLUSION. dPmax is not substantially influenced by biometry, MAP, rhythm and CI. The main determinants are pulse pressure, low peload (GEDVI) and low afterload (SVRI).

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000507

INTRODUCTION. Gastric tubes (GT) are common in intensive care units (ICU) used for enteral feeding, administration of drugs or aspiration of the digestive tract. Current GT have excellent clinical tolerance. Although a malposition may appear as rare, it may have serious consequences that could lead to patient's death. The only method recommended confirming correct positioning of the GT is chest x-ray. However, restrictive strategies for prescribing chest X-rays are being developed to limit their negative effects (irradiation, accidental removal of medical devices, microbial spread, cost). We hypothesized that ultrasonography (US), now widely used in ICU, would allow the evaluation of the correct positioning of the GT.
OBJECTIVES. The aim of this study was to evaluate the performance of gastric US for the validation of the good positioning of the GT.
METHODS. We carried out a prospective, bicentric study in Medical and Cardiosurgical ICU in Rouen University Hospital. All patients with new placement of GT, except patients in the post-operative period of visceral surgery, were included. For each inclusion we compared the results of a gastric US to the interpretation of a chest x-ray, to validate the good positioning of the GT.
RESULTS. Two hundred and nineteen US were performed from July 2016 to August 2018. In 160 cases, US concluded that the gastric tube was correctly positioned. In 59 cases, US did not visualize the tube in gastric area. Among these 59 cases, only 12 cases of malposition were detected by the chest x-ray. The sensitivity and specificity of gastric US were 0.77 [0.71; 0.82] and 1 [0.75; 1]. Positive and negative predictive values were 1 and 0.20, respectively. The median duration of US was 3 minutes [1; 10]. The median time spent before US was performed was 60 minutes [0; 1275]. It was 150 minutes [0; 1900] before the x-ray was performed which is a significant difference (p<0,0001). US was performed 50 minutes [-781; 1630] earlier than chest x-ray after gastric tube insertion.
CONCLUSION. Our results suggested a good performance of gastric US to check the positioning of the gastric tube. This result must be interpreted with caution because of a low power of the study. A multicentre study with greater power would be necessary to validate this practice.

Functional trajectory and outcome: the missing link in frailty studies?

J. Gross, D. Chauhan, K. Dombrowsky, J. Borkowski
Intensive care, London North West University Healthcare NHS Trust, London, United Kingdom
Correspondence: J. Gross
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000513

INTRODUCTION. Frailty characterises increased vulnerability to a dramatic decline in functional status from a relatively minor stressor. There is increasing evidence that frailty is associated with lower survival and poorer non-mortality outcomes following ICU admission(1). However, the majority of published frailty studies in critical care focus on a patient's frailty status at a single point in time - usually just prior to hospital or ICU admission. Trajectory may also play an important role(2).
OBJECTIVES. To explore the range of frailty status in patients admitted to ICU
To investigate the association of frailty and worsening trajectory with survival outcome
METHODS. Single centre observational study over a 13-month period from 1/10/2017 to 31/10/2018. Worsening functional trajectory was defined by a single Y/N question as to whether there was any functional deterioration in the 1-year preceding ICU admission. Frailty was defined by scores of ≥5 on the Rockwood Clinical Frailty Scale (RCFS).
RESULTS. Of 916 patients that were admitted to ICU during the study period, median age was 67 (age range 16-93) with 516 patients ≥65 years of age. Frailty and trajectory data was collected for 634 and 629 patients respectively (349 and 346 in ≥65 years subgroup). From this cohort, prevalence of frailty was 25.9% overall which increased to 34.7% for those ≥65 years. The range of frailty scores is shown (figure).
39.4 % patients (48.8% age ≥65 years) showed a worsening functional trajectory in the 1 year lead up to ICU admission.
There was a significant association between frailty and in-hospital mortality. Chi-squared=18.397, P<0.0001 (Chi-squared=14.284, P= 0.0002 age ≥65 years)
Worsening trajectory was also significantly associated with in-hospital mortality Chi-squared=24.125, P<0.0001 (Chi-squared= 11.726, P=0.0002 age ≥65)
Functional deterioration within last 12 months showed much stronger correlation with mortality outcome (R=-0.93181, AUCROC = 0.613) compared with frailty (R= -0.85117, AUCROC = 0.588)
CONCLUSION. This study shows a significant proportion of patients have a functional deterioration in the 1 year preceding ICU admission which is more strongly correlated with mortality outcome compared with frailty status. The concept of functional trajectory warrants further exploration in future studies.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000523

INTRODUCTION. Low phase angle (PA) values and persistence of a positive fluid balance (FB) are associated with an increased risk of long-term mortality of intensive care unit (ICU) patients.
OBJECTIVES. We sought to assess the prognostic value of PA and FB for mortality in critically ill patients.
METHODS. Fat-free tissue mass was assessed by measuring the 50-kHz phase angle on the first, fifth and seventh day. The inclusion criteria were: length of ICU stay of ≥7 days; SOFA score of ≥ 3. FB was calculated at 24, 72 hours and at 7 days upon ICU admission. We collected demographic and clinical characteristics of the patients. The APACHE II and SOFA scores were employed to evaluate the severity of illness and the degree of organ dysfunction respectively. We documented the highest vasopressor dose administered within the first 24 and 72 hours of ICU stay. Binary logistic regression analysis was performed to identify independent risk factors associated with ICU mortality.
RESULTS. A total of 90 patients admitted to the ICU were included in the present study. 33 patients died during ICU stay. Age 56± 15 y., male 71%, APACHE II 19±7 and SOFA 8±3. There was no statistical difference of gender distribution, APACHE II and SOFA score averages between the outcome groups. Patients in the non-survivor group were significantly older (53,5±14,5 vs. 60±15,1, P=0,045) and had a lower BMI (30,5±6,7; 27,2±4,7 P=0,018) compared to the survivor group. The PA at day 1 and 7 was lower in non-survivors (3,4°± 1,3° vs. 4,0°± 1,2°, P = 0.014 vs. 3,0°± 0,9° vs. 4,1°± 1,4 P= < 0.001). Relative to survivors, non-survivors and patients with lower PA had greater cumulative FB on

day 7 - 4,9l±5,5 vs. 0,1l±5,0, (P=< 0.001) and 4,9l±5,4 vs. 0,6l±5,6 (P=0,001) respectively. Mean vasopressor dose during the first 72 hours upon admission was significantly higher in non-survivors (0,17 mcg/kg/min±0,19 vs. 0,08 mcg/kg/min ±0,96, P=0,016). The results of binary logistic regression revealed that greater positive FB during the first week of ICU stay was independently associated with increased mortality (OR 2,2 [1.15- 4,22], P=0,017).
CONCLUSION. Fluid accumulation during the first week of ICU stay impacts the PA value and is an independent predictor of mortality. PA at admission is lower in non-survivor. PA is a good prognostic marker of mortality for critically ill patients.

Review of referrals to Intensive Care Unit (ICU) in a British District General Hospital (DGH)

J. Herzig, E. Landymore, M. Alice, T. Samuels
Critical care, East Surrey Hospital, Redhill, United Kingdom
Correspondence: J. Herzig
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000536

INTRODUCTION. The NCEPOD and NICE reports state that consultant physicians should be involved in referral of patients to critical care. It is also stated that it is inappropriate for referrals to be made at junior doctor level. Referrals require the doctor to leave ICU in order to assess patients on general wards. Appropriate referrals make the best use of ICU resources and prevent delays in treatment.
OBJECTIVES. To review the degree of consultant involvement in the referral and admission process and to ascertain reasons for deeming a referral inappropriate.
METHODS. Prospective review of ICU referrals from 01/01/18 to 19/02/18 to a 16 bed adult general ICU. Data was collected by the receiving doctor including; time, demographics, referrer grade, specialist involvement and whether the patient was admitted or not (with reasoning). Data was transcribed for analysis using Microsoft Excel.
RESULTS. Data came from 64 referrals over a period of 50 days. The incidence of consultant level referral was 14.1%, with the majority of referrals, 67.1%, originating from non-consultant grades. Allied health professionals and cardiac arrests accounted for 18.8% of referrals. A higher proportion of junior doctor referrals were associated with patients that were not admitted (36.2%) than those that were (24.8%). Referring team consultant awareness occurred in 48.4% of referrals, with an a higher (60.7%) awareness in patients subsequently admitted to ICU than in those then not admitted. Reasons for non-admission to ICU following referral predominantly fell into three categories; no requirement for organ support/invasive monitoring (36.1%), sub-optimisation (27.8%) and inappropriate/irreversible pathology (22.2%). A number of patients were discussed with an ICU doctor but not formally referred for bedside review (8.3%).
CONCLUSION. The majority of referrals were from non-consultant grades and in over half the referrals there was no referring team consultant involvement. Incidence of admission to ICU was higher with referring team consultant awareness, suggesting that more appropriate referrals were being generated. Senior involvement, such as that stated in NICE guidance, may result in better optimisation, decision making and escalation planning. Further correlation to mortality data and Apache 2 scores is planned. It is more difficult for escalation decisions to be made out of hours by the critical care team, rather than by the parent team who have been caring for the patient over time. Despite guidance from NCEPOD and NICE there is a continued trend of low referring team consultant level involvement in decision making for patients being referred to ICU. This is potentially due to culture differences in consultant working styles across speciality disciplines. Education, from junior doctor to consultant may be useful in improving senior involvement in decision making for complex and critically unwell patients. Particularly, focussed education at non-consultant level may breed a culture change in the future consultant body.

INTRODUCTION. Bedside ultrasonography is a non-invasive, convenient method for volume status evaluation. Recently, Duplex common carotid artery evaluation was reported to predict fluid responsiveness in critical patients. But there is no consensus about optimal index evaluation and very few data on spontaneously breathing patients.
OBJECTIVES. To check the validity of Duplex Carotid ultrasonography evaluation in predicting fluid responsiveness and volume status and to assess their correlation with Cardiac Output (CO) in spontaneously breathing patients.
METHODS. This review was based on the PRISMA guideline . The systematic search of the literature published from 1941 through 31 December 2018 explored the PubMed, Cochrane Library, Web of Knowledge and Scopus databases. Inclusion criteria were studies who investigated Carotid Ultrasonography correlation with CO, its reliability and accuracy in predicting fluid responsiveness and volume status in adult (>18yrs) spontaneously breathing patients . Two researchers selected studies using inclusion criteria and then assessed their quality using the QUADAS-2 guidelines. The key words for literature search were: fluid responsiveness, spontaneously breathing, ultrasonography, ultrasound echography, volume status, cardiac output.
RESULTS. We collected 683 studies: 673 didn't meet inclusion criteria. 10 studies were included in the final analysis. Duplex common carotid artery measures (Corrected Carotid Flow Time, CCFT; Carotid blood flow CBF; variation of carotid artery blood flow peak velocity, Δ V peak) showed an inter-rater agreement range from good to excellent . The CCFT and CBF showed a good correlation with CO but there was a wide range of performance with a range of "r" value from 0,29 to 0,66 . We found only one study which tested the CCFT 's validity in predicting fluid responsiveness: a cut-off value 349 msec has a good accuracy (AUC = 0.84) . Many studies on healthy volunteers showed an increase of CCFT after Passive Leg Raise . The quality of studies were low : many reports had an high risk of Bias in the Reference Standard and index test according to QUADAS-2 guidelines. The main limit of this review is the heterogeneity in design, population and setting of studies included.
CONCLUSION. There is only one study investigating duplex carotid ultrasonography's validity in predicting fluid responsiveness in spontaneously breathing critical patients. The quality of the studies included in this systematic review was low. CCFT and CBF seem to correlate with Cardiac Output in healthy volunteers.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000552

INTRODUCTION. The long-term prognosis of post-intensive care unit (ICU) patients is worse than that of the general population. [1] They suffer a significant healthcare burden with many survivors requiring ongoing medical care for over two years. [2] Current scoring systems focus primarily on predicting ICU death and in-hospital deterioration. The Sabadell score has previously been shown to be predictive of survival to hospital discharge. [3,4]
OBJECTIVES. To investigate the Sabadell score as a predictor of long-term outcomes following ICU discharge.
METHODS. We performed a single centre, observational study at University Hospital Aintree. All patients discharged alive from the ICU between September 2011 and December 2017 were stratified according to the Sabadell score as descrived previously [3,4] and scores recorded along with data including demographics, Acute Physiology and Chronic Health Evaluation II (APACHE II) score and diagnosis. Hospital electronic records were reviewed in July 2018 to determine long-term outcomes.
RESULTS. A total of 5953 patients were included in the analysis. Overall in-hospital mortality following ICU discharge was 5.6%. Median survival was 2.2 years in those with a Sabadell score of 2 and 12 days in those with a score of 3. Sabadell score was strongly related to survival ($p<0.001$) (see figure 1), demonstrating effective discrimination at all time intervals up to five years (area under the receiver operating characteristic curve >0.7). Increasing age and APACHE II score were also associated with mortality ($p<0.001$).
CONCLUSION. The Sabadell score is an effective predictor of long term outcome after ICU discharge with significantly reduced survival in patients classified as Sabadell score of 2 and 3. The score may be used to identify patients more likely to deteriorate following discharge, in order to target early intervention aiming to reduce poor outcomes and, where appropriate, to facilitate timely, informed discussions regarding advance care planning.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000561

INTRODUCTION. Pressure injuries (PI) are a global health issue of multifactor and complex causes, being a problem for health services with physical, psychological and economic implications, given that they cause pain and suffering, and are the gateway for infections. The occurrence of PI in hospitalized patients results on an increase in the hospitalization period, being connected to high morbidity and mortality rates and, consequently, increasing direct and indirect spending. In 2001, a group of Spanish specialists proposed the Escala de Valoración Actual del Riesgo de desarrollar Úlceras por Presión en Cuidados Intensivos (EVARUCI) considering the most frequent known risk factors to which critical patients are exposed and the opinion of health professional about which would be the most frequent risk factors in ICU patients. EVARUCI was translated and adapted to Brazilian Portuguese, having satisfactory results concerning the internal coherence and inter-examiner reliability. To continue the validation process of the Portuguese version, this study was performed, aiming to widen the analysis of the scale's performance and to obtain another option for the evaluation of PI risk specifically for critical patients.
OBJECTIVES. To analyze the concurrent converging validation of EVARUCI and its correlation with illness severity in ICU patients.
METHODS. This methodological study was conducted in three ICU of the University Hospital of the Universidade Federal de São Paulo, Brazil. The inclusion criteria of patients to the sample were age ≥ 18 years old, absence of PI and length of ICU stay > 24 hours. The Braden Scale was used for concurrent converging validation, and Simplified Acute Physiology Score (SAPS 3) for correlation with the illness severity. Both, Braden Scale and SAPS 3 were considered as gold standart and it was applied simultaneously. The analysis was made applying the Spearman's Correlation Test.
RESULTS. 324 patients were includes in the sample. 49.4% were female and the average age of patient was 58 years old (18-95; SD 19.2). 53.7% were surgical patients and 85.8% were discharged from ICU. A strong significant correlation was observed between Braden and EVARUCI scores ($r = - 0.778$ e $p<0.001$). EVARUCI's values moderately and significantly correlated with those from SAPS 3 score ($r = 0.508$ e $p<0.001$).

CONCLUSION. EVARUCI scores correlated with Braden Scale scores indicating its possibility of use to evaluate PI risk in critical care patients. The correlation between EVARUCI and SAPS 3 indicated that the greater the illness severity the greater the risk for PU.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000563

INTRODUCTION. Upper airway oedema following cervical spine surgery can lead to serious complications such as respiratory failure after extubation. The cuff leak test (CLT) has been performed on patients undergoing cervical spine surgery for evaluating the success of extubation because the CLT is used to predict the occurrence of post-extubation laryngeal oedema and stridor. However, the cut-off value of the CLT differs between different studies and there is controversy about its usefulness.
OBJECTIVES. This study aimed to evaluate the usefulness of the CLT in patients undergoing cervical spine surgery, as the index of successful extubation.
METHODS. We retrospectively reviewed the medical records of patients who underwent a CLT after cervical spine surgery from January 2017 to December 2018. Data from 84 patients were analysed, except for patients in whom the CLT failed or those with incomplete records. The CLT was performed by three respiratory care clinical nurse specialists and values measured using a mechanical ventilator or a wright respirometer. In this study, the cut-off value of CLT for successful extubation was 15% based on the previous studies.
RESULTS. All 84 patients had successful extubation. One patient with underlying asthma had a post-extubation stridor and this patient had a cuff leak of 15.7%. Regarding the CLT results, 51 patients (60.7%) had an initial leak of less than 15% and 33 patients (39.3%) had an initial leak of more than 15%. The average leak in the group with initial leak <15% was 6.1% and that in the other group was 30.2%. In the initial leak<15% group, the proportion of women (56.9% vs 27.3%, $p = 0.008$) and obesity (19.4 ± 19.7% vs 11.0 ± 15.5%, $p = 0.042$) were higher than those in the initial leak≥15% group. In the initial leak<15% group, the intensive care unit (ICU) length of stay was increased by 1 day (3.3 ± 1.3 days vs 2.3 ± 0.7 days, $p < 0.001$) and intubation days by 0.9 day (3.2 ± 1.1 days vs 2.3 ± 0.7 days, $p < 0.001$). There was no significant difference in the use of steroids before and after the CLT and the method of CLT. Thirty-two patients (62.7%) in the initial leak<15% group had CLT results more than 2 times. In this group, the leak just before extubation showed a significant increase compared to the initial leak (5.2 ± 4.7% vs 16.3 ± 11.1%, $p < 0.001$). Among patients with an initial leak of less than 15%, the intubation days were increased by 1.6 days (3.8 ± 0.8 days vs 2.2 ± 0.8 days, $p < 0.001$) and ICU length of stay increased by 1.6 days (3.9 ± 1.0 days vs 2.3 ± 1.0 days, $p < 0.001$) in the group with CLT more than 2 times compared to the group of single CLT.
CONCLUSION. Earlier successful extubation was performed when the cut-off value of CLT was more than 15% in patients undergoing cervical spine surgery. However, it is necessary to adjust the cut-off value considering factors such as female sex and obesity.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000575

INTRODUCTION. The World Health Organisation has established that medical errors are the 14thcause of mortality and morbidity worldwide. Due to the specific characteristics of critically ill patients, ICU setting is prone to errors. The use of a checklist has been advocated as a useful tool for reducing the occurrence of errors (1).
OBJECTIVES. The objective of our quasi-experimental study is to evaluate whether the use of a daily checklist could improve the clinical outcomes of critically ill patients admitted to ICU with resident program (2,3).
METHODS. In 2018 a specific checklist was developed and applied during the morning ICU round to all adult patients admitted to our ICU with an expected length of stay > 24h. To evaluate the effects of check-list use, ICU mortality and length of stay, occurrence of ventilator associated pneumonia (VAP) and catheter-related bloodstream infections (CR-BSI), mechanical ventilation (MV) and central venous catheter (CVC) free days were compared between patients admitted to ICU in 2018 (intervention group) and in the two years before (control group).
RESULTS. 264patients in the first nine months of 2018 and 838 in the 2 years before were admitted to ICU and evaluated in the study. No significant differences in age, sex, GCS and SOFA score were observed between the 2 groups. In the intervention group, SAPS II score (44,6 ± DS 19,4) was higher than in the 2 previous years (42,3 ± 19,4). No differences in ICU mortality, ICU length of stay and MV free-days were observed between groups. Differently, incidence of VAP and CR-BSI had a trend in favor of intervention group (1,9% and 1,5% vs 2,7% and 2,3 %) and CVC free-days increased (p<0,05) in 2018 (3 days) compared to other 2 years (2,2 days).
CONCLUSION. Our data indicated that the daily use of a check-list in ICU setting with resident program may improve patients' management with reduction of healthcare infections and use of central venous catheter.

Improving Targeted Temperature Management (TTM) in the Neurointensive Care Unit (NICU)

C. Gu[1], YL. Wong,[2], J. Jensen Ng[2], Q. Chen[2], ML. Lim[1]
[1]Nursing service, Tan Tock Seng Hospital, Singapore, Singapore; [2]Anaesthesiology, intensive care and pain medicine, Tan Tock Seng Hospital, Singapore, Singapore

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000598

INTRODUCTION. Fever is predictive of higher mortality and poorer neurological outcome [1-3] in patients with subarachnoid haemorrhage (SAH), intracerebral haemorrhage (ICH) and traumatic brain injury (TBI). In accordance with expert panel guidelines [4], normothermic TTM should be instituted to improve intracranial pressure control and outcomes.
Retrospective data (Jan-Mar 2018) from our NICU showed that 33% of our target population had persistent fever defined as a core body temperature of ≥38°C for ≥4 hours. Only 48.4% of all febrile patients had hourly temperature monitoring despite an existing protocol.
OBJECTIVES. Our project aims to reduce the incidence of persistent fever in patients with SAH, ICH and TBI.
METHODS.
A multidisciplinary committee comprising doctors, nurses, pharmacists and support staff was convened.
Macro- and micro-processes of current temperature management were mapped and barriers to existing practices were identified.
An ishikawa diagram was produced using root cause analysis.
Three main causes were identified using Pareto Chart of team votes:

1) Lack of standardised anti-shivering protocol

A new protocol was developed based on existing international guidelines [5].

2) Lack of awareness regarding importance of fever management

We promoted knowledge and skills acquisition through in-service training, roll-call and handovers for nurses. New medical officers were educated during orientation.

3) Lack of effective cooling devices

An auto-feedback temperature regulated machine was put on trial. This device allowed reliable temperature control with minimal increase in staff effort.
RESULTS. Since the commencement of an iterative Plan-Do-Study-Act (PDSA) Cycle, there has been increased compliance in hourly temperature monitoring.
After 6 months, the median incidence of persistent fever had reduced from 31.8% to 19%.
TTM can potentially decrease ICU LOS by 3.2 days [6]. Based on a census of 400 patients/year and the 10% reduction we have achieved in patients with persistent fever, the annual cost savings would be $42k-$133k.
CONCLUSION. TTM requires education and engagement of a multidisciplinary team. It is a step towards improved patient outcomes and significant cost savings. If further extended to patients with ischemic stroke, we can broaden the spectrum of patients who will benefit from this initiative.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000618

INTRODUCTION. In the French healthcare system, intermediate care units (ItCU) were implemented in 2002 under specific legal and financial regulations. Their goal is to admit patients whose acute severity requires continuous surveillance of vital functions but no organ supply. Their use varies among hospitals, depending on the availability of regular ICUs, of emergency department or surgical activities. Some of them may be developed only because their funding is higher than that of regular medical or surgical ward.
OBJECTIVES. The aim of this study was to define criteria for intermediate care units, as the first part of a research project designed to establish an admission score to help physicians in the triage process.
METHODS. 189 physicians were selected because they had been suggested as experts by French societies of Intensive care, anesthesiology, emergency medicine or surgery, and were working either in public or private hospitals. They were sent a series of 107 criteria, split into 5 categories: chronic disease (n = 29), acute dysfunction (n = 26), etiology of acute disease or specific pathway (n = 35), nursing work-load (n = 11) and hospital organizational aspects (n = 6). Through Delphi analysis, the responders had to assess each item for validity and feasibility with a 0 to 9 Lickert scale. Criteria with a median validity and feasibility over 7 and a concordant response in at least 60% of the responders on the first survey were kept definitively. The other criteria were sent for a second Delphi round. Criteria had to be considered sufficient for ItCU admission either alone or in combination, and had to have the same minimal levels of validity, feasibility and concordance than for the first Delphi round.
RESULTS. 81 out of 189 physicians participated in the first round and 62 out of 81 in the second round. They worked mostly in public hospitals (78%) and were aged 54 [47-59] years. 52/107 criteria were kept from the 1st round. Out of the remaining 55 criteria, 11 were kept after the 2nd round and the other ones were definitively discarded. The categories of the kept items after rounds 1 and 2 were: chronic disease (round 1/2 : 1/5), acute dysfunction (26/2), etiology of acute disease (29/2), nursing work-load (3/0) and organizational aspects (3/2).
CONCLUSION. In our series or French physicians, criteria for medical eligibility to an ItCU admission are mostly indicators of acute dysfunction and causal acute disease. These criteria will be used in a multicenter prospective study to build and validate a score for admission eligibility.

Outcomes of patients with Learning Disabilities admitted to the Critical Care Unit of a UK District General Hospital: 2012-2017

B. Hopkins[1], M. Spivey[1], R. Mawer[2], W. Woodward[1]
[1]Critical care unit, Royal Cornwall Hospital, Truro, United Kingdom; [2]Department of anaesthetics, Royal Cornwall Hospital, Truro, UK, United Kingdom
Correspondence: B. Hopkins
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000620

INTRODUCTION. Learning Disability (LD) describes an individual's "reduced intellectual ability and difficulty with everyday activities – which affects someone for their whole life". LD patients have a shorter life expectancy and a higher associated comorbidity e.g. obesity, epilepsy and swallowing problems (1). A UK confidential inquiry in 2013 into premature deaths of LD patients (CIPOLD) identified problems with delayed diagnosis, treatment and advanced health care planning as contributory factors (2). There is a paucity of data examining these healthcare outcomes with relation to Critical Care and so a retrospective study was undertaken to assess this relationship.
OBJECTIVES. To identify the number of admissions of patients with LD to Critical Care and conduct an initial review of health outcomes. Primary Outcome Measure: Survival to discharge from Critical Care. Secondary Outcome Measures: Length of Stay, Survival to Hospital discharge.
METHODS. A retrospective observational study was performed of all patients with LD admitted to the 15-bed Critical Care Unit, Royal Cornwall Hospital from 01/01/2012 - 31/12/2017. Patients with a registered LD are recorded on the hospital's central database, an automated search identified those admitted to Critical Care in the time period. Patient specific data was captured by a manual review of the electronic patient record (Philiips ICCA).
RESULTS.
CONCLUSION. Patients with LD represent only 1% of the Critical Care population, yet 1.8% of the general population. Our data suggests LD patients present at a much younger age; 20% of our LD patient cohort were children, compared to only 4.6% of the non-LD patient cohort. Despite comparable illness severity scores, the average length of stay for LD patients was twice that of non-LD patients, reflecting perhaps their complex health and social care needs. Furthermore 25% of LD patients were admitted more than once, compared to just 8% of the non-LD patient group. In our cohort, contrary to what might be expected by existing data regarding outcomes for LD patients, mortality was found to be lower. This might reflect the younger age of the LD cohort, or perhaps lower mortality is explained by higher readmission rates; but this unexpected result demonstrates the importance of further study in this area.
These issues highlight the importance of individualised multidisciplinary care, advanced care planning and treatment escalation discussions, with patient support by specialist LD Liason teams for individuals who may well present on multiple occasions to Critical Care. This study identifies the need for further research in this area, to establish areas for improvement in Critical Care for this vulnerable patient group.

Clinical Frailty Score (CFS): is there a magic number? An observation of mortality in relation to score on the CFS in patients in the Intensive Care Unit (ICU)

T. Sanderson[1], M. Alice[2], S. Ranjan[2], P. Morgan[2], T. Samuels[2]
[1]Intensive Care Unit, East Surrey Hospital, London, United Kingdom; [2]Critical care, East Surrey Hospital, Redhill, United Kingdom
Correspondence: T. Sanderson
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000623

INTRODUCTION. A growing body of evidence shows that frailty is an independent risk factor for hospital mortality (1, 2). Frailty has also been associated with worse ICU outcomes including increased mortality risk (3, 4). This knowledge base highlights the value of the CFS as a tool included in ICU admission screening. Clinicians have been shown to be accurate assessors of CFS (5), but is there evidence for a "critical value" on the CFS that could increase its utility as part of admission screening by more easily and tangibly predicting increased mortality risk?
OBJECTIVES. To review CFS scores in relation to mortality rates to assess evidence for a critical CFS value in predicting mortality, in order to practically aid ICU admission screening.
METHODS. Electronic patient records at 1 district general hospital were interrogated to identify all patients admitted to the ICU with a recorded CFS. Data were collected on CFS at ICU admission, ICU outcome ("Improved", "No change", "Worse", "Death") and ultimate hospital outcome ("Lived" or "Died"). Statistical analysis was carried out using R version 3.5.3 (including packages *ggplot2*).
RESULTS. A total of 457 patients were identified as having CFS scores on recorded on ICU admission (from 5/10/15-23/1/19), making 3.3% of the 13,882 patients admitted to the ICU during this time period. The Kruskal-Wallis test showed a significant difference in CFS scores between the 4 categories of ICU outcome ($p= 0.02572$). Pairwise comparison using the Wilcoxon rank sum test demonstrated that this significance lay between the "improved" and "died" groups only ($p= 0.019$). Median CFS scores in these groups were 3 (*IQR: 2-4*) and 4 (*IQR: 3-6*) respectively. In ultimate hospital outcome, an unpaired Wilcox test found a significant difference in CFS between the "lived" and "died" groups ($p= <0.001$). Median CFS scores in these two groups were 3 (*IQR: 2-4*) and 4 (IQR: *3-6*) respectively.
CONCLUSION. This retrospective, observational study further adds to the evidence base that CFS is associated with ICU and hospital mortality. The small proportion of ICU admissions that recorded CFS demonstrated a current inconsistency in its use during admission screening, possibly uncovering lack of clinicians' confidence in the role of CFS in mortality risk prediction. We found a significant difference in the CFS values between patients who survived ICU or hospital admission and those who did not. These CFS scores may represent critical CFS values at which point ICU or hospital mortality becomes more likely. In a "real-world" setting this could suggest that CFS above a certain level may be a poor prognostic factor of mortality. The findings of this small study may suggest that CFS could be incorporated into well-established prognostic tools, such as the APACHE system. If studied further, the role of the CFS in admission screening could be better defined; allowing clinicians to have another pragmatic, tangible tool to aid them in the real-world when screening patients for mortality risk during ICU admission.

000634

Central venous oxygen saturation (ScvO2), lactic acid (LA) and base excess (BE) as determinants of mortality in critically ill patients: A prospective cohort study

M. Torres[1], JC. Torres[1], F. Jaimes[2]
[1]Critical care, SERVIUCIS SA, Medellín, Colombia; [2]Internal medicine, Universidad de Antioquia, Medellin, Colombia
Correspondence: F. Jaimes
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000634

INTRODUCTION. In critically ill patients, tissue deficit of oxygen can generate hyperlactatemia, acidosis and a dysfunction in venous oxygen saturation, all of them at different body levels. This "dysoxic" disorder is associated with a high mortality rate but a broad assessment of the full state of hypoperfusion, in different categories of critically ill patients, has not been made.
OBJECTIVES. To determine the association between several combinations of LA, BE and ScvO2 -at admission to the intensive care unit (ICU) and 12, 24 and 48 hours afterwards- and the probability of hospital death in critical patients admitted to the ICU.
METHODS. Prospective cohort study of patients older than 16 years admitted to polyvalent ICUs of two university hospitals in Antioquia, Colombia, between August 2014 and May 2017. Those with cancer, liver failure, expected ICU length-of-stay less than 48 hours or death within 24 hours of admission were excluded. Several logistic regression models were fitted for the analysis, including the main perfusion variables (LA, BE and ScvO2) and their temporal kinetics, as well as acknowledged confounding covariates of clinical importance for the outcome hospital mortality rate.
RESULTS. The cohort was composed of 1008 patients, the average age was 55 ± 21 years, 57% (n=575) were men, 85% (n=855) required mechanical ventilation, 56% (n=561) were admitted due to medical problems, 21% (n=211) were post-operative and 23. 4% (n= 236) were trauma patients. At ICU admission, the median SOFA score was 7 (IQR=5;10), the median APACHE-II was 19 (IQR=15;23) and the median LA, BE and ScvO2 were 2,3 (IQR=1,4;4), -5.9 (IQR=-9,6;2,3) and 72,8 (IQR=66,2;78,7), respectively; with an overall hospital mortality of 19.6% (n=198). The multivariate analysis found that, among several potential combinations, only the persistence of abnormal LA and BE at 24 hours after admission to the ICU were associated with a higher mortality (LA > 2 mmol/L, OR = 3,06; 95% CI = 2,05 – 4,61 and BE < -2mm/L, OR 1,56; 95% CI = 1,05-2,32).
CONCLUSION. Twenty four hours after admission to the ICU, the persistence of hyperlactatemia and metabolic acidemia (LA> 2 mmol/L and BE < -2mmol/L) indicate the greater risk of mortality in critically ill patients. The abnormality in ScvO2, however, loses clinical importance early in this population.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000642

INTRODUCTION. Mexico is experiencing an epidemiological transition that is adversely impacting and pushing for restructuralization in the healthcare industry. Only a few health institutions in Mexico (public or private) disclose their ICU data. There is a lack of nationwide data to assess the impact of cancer patients admitted to the ICU in our country. Cancer outcomes are important to understand its influence in the health care system. Therefore, it is necessary to standardise statistical cancer-related data across countries, institutions and ICUs.
OBJECTIVES. This study aims to scrutinise the outcomes of cancer patients admitted to the ICU in a private hospital in Mexico through statistical analysis.
METHODS. Retrospective, observational and descriptive study conducted in the ICU of a private teaching hospital in Guadalajara, Mexico. From January 2017 through December 2018, a total of 201 admissions related to cancer were registered. We enrolled 162 patients, fifteen years of age or older who had cancer and were admitted to the ICU. Patients who were bedridden or receiving palliative care were not excluded.
RESULTS. A total of 162 patients were included [56.2% (n=91) were men and 43.8% (n=71) were women], representing 28.2% of the total ICU population. Mean age was 61.27 ± 15.26 years and mean length of stay was 9.6 ± 31.9 days. The most common malignancies were Lung Cancer 18.5% (n=30), Colorectal Cancer 16% (n=26) and Pancreatic Cancer 13.6% (n=22). Most of the patients were admitted for the Oncology service because of complications of its underlying malignant disease 48.1% (n=78). 41.4% (n=67) of the patients were known to have metastases and 59.9% (n=97) underwent surgery. Nearly half of the patients admitted to the ICU presented chronic degenerative conditions 47.5% (n=77) [Hypertension 28.4% (n=46) followed by Type 2 Diabetes Mellitus (T2DM) 19.8% (n=32)]. During their stay in ICU, 14.8% (n=22) required Mechanical Ventilation (MV) and 8.1% (n=12) died ($p< 0.001$). ICU mortality rate was 14.2% (n=23).
CONCLUSION. Cancer incidence in ICU is high and it is common that these patients present with comorbidities such as Hypertension and T2DM. In our study mean length of stay was four days less on average compared to data found in prior studies, this could be due to the improvement in cancer management and critical care in general.
Most common primary tumor was lung cancer, followed by colorectal cancer and pancreatic cancer. These same malignancies were more likely to cause readmission to the ICU, this could be due to metastases, however, we did not find any association between metastases, previous ICU admission and mortality.
MV has been associated with higher mortality rates in numerous studies. In our study only a few patients required MV but it was still associated with a higher mortality rate than non-intubated patients.
Further research in specific groups is required to clarify the variables that contribute to the complexity of the associations between cancer and co-morbidities, its complications, and its impact in outcomes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000644

INTRODUCTION. Increasing numbers of patients who are admitted to the ICU are older and have co-existing chronic diseases and frailty. Whilst acute illness is strongly associated with mortality risk, there is increased recognition that chronic disease and functional status plays an important role in mortality and long-term ICU outcomes1. This questions the suitability of using physiological scoring systems that largely focus on acute physiology. Recent evidence suggests antecedent factors play a more important role in outcome prediction than acute illness factors for those with prolonged ICU stay2.
OBJECTIVES. To compare the performance of APACHE II and SOFA scores in patients with shorter versus more prolonged ICU admission.
METHODS. Retrospective analysis of all patients admitted to the ICU at our institution between 1/10/2017 and 30/10/2018. SOFA and APACHE II scores were calculated on admission to the ICU. The discrimination ability of each scoring system for in-hospital mortality (defined by AUROC) was compared in those with short (ICU stay of $\leq$5 days) versus prolonged (ICU stay of $\geq$6 days) ICU admission.
RESULTS. Over the 13-month period, 916 patients were admitted to the ICU. Median age was 67 years (age range 16-93). From those admitted, APACHE II and SOFA scores were calculated for 601 patients. From this cohort, 307 and 294 patients had short and prolonged ICU stays respectively. For those with short ICU stays, the AUROC for APACHE II and SOFA scores were 0.83 and 0.84 respectively. For those with prolonged ICU stay, the AUROC for APACHE II and SOFA were 0.57 and 0.60 respectively.
CONCLUSION. This study shows that the performance of APACHE II and SOFA scores weakens for patients with more prolonged ICU admission. Because APACHE II and SOFA scoring systems are largely based on acute physiology, there may be a greater role for non-

physiological factors (e.g. frailty, chronic disease and functional status) in patients that survive beyond the initial catabolic phase of critical illness. Future studies should explore the relevance of these factors in prolonged critical illness.

INTRODUCTION. Cardiopulmonary arrest's (CPA's) in the intensive care unit (ICU) are common (1) and guided by advanced cardiovascular life support (ACLS) algorithms. Protocol violations are anecdotally common and their incidence or relation to return of spontaneous circulation (ROSC) in the ICU setting are unknown.
OBJECTIVES. To establish the categories and frequency of errors of omission and commission during CPA in the ICU setting and its relationship with CPA outcomes.
METHODS. We retrospectively analyzed CPA data entered into the Get with the Guidelines registry from 2015 to 2017. Inclusion criteria: Age above 18, non-traumatic cardiac arrest in the ICU setting. Exclusion criteria: cardiac surgical patients or patients missing data points. Errors of omission were drugs or procedures which were omitted during a CPA but would have been recommended by ACLS algorithms. Errors of commission were drugs or procedures that were committed during a CPA but were not recommended by ACLS algorithms. CPA's with ventricular tachycardia(VT) or ventricular fibrillation(VF) were pooled as were CPA's with asystole and pulseless electrical activity (PEA) for analysis.
RESULTS. Of 140 CPA's that met inclusion criteria, 14 were excluded due to missing data fields. Of the final 126 CPA's studied, 103 had asystole/PEA with 65 attaining ROSC and 18 being alive at hospital discharge. Of 23 CPA's with VT/VFib, 20 attained ROSC and 10 were alive at hospital discharge. Mean CPA duration for those achieved ROSC vs those that didn't achieve ROSC were 8.46 minutes and 31.28 minutes respectively.Overall, as errors of omission and commission increased, the percent of patients who attained ROSC decreased. The number of patients with no protocol violations during a CPA was 13.Errors of commission had a statistically significant odds ratio (OR) of 0.52 (95% CI: 0.38 to 0.72) for ROSC during a CPA. Use of sodium bicarbonate (OR-0.22,95% CI: 0.08 to 0.60), calcium chloride (OR-0.25,95% CI: 0.09 to 0.69) and atropine (OR-0.50,95% CI: 0.12 to 2.00) were the most common errors of commission.Errors of omission also had a statistically significant odds ratio (OR) of 2.25 (95% CI: 1.28 to 3.98) for ROSC during a CPA. Errors of omission studied were rate and depth of chest compressions and compression fractions. Mean depth of chest compressions, rate of chest compressions and compression fractions for patients who achieved ROSC vs those that didn't achieve ROSC were 2.52 vs 2.49 inches, 113.55 vs 115.85 per minute and 0.43 vs 0.72 respectively.-Vasopressor infusions initiated prior to but continued during a CPA were also analyzed.This intervention was neither an error of commission or omission but had a statistically insignificant OR of 0.75 (95% CI: 0.52 to 1.10) for attaining ROSC during a given CPA.
CONCLUSION. Errors during CPA in the ICU setting were common.Errors of commission,namely sodium bicarbonate and calcium chloride use were statistically significant in decreasing the likelihood of attaining ROSC and likely represent older clinical practices.Errors of omission did not decrease the likelihood of attaining ROSC but effects may be statistically misleading owing to effects of dynamic feedback during CPR.Vasopressor infusions initiated prior to but continued during a CPA decreased the likelihood of ROSC and were almost statistically significant.

INTRODUCTION. Cerebral reperfusion injury occurs when cerebral blood flow is restored after cardiac arrest and resuscitation. Increased intracellular levels of glutamate, an excitatory neurotransmitter released from presynaptic terminals, activate ion-channel complexes that cause calcium to shift from the extracellular to the intracellular fluid, leading to the accumulation of oxygen free radicals and the activation of degradative enzymes. In addition, cerebral hemodynamics may remain abnormal after resuscitation from cardiac arrest. Several studies mentioned that induced hypothermia improves outcomes in patients with comatose after resuscitation from out-of-hospital cardiac arrest(OHCA). The aim of this study is to investigate the impact of multidisciplinarytargeted temperature management(TTM) strategies on outcome of patients after cardiac arrest.
METHODS. From May 2017 to December 2018, a multidisciplinary CQI team including emergency physician, intensivists, cardiologists, nurses, and quality management team was organized in a tertiarymedical center in Taiwan. The key interventions includedemergent department (ED) activation system, nursing staffs reminding protocol, TTM share decision making protocol, green channel for rapid computerized tomography examination, TTM ED prescription formula, TTM ED quick laboratory and treatment package, comprehensive critical care system and TTM simulation training. The patientswere divided into three groups: pre-interventionalgroup from Jan to Oct 2017, interventional groupOct 2017 to July 2018 and post-interventional group from Aug to December 2018.
RESULTS. After implementing multidisciplinary TTM strategies since 2017, the rate of patients with cardiac arrest received TTMincrease from 0% to 33.3% and finally achieved 86.6% ($p<0.001$). The rate of TTM recognition also improved from 50% to 90% in physicians and from 66% to 90% in nursing staffs. Return of spontaneous circulation (ROSC) to targeted temperature time decreased from 540 to 270 minutes.

The survival rate of OHCA with ROSC improved from 22.7% to 25% and the survival rate of OHCA with ROSC received TTM therapy could increase up to 48.4%.
CONCLUSION. This study demonstrated multidisciplinary TTM strategies CQI program could improve rate of patients with cardiac arrest received TTM therapy, rate of TTM recognitionin physicians and nursing staffs, ROSC to targeted temperature time, and further survival of cardiac arrest patients.

INTRODUCTION. Extracorporeal cardiopulmonary resuscitation (ECPR) has been introduced as a life-saving procedure in refractory cardiac arrest.
METHODS. Eligible patients for this analysis had to undergo ECPR after unsuccessful cardiopulmonary resuscitation with a minimum of three defibrillation attempts. For extracorporeal life support (ECLS) was used Cardiohelp system (Maquet-Cardiopulmonary-AG, Hirrlingen, Germany) or Levitronix CentriMag blood pump (Levitronix LLC, Waltham, MA, USA). LUCAS II (Physio-Control, Lund, Sweden) system was used for chest compressions during cardiac arrest. The relations of blood lactate and pH levels, measured before ECPR insertion and after 24 hours as well as comorbities (diabetes, hypertension, BMI) to the clinical outcomes at 2 years were evaluated.
RESULTS. We analyzed data from 49 patients treated with ECPR for refractory cardiac arrest. The mean age of our patients was 59 years. Out-of-hospital cardiac arrest (OHCA) occurred in 25 patients, 24 patients suffered from in-hospital arrest (IHCA). Baseline value of lactate was 11.57 ± 4.22 mmol/l, initial pH 6.95 ± 0.31. In comparison with survivors, patients who died had significantly higher initial lactate levels (12.05 ± 0.81 vs. 8.01 ± 0.77; P< 0.05). Moreover, survivors had significantly lower lactate levels after 24 hours (7.39 vs 2.56) and lower BMI (27.4 vs 31.2; P< 0.05). Diabetes or hypertension in our group have no influence on the mortality. The difference of mortality in the group of OHCA or IHCA was also not significant. 32% patients survived one month with good neurological outcome (CPC 1-2), 30% six months, 23% one year and 21% two years.
CONCLUSION. ECPR give the last chance to survive refractory cardiac arrest. The levels of blood lactate are significantly associated with clinical outcomes of ECPR. Obesity was associated with significantly higher mortality in our group.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001317

INTRODUCTION. In recent years, novel AKI biomarkers, such as NGAL, KIM-1, IL-18, L-FABP, IGFBP7, TIMP2 have been discovered and validated to improve early detection for progressive renal failure, need for renal replacement therapy (RRT), or death. Last year, we reported the usefulness of urinary L-FABP for the predictive marker of RRT requirement in critical ill patients and prognosis in patients with septic shock. We are focusing on urinary L-FABP for the diagnostic biomarker of AKI as well as the prognostic marker in critical ill patients.
OBJECTIVES. This study was to evaluate whether urinary L-FABP POC kit can predict mortality of refractory ventricular fibrillation (VF) patients treated with extracorporeal cardiopulmonary resuscitation (ECPR).
METHODS. This was a single-center retrospective observational study of refractory VF patients treated with ECPR admitted in our intensive care unit (ICU) from December 2017 to January 2019. A total of 16 patients were screened and 14 patients were included, 2 patients died within 24 hours after admission were excluded. We examined the relation of urinary L-FABP POC kit data at ICU admission and 28-day mortality and 90-day mortality.
RESULTS. A total of 14 patients were included. Median age was 60 years (IQR 51-67) and all patients were male. Median SOFA score and APACHE2 score were 12 (IQR 10-14) and 35 (IQR 26-38), respectively. Median urinary L-FABP (ng/ml) value was 804.5 (IQR 172.9-3944.3). 12 patients (85.7%) acquired AKI based on KDIGO criteria. All patients had received mechanical ventilation and 6 patients (42.9%) had received RRT. 28-day and 90-day mortality was 42.8% and 64.3%, respectively. The patients were divided into 2 groups according to the results of urinary L-FABP POC kit (group L: negative or slightly positive, group H: strongly positive). The patients who received RRT was 33.3% in group H and 60.0% in group L (p=0.58). There was no significant difference between the groups about initiation of RRT. 28-day mortality was 62.5% in group H and 11.7% in group L. 90-day mortality was 88.9% in group H and 20.0% in group L. Kaplan-Meier curves showed 28-day and 90-day mortality were higher in group H than in group L (p=0.167 and 0.021, respectively).
CONCLUSION. Urinary L-FABP POC kit can predict long term prognosis of refractory VF patients treated with ECPR.

INTRODUCTION. Prolonged duration of targeted temperature management (TTM) after out-of-hospital cardiac arrest does not improve neurological outcome.
OBJECTIVES. To describe the quality of TTM after out-of-hospital cardiac arrest according to the duration of cooling.
METHODS. A retrospective analysis of data from the TTH48 study (NCT01689077), which compared whether TTM at 33°C for 48 hours results in better neurologic outcomes (i.e. good neurological outcome defined by Cerebral Performance Category of 1-2) when compared with standard 24-hour duration. Admission temperature, speed of cooling and rewarming rates were collected in each patient. Precision was assessed by measuring temperature variability (TV), i.e. the standard deviation (SD) of all temperature measurements in the cooling phase. Overcooling and overshoot were defined as one temperature <32°C or >35°C during the cooling phase, respectively. Post-cooling fever was defined as a body temperature exceeding 38.5°C.

RESULTS. A total of 352 patients were analyzed in this study; of those, 175 (50%) were treated with TTM for 48 hours. The proportion of patients treated with intravascular catheter was similar between 48-h and 24-h groups (65% vs. 59%; p=0.22). Time from arrest to target (≤34°C) was significantly shorter for patients treated with TTM for 48-h (5.2 [3.9-6.9] vs. 6.0 [4.4-8.4] hours,p= 0.02), with similar body temperature on admission (35.2 [34.3-35.8] vs. 35.0 [34.4-35.7] °C;p=0.44). Temperature variability was similar between TTM for 48-h and 24-h (0.66 [0.46-0.91] vs.0.69 [0.49-0.91]°C; p=0.59), as was rewarming rate (0.34 [0.24-0.46]°C/ hour vs. 0.35 [0.22-0.47]°C/hour; p=0.96). The number of patients with overcooling (11% vs. 14%) or overshoot (29%vs. 23%) was also similar between groups. However, the proportion of time outside the target ranges was 13 [5-32]% in the 48-h and 18 [8-37]% in the 24-h groups (p=0.049). The proportion of patients with fever was significantly lower in the 48-h groups than the other (52% vs. 64%; p=0.03).
CONCLUSION. TTM for 48 hours was associated with a lower proportion of time with body temperature outside ranges and a lower occurrence of post-cooling fever.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001407

INTRODUCTION. Resuscitation guidelines suggest that patients with hypothermic cardiac arrest should receive prolonged CPR because reduced core temperature is postulated to result in a neuroprotective effect, in the absence of clinical evidence.
OBJECTIVES. To investigate whether patients with hypothermic cardiac arrest can tolerate prolonged CPR and gain a better neurological outcome compared with patients with other etiology of cardiac arrest.
METHODS. We performed retrospective analysis using data from Japan's nationwide out-of-hospital cardiac arrest (OHCA) registry, which includes all patients with OHCA transported to the hospital by emergency medical services from January 2013 through December 2016. Patients with CPR duration > 20 min were stratified into hypothermic arrest group and non-hypothermic arrest group, depending on etiology of cardiac arrest. The relationship of CPR duration with neurologically intact survival (defined as cerebral performance category 1 or 2) at 1 month after cardiac arrest was assessed using multivariable logistic regression.
RESULTS. Of the eligible 310161 OHCA patients with CPR duration > 20 min, 398 were stratified in hypothermic arrest group and 309763 in non-hypothermic arrest group. Intact survival rate decreased linearly 8.9% per 10 min of CPR duration in non-hypothermic arrest group, but there was no relationship between CPR duration and intact survival in hypothermic arrest group. Compared with non-hypothermic arrest group, hypothermic arrest group had higher adjusted probabilities of intact survival through entire CPR duration; 6.8% vs. 0.84% for 21-30 min of CPR duration, 3.7% vs. 0.75% for 31-40 min, 7.0% vs. 0.7% for 41-50 min, 7.0% vs. 0.67% for 51-60 min and 7.4% vs. 0.68% for > 61 min. Adjusted odds of intact survival for hypothermic arrest were 7.0 (95%CI, 3.7-13.3) for 21-30 min, 7.6 (2.2-25.8) for 31-40 min, 36.9 (12.7-107.4) for 41-50 min and 11.5 (2.2-61.9) for 51-60 min, but no significant odds ratio was found for >61 min.
CONCLUSION. Patients with hypothermic cardiac arrest tolerated prolonged CPR. The therapeutic time window of CPR duration might be extended up to 60 min in hypothermic OHCA setting.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001413

INTRODUCTION. The correct identification of patients that are not going to recover consciousness after cardiac arrest is not only clinically challenging but is associated with important ethical and legal implications.
Current guidelines advocate the combination of bedside clinical neurological examination, imaging (CT and MRI) in addition to complex neurophysiological investigations (e.g. SSEPs) and biomarkers (1). These last investigations are not normally available in most centres in the UK. We communicate our appraisal of current practice.
OBJECTIVES. To provide further insight into how patients admitted post cardiac arrest are being neuroprognosticated in our general intensive care unit.
METHODS. The clinical records of 42 patients admitted to Intensive Care post cardiac arrest over a period of 12 months were revised (1st January 2018–1st January 2019).
RESULTS. Out of the 42 patients, thirty-one (74%) were admitted after in hospital cardiac arrest and twenty five (60%) died within first 72 hours. Seventeen (40%) patients underwent post-cardiac arrest prognostication after a period of 72 hours. Sixteen (94%) had a head CT within 24 hours of admission and six (35%) a second CT scan the third day post cardiac arrest. Eight (47%) underwent EEG assessment to neuroprognosticate.
Prognostication was based on bedside clinical examination in all patients (pupillary reactivity and abnormal motor responses). Even though nurse records were complete in all the 17 cases (hourly documentation of pupillary and motor response), we found that the medical clinical notes did not have the same consistency. Furthermore, in the notes of 13 (68%) patients the 24 hours' pupillary reactivity were not stated.
CONCLUSION. This assessment of our current practice showed that prognostication of patients post cardiac arrest relies on clinical assessment. In addition to a not protocolised use of auxiliary tests, medical notes documentation need improvement. We should adjust our practice to international recommendations.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001437

INTRODUCTION. Neuron-specific enolase (NSE) is a well established additional prognostic marker in cardiac arrest survivors. However, the prognostic value of NSE in specific populations remains not fully understood.
OBJECTIVES. The aim of our study was to compare the prognostic value of NSE in male and female cardiac arrest survivors at specific time intervals from collapse.

METHODS. We analyzed data from a single-center prospective registry of out-of-hospital cardiac arrest survivors admitted between 2010 and 2017 to the tertiary cardiovascular center. All subjects were treated with endovascular hypothermia (33°C for 24 hours). NSE was measured at 1, 2, 3, and 4 days from collapse. Clinical outcomes were assessed according to the Cerebral Performance Category (CPC) at 30 days (good neurologic outcome was defined as CPC 1-2). Prognostic value of NSE for prediction of 30-days outcomes was determined using ROC analysis.
RESULTS. A total of 271 individuals were included into the study, 77 female (28%) and 194 male (72%). Female (F) and male (M) population were comparable regarding age, time to return of spontaneous circulation, baseline lactate and pH, and survival with good neurological outcome (57% vs. 61%, P=0.53); however, women had significantly more frequently non-shockable rhythm (43% vs. 19%, P< 0.001). Area under the ROC curve (AUC) at day 1 was 0.78 (P<0.001) in the F group and 0.74 (P<0.001) in the M group. At day 2 the AUC was only 0.85 (P<0.001) in F group and 0.92 (P<0.001) in M group. At day 3 the AUC was only 0.86 (P<0.001) in F group, whereas in M group we observed the highest AUC value (0.94, P<0.001). The highest AUC value in F group was found at day 4 (0.93, P<0.001), corresponding with the AUC of 0.91 (P<0.001) in the M group. NSE values >39.9 mcg/L recorded at any time in the F group were associated with poor prognosis with 100% specificity and 61% sensitivity. On the other hand, the threshold for poor prognosis with 100% specificity in the M group was >57.2 mcg/L (with 52% sensitivity).
CONCLUSION. Our results indicate marked sex-differences in the prognostic value of NSE in cardiac arrest survivors. Whereas in women were the prognostic values lower at days 2 and 3 lower in comparison to men and the highest prognostic value was observed 4 days after collapse with lower threshold for poor prognosis, in male was the highest prognostic values of NSE 3 days form collapse with higher threshold for poor prognosis.

INTRODUCTION. Neuron-specific enolase (NSE) is a well established additional prognostic marker in cardiac arrest survivors. However, the prognostic value of NSE in specific populations remains not fully understood.
OBJECTIVES. The aim of our study was to compare the prognostic value of NSE in groups with shockable and non-shockable initial rhythm at specific time intervals from collapse.
METHODS. We analyzed data from a single-center prospective registry of out-of-hospital cardiac arrest survivors admitted between 2010 and 2017 to the tertiary cardiovascular center. All subjects were treated with endovascular hypothermia (33°C for 24 hours). NSE level was measured at 1, 2, 3, and 4 days from collapse. Clinical outcome was assessed according to the Cerebral Performance Category (CPC) at 30 days (good neurologic outcome was defined as CPC 1-2). Prognostic value of NSE for prediction of 30-days outcomes was determined using ROC analysis.
RESULTS. A total of 271 individuals were included into the study, 201 patients (74%) had shockable (S) initial rhythm and 70 subjects (26%) had non-shockable (NS) initial rhythm. Patients in the S group were younger (mean age 62 vs. 70 years, P<0.001), more frequently male (78% vs. 53%, P<0.001), had lower baseline lactate (P<0.05), and had better survival with good neurological outcome (67% vs. 41%, P<0.001); time to return of spontaneous circulation was comparable (21 min vs. 18 min, P=0.09). Area under the ROC curve (AUC) at day 1 was 0.70 (P<0.001) in the S group and 0.86 (P<0.001) in the NS group. At day 2 the AUC was 0.92 (P<0.001) in S group and only 0.84 (P<0.001) in NS group. At day 3 the AUC was 0.95 (P<0.001) in S group and only 0.84 (P<0.001) in NS group. At day 4 the AUC was 0.93 (P<0.001) in S group and 0.90 (P<0.001) in NS group. NSE values >50.2 mcg/L recorded at any time in the S group were associated with poor prognosis with 100% specificity and 55% sensitivity. On the other hand, the threshold for poor prognosis with 100% specificity in the NS group was >57.2 mcg/L (with 56% sensitivity).
CONCLUSION. Our results indicate that initial rhythm influences the prognostic value of NSE in cardiac arrest survivors. In patients with non-shockable initial rhythm the prognostic values of NSE were generally lower with the highest value 4 days after collapse.

INTRODUCTION. Successfully resuscitated patients from a cardiac arrest by out or in-hospital emergency teams are admitted to the Intensive Care Unit (ICU) for post-resuscitation care. However, the prognosis of these patients remains dismal, with only a minority surviving to hospital discharge.
OBJECTIVES. To characterize the population admitted to the ICU after successful reanimation from a cardiac arrest, and to analyse the factors associated to the clinical outcomes.
METHODS. A retrospective, descriptive and correlational study was performed encompassing patients admitted in the first 24h after a cardiac arrest in an ICU, from 1st January 2014 to 31st December 2018. Through consultation of electronical clinical records, we analysed patient's demographic factors, characteristics of the cardiac arrest, immediate and in-hospital approach, mortality and neurologic (evaluated by Cerebral Performance Category (CPC) Scale) outcomes. Correlation between variables was performed by Chi-square test and Mann-Whitney test, with a significance level of 95%. Independent predictors of clinical outcomes were identified through a binary logistic regression analysis, considering p=0,05. Statistical analysis was conducted using SPSS 23.0.
RESULTS. During the defined period, 187 patients were admitted after a cardiac arrest, 65% of whom were male. The median age was 67 years and 39% suffered an out-of-hospital cardiac arrest. 87% had an initial non-shockable rhythm and the most frequent presumed etiology was cardiac (31%). Glasgow coma scale after return of spontaneous circulation was higher in patients that suffered an in-hospital cardiac arrest (p= 0,003) and in patients that survived to discharge (p=0,003). The in-hospital mortality rate was 63%, with most of the deaths associated with initial non-shockable rhythms (93%; p=0,001), higher severity indices (p< 0,001), longer invasive mechanical ventilation (IMV) and vasopressor support (p<0,001). Furthermore, basic life support (BLS) was more frequently initiated in patients who survived to discharge (p=0,027). SOFA score at the admission was statistically significantly higher in males (p=0,007). 30% of the survivors had significant neurologic dysfunction at hospital discharge (CPC 3 and 4). Non-shockable rhythms (p=0,018), non-immediate initiation of BLS (p=0,01), higher SAPS II score (p<0,001) and higher relative duration of vasopressor support (p=0,008) were

independent predictors of in-hospital mortality. The absence of post-cardiac arrest shock (p=0,016) and epileptic seizures (p=0,026) were independent predictors of worse neurologic outcome.
CONCLUSION. This study confirms the importance of immediate initiation of BLS and, consequently, the need for training out and in-hospital population. Patients with early neurologic dysfunction but no cardiovascular dysfunction may exhibit a worse neurologic outcome.

INTRODUCTION. Although targeted temperature management (TTM) is recommended in comatose survivors after cardiac arrest (CA), the optimal method to deliver TTM remains unknown. We performed a meta-analysis to evaluate the effects of different TTM methods on survival and neurological outcome after adult CA.
METHODS. We searched on MEDLINE/PubMed database until 22/02/2019 for comparative studies that evaluated at least two different TTM methods in CA patients. Data were extracted independently by two authors. We used QUADAS-2 tool for assessing risk of bias of each study. The Jadad quality scoring system was used to assess the methodological quality of randomized clinical trials (RCT). Primary outcome was the occurrence of unfavorable neurological outcome (UO); secondary outcomes included overall mortality.
RESULTS. Our search identified 6886 studies; 22 studies (n=8027 patients) were included in the final analysis. When compared to surface cooling, core methods showed a lower probability of UO (OR 0.85 [95% CIs 0.75-0.96]; p=0.008) but not mortality (OR 0.88 [95% CIs 0.62-1.25]; p=0.21). No significant heterogeneity was observed among studies. However, these effects were observed in the analyses of non RCTs. A significant lower probability of both UO and mortality were observed when invasive were compared to non-invasive TTM methods and when temperature feed-back devices (TFD) were compared to non-TFD methods. These results were significant particularly in non RCTs.
CONCLUSION. Although existing literature is mostly based on retrospective or prospective studies, specific TTM methods (i.e. core, invasive and with TFD) were associated with a lower probability of poor neurological outcome when compared to other methods in adult CA survivors (CRD42019111021).

INTRODUCTION. Steroid administration during post-arrest period has been reported to improve myocardial dysfunction and hemodynamic following return of spontaneous circulation (ROSC) in cardiac arrest survivors. However the mechanism how post-arrest steroid use ameliorate myocardial injury in cardiac arrest survivors remains largely unknown.
OBJECTIVES. To evaluate the effect of post-arrest hydrocortisone administration on myocardial mitochondrial injury and dysfunction in a rat model of ventricular fibrillation (VF) cardiac arrest model.
METHODS. VF cardiac arrest was induced and left untreated for 5 minutes in adult male wistar rats. Cardiopulmonary resuscitation and electric shocks were then applied to achieve ROSC. Successfully resuscitated animal were randomized into steroid and non-steroid groups. The steroid group received intravenous hydrocortisone of 8 mg/kg immediately after ROSC and the non-steroid group received saline as placebo. The histology and ultrastructural changes of myocardium, myocardial mitochondrial function, and survival and neurological function at 72nd hour following ROSC were compared between groups.
RESULTS. There were 12 animals in each group. Within 4 hours following ROSC, the steroid group had significantly better systolic function (dp/dt) and cardiac output than the non-steroid group. At 4th hour following ROSC, the histology examination and transmission electron microscopy demonstrated less myocardial damage and mitochondrial injury in the steroid group. Besides, steroid prevented the acceleration of Ca2+-induced mitochondrial swelling (mitochondrial permeability transition pore opening) as noted in the non-steroid group. As compared to the non-steroid group, the steroid group also had a significantly higher 72 hour survival rate (91.7% v.s. 50%, p = .013) and higher percentage of good neurological function (75% v.s. 25%, p = .02) at 72nd hour.
CONCLUSION. Post-arrest hydrocortisone administration mitigates myocardial damage, ameliorates cardiac mitochondrial injury and improves 72-hour survival and neurological recovery in a rat model of VF cardiac arrest.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000384

INTRODUCTION. Acute hypoxia results in uncontrolled release of glutamate and the consequent stimulation of N-methyl-D-aspartate (NMDA) receptors, which affects the homeostasis (1). A potential therapeutic approach to prevent this sequence of events is a blockade of NMDA receptors. Meanwhile, in different models of acute hypoxia, activation of opioid receptors demonstrates significant cardio- and neuroprotective effects with a consequent increase in animal survival (2).
OBJECTIVES. Thus, we aimed to test the effects of S-ketamine and alfentanil on lactate, blood glucose, acid-base status and early survival in rats after asphyxia cardiac arrest (ACA).
METHODS. After instrumentation under anaesthesia with Isoflurane, Wistar rats (n=26) weighing between 350–400 g were assigned to three groups where: 1. Alfentanil 2.5 mcg/kg iv (n=12) was given 10 min before ACA; 2. S-ketamine 40 mg/kg iv (n=7) was given 10 min before ACA; 3. Control (n=7), the same amount of NaCl 0,9% iv was given 10 min before ACA. The rats were asphyxiated by clamping the endotracheal tube at the end of expiration for 5 min. Resuscitation was initiated by an injection of epinephrine (0.02 mg/kg, iv), followed by manual thoracic compressions (180 compressions/min) and mechanical ventilation (21% O2, 80 breaths/min). Invasive mean

arterial pressure (MAP) was recorded at the baseline (BL), injections (Inj), every 1 min during ACA (As) and every 5 min in post-resuscitation (PR) period. Blood gas samples, blood for lactate and glucose were taken at the BL and 20 min at the PR period. Early survival was determined at the 60 min after ACA.
RESULTS. Selected groups of animals did not differ on the pre-resuscitation parameters. No differences in blood glucose level and survival between the rats was found at the postresuscitation period. The rats pre-treated by S-ketamine got significantly higher production of lactate (11,4±1,4 mmol/l vs 2,8±1,3 mmol/l, p < 0,002) when compared to the rats treated by alfentanil. Base deficit was significantly lower in group with using of alfentanil (-1.5±1,3 vs -16,5±3,2, p < 0,001) when compared to the rats treated by S-ketamine.
CONCLUSION.
Pre-treatment with alfentanil attenuated significantly disturbances in acid-base balance and production of lactate after ACA when compared to the rats pre-treated by S-ketamine.

INTRODUCTION. Treatment of post cardiac arrest (CA) syndrome represents a clinical priority. Argon represents an attractive therapeutic option.
OBJECTIVES. The purpose of this study was to determine efficacy, safety and the most effective dose of argon in a porcine model of high-severity CA and cardiopulmonary resuscitation (CPR).
METHODS. Left anterior descending coronary artery was occluded in 36 pigs, and ventricular fibrillation was induced and left untreated for 12 min. CPR was then performed for 5 min prior to defibrillation. Following successful resuscitation, animals were subjected to 4 hr ventilation with (a) 70% argon - 30% O2 (n=10); (b) 50% argon - 50% O2 (n=10); (c) 70% N2 - 30% O2 (n=10). Hemodynamic parameters were monitored and serial blood samples were obtained for blood gas analysis. Animals were observed up to 96 h for assessment of survival and neurological recovery.
RESULTS. Ten animals of 12 were successfully resuscitated in each group. After resuscitation, animals treated with Argon 70% showed higher systolic, mean and diastolic arterial pressure compared to controls and to the Argon 50% treated animals (p<0.05). Ventilation with argon did not have any detrimental effects on respiratory gas exchange during the 4 hr ventilation. There was no statistically significant difference in the number of the resuscitated animals survived up to 96 hrs. However, 6 (60 %) and 8 (80 %) resuscitated animals in the Argon 50% and Argon 70% groups respectively achieved a complete neurological recovery (Overall Performance Categories, OPC=1 or 2), whereas only 3 (30%) animals survived up to 96 hours with a complete neurological recovery in the control group (p<0.0001).
CONCLUSION. Argon prevented post CA brain injury in swine model of severe CA, without detrimental effects on hemodynamics and respiratory gas exchanges. Beneficial effects was higher at a concentration of 70% than of 50%.

Hemoglobin A1c is related to 6-month survival on patients who survived after out-of-hospital cardiac arrest

JH. Lee, SO. Joo
Emergency medicine, Uijeongbu St. Mary's Hospital, The Catholic University, Euijeongbu, Republic of Korea
Correspondence: J.H. Lee
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000676

INTRODUCTION. Out-of-hospital cardiac arrest(OHCA) is associated with poor survival and can be considered a major global health problem. The early determination of neurologic outcomes is an essential element of risk stratification to identify aggressive treatment of OHCA patients. Hemoglobin A1c(HbA1c) serves as a surrogate marker of glycemic control and is a key risk indicator for diabetes associated microvascular and macrovascular complications and mortality.
OBJECTIVES. This study aimed to investigate the association of HbA1c level and out-of-cardiac arrest patients who underwent hypothermic-targeted temperature management.
METHODS. This retrospective observational study included adult out-of-hospital cardiac arrest who underwent hypothermic-targeted temperature management from December 2011 to February 2019. Serum HbA1c was measured immediately after return of spontaneous circulation. The primary outcome was 6-month survival.
RESULTS. In total, 282 patients were analyzed. Among those, eighty-three patients survived six months. The mean HbA1c in patients surviving six months was 5.67%±SD, which was significantly lower than in patients who did not survive six months (6.21%±SD, P<0.001). The AUC calculated on ROC analysis predicting six month survival was 0.66 (95% confidence interval, 0.60 to 0.71; P<0.001), with a sensitivity of 72% and specificity of 57% at a cut-off of 5.4%. In multivariable logistic regression model, HbA1c level ≥ 5.4% (OR 5.61, 95% CI 2.46-12.81, P<0.01), non-cardiac cause (OR 3.21, 95% CI 1.29-8.01, P=0.01), non-shockable rhythm (OR 2.43, 95% CI 1.02-5.78, P=0.04), non-witness (OR 2.75, 95% CI 1.29-5.88, P=0.01), older age (OR 1.05, 95% CI 1.03-1.08, P<0.01), longer anoxic time (OR 1.08, 95% CI 1.06-1.11, P<0.01) as independent factors of 6-month survivor. The AUC calculated on ROC analysis of multivariable logistic regression model was 0.89 (95% CI 0.85-0.93, P<0.01).
CONCLUSION. This study showed that HbA1c of out-of-cardiac arrest(-OHCA) was associated with survival in patients underwent hypothermic-targeted temperature management. But its sensitivity and specificity are unsatisfactory for a single prognostic marker. HbA1c should be considered as an additional modality for prognostification and not as a single reliable variable. Further large multicenter studies are needed to evaluate the utility of HbA1c for early prognostic factor.

INTRODUCTION. Severe obstructive shock with cardiac arrest leads to a decline in cardiac output of primarily the right heart chamber. We hypothesize, that with return of spontaneous circulation (ROSC) after an obstructive cardiac arrest, the right heart generates cardiac output several heartbeats before the left heart, thereby proving the primary role of venous return for the reconstitution of the circulation.
OBJECTIVES. Description of the time course of stroke volume generation of right and left heart after resolution of an obstructive cardiac arrest to clarify the role of venous return in the achievement of ROSC.
METHODS. This abstract is based on data from a previous study (1). We induced obstructive circulatory arrest in ten anesthetized pigs (equipped with an ultrasonic flow probe on the pulmonary artery and a pressure catheter in the carotid artery) by balloon occlusion of the right atrium (inflatable high-compliance balloon) over one minute in five experimental conditions (PEEP5, PEEP10, euvolemia, bleeding and hypervolemia). Pulmonary artery pressure and flow tracings confirmed circulatory arrest and ROSC. Single heartbeats were analysed during balloon inflation to create circulatory standstill and then deflation of the balloon after one minute to achieve ROSC. ROSC was defined as the earliest heart beat from which a steady rise in PA flow over the succeeding beats could be observed. After ROSC, PA flow increases by 200%, MAP increases by 10% and arterial stroke volume (calculated from pulse contour) increases by 50% were considered clinically significant. The number of beats until these values were achieved were counted. Comparisons were done with Friedman's ANOVA on ranks and post-hoc Tukey's test and data presented as median (range).
RESULTS. We achieved ROSC in 43/50 conditions after 46 (21-84) sec with a flow in the pulmonary artery of 92 (-18-800) ml/min and a mean arterial pressure of 32 (18-51) mmHg. During arrest, MAP increased by 8 (1.9-10) mmHg due to increased sympathetic activity occurring 19-22 sec after arrest (1), while no significant change in PA flow was observed. After ROSC pulmonary flow doubled after 2 (1 to 20) heartbeats, whereas MAP increased 10% only after 7 (1 to 20) beats and arterial stroke volume increased 50% only after 15 (1 to 20) beats, $p < 0.001$ for all comparisons. Arterial stroke volume and ABP increased by 50% or 10% after 120 (0 to 339) ml or 3.2 (0 to 9) ml/kg and 41 (0 to 333) ml or 1 (0 to 9) ml/kg flow through the pulmonary artery, respectively. Central venous pressure consistently and immediately dropped after ROSC.
CONCLUSION. We interpret the time delay between the increase in pulmonary artery flow and arterial pressure and stroke volume as proof of the role of venous return for the recovery from obstructive shock. This is supported by the immediate drop of central venous pressure after ROSC. To what extent these findings may be generalized to non-obstructive forms of cardiac arrest needs further investigation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001610

INTRODUCTION. Capnographic CO2 oscillations have been described during Cardiopulmonary Resuscitation (CPR).
The Airway Opening Index (AOI) has been recently proposed to quantify the CO2 oscillations at capnography during chest compressions (CCs).(1) It has been proposed that a low oscillating EtCO2 during CCs is a result of airway collapse, which obstructs the expiratory airflow. The aim of this study is to assess the change of AOI over time during 18 minutes of CPR in a porcine model of cardiac arrest (CA). We will assess the relationship between manual and mechanical CCs, the compliance of the respiratory system (Cpl,rs) and the duration of CPR with the AOI.
METHODS. Adult male swine were randomized to 18 min of CPR with mechanical (LUCAS® 3.0) or manual CCs after 2 minutes of CA. Mechanical ventilation was provided with tidal volume 500 ml, 10 bpm, FiO2 1.0, ZEEP). Hemodynamic parameters, EKG, SpO2, EtCO2were continuously recorded. Cpl,rs was assessed after return of spontaneous circulation (ROSC). The AOI was computed as ΔCO2/CO2max and the values were averaged on the number of CCs (n=6) during each minute of CPR.
RESULTS. The mean AOI was significantly higher in the manual CCs group compared to the mechanical group(58±5% *vs* 24±3%, p< 0.0001 **Fig 1a**). The AOI was higher in the manual CCs group compared to the mechanical group throughout the time of CPR. No decrease of AOI has been identified over time within each group (**Fig 1b**). The mean value of AOI measured at the end of CPR (minute 18) showed a good correlation with Cpl,rs (r=0.749, p=0.0006, Fig **1c**).
CONCLUSION. In a randomized porcine model of CA, AOI was significantly higher in the manual compared to the mechanical CCs group during the all 18 minutes of CPR. Cpl,rs was strongly associated with the AOI at the end of CPR.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001418

INTRODUCTION. Traumatic bleeding is characterized by trauma-induced coagulopathy and enhanced endothelial permeability. Currently, transfusion strategies have been adopted using a balanced component strategy to prevent or treat coagulopathy. Interventions aimed at reducing endothelial permeability may further improve outcome. Tyrosine kinase inhibitors such as bosutinib have the potential to reduce vascular permeability by increasing intercellular endothelial adhesion molecules.
OBJECTIVES. To examine whether bosutinib in combination with a balanced component strategy reduces endotheliopathy, thereby limiting transfusion requirements and organ failure, in a rat polytrauma transfusion model.
METHODS. Blood products were made using syngeneic donor rats according to national blood bank standards. Spraque Dawley rats (n= 13 per group) were sedated and mechanically ventilated. Trauma was induced by crush injury to both the small intestine and liver and by a femur fracture. Following trauma, rats were exsanguinated until a MAP of below 40 mmHg, lasting 1 hour. Subsequently, rats were randomized to receive resuscitation with red blood cells, plasma and platelets in a 1:1:1 ratio with either bosutinib or vehicle or only Ringer's Lactate (RL) infusion. Resuscitation was stopped when MAP was 60 mmHg. After six hours, organs were harvested for wet/dry (W/D) ratio. Data are median with interquartile range. A p-value of less than 0.05 was considered to be statistically significant. Bonferroni corrections were applied to correct for multiple testing.
RESULTS. The model resulted in shock with increased lactate levels in all animals. Mortality only occurred in RL infused rats (13%). The amount of transfusion or infusion needed to obtain a MAP of 60 mmHg was significantly lower in the bosutinib treated animals (1.0 [1.0 – 1.2] ml) when compared to vehicle (2.0 [2.0 – 2.6] ml) and RL controls (4.0 [4.0 - 5.0] ml, p<0.001). Also, at the end of the experiment, lactate levels were lower in the bosutinib group (2.9 [1.7 – 4.8]) compared to vehicle (6.2 [3.1 – 14.1], p=0.058) and RL controls (11.7 [4.9 – 16.6] mmol/L, p=0.004). Bosutinib resulted in significant lower lung W/D ratios (5.1 [4.6 – 5.2]) when compared to vehicle (5.7 [5.4 – 6.0], p=0.003) and RL controls (5.5 [5.3 – 5.7], p=0.012). Kidney W/D ratios were similar.
CONCLUSION. In this model, bosutinib reduces resuscitation volume and results in a better stabilized shock as well as a reduction in pulmonary edema. Whether bosutinib improves outcome should be determined in a trial in patients with traumatic bleeding.

Nationwide Age-specific Infection and Sepsis Mortality in Hospitalized Children in Germany

C. Fleischmann[1], A. Mikolajetz[2], S. Born[1], D. Schwarzkopf[1], D. Thomas-Rueddel[2], K. Reinhart[1]

Correspondence: C. Fleischmann
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000759

INTRODUCTION. As most severe complication of infection, sepsis is a major health threat for vulnerable populations such as infants or children with comorbidity. Every year, sepsis affects more than 4 million children worldwide, of which 9-20% die (Fleischmann-Struzek et al. 2018). For Germany, data on nationwide and population-level age-specific pediatric sepsis mortality is scarce.
OBJECTIVES. We aimed to assess infection and sepsis mortality in hospital-treated children in different age groups between 2010-2015 based on representative hospital discharge data in Germany.
METHODS. Patients <18 years with infection and sepsis were identified in a nation-wide database (DRG statistics) between 2010-2015 based on ICD-10 coded primary and secondary hospital discharge diagnoses. The DRG statistics includes nearly complete inpatient data from German hospital except for military or psychiatric hospitals and contains more than 18 million annual hospitalizations. Sepsis was defined as organ failure due to infection and was identified by ICD-10-codes R65.1 and R57.2. To identify infection-related hospitalizations, ICD-9 infection codes were adapted from Angus et al. and translated into ICD-10 (Angus et al. 2001).
RESULTS. Between 2010 and 2015, 2.54 million children with infectious diseases were treated in German hospitals. Overall in-hospital mortality was 0.2%, which corresponds to a mortality rate of 7 deaths per 100 000 children. Highest mortality rates were found in children <1 years (0.5%); in all other age groups, mortality ranged between 0.1-0.2%. Among hospitalized children with infection, 10,975 children had sepsis (0.43%) with an overall mortality of 17.2% (2.4 deaths/100 000 children). Mortality peaked in newborns (18.7%) and was lowest in 2-5year old children (14.5%). Approx. 25% and 8% of all decedents <17 years in Germany received an infection and sepsis code during their terminal hospitalization, respectively.
CONCLUSION. Sepsis is an important cause of death in children in Germany. Mortality from pediatric sepsis is higher in Germany than in other high-income countries such as the US with an observed sepsis mortality of 11.8% in children between 2014 and 2016 (Evans et al. 2018). This underlines the need for targeted prevention strategies and quality improvement initiatives in Germany as demanded by the WHO resolution on sepsis (WHA Resolution 2017).

INTRODUCTION. Hypertonic sodium lactate have recently shown interesting effects for fluid management in endotoxemia models1. We therefore evaluated its effects on microcirculation, capillary leakage, cardiac function and different biological parameters in a sepsis rat model of caecal ligation and puncture (CLP).
METHODS. 30 rats were randomized in 3 groups (n=10 per group): Sham; CLP-NaCl 0.9%; CLP-Lactate 11.2%. 2.5 mL/kg/h of fluids were intravenous administrated from the CLP procedure and during 18 hours. We then evaluated mesenteric microcirculation (laser speckle imager), cardiac function (echocardiography and pressure-volume (PV) loops) and inflammation (uremia, VEGF-A, IL-1β, IL-10, TNFα).

Capillary leakage was explored using Blue Evans extravasation in the lung and gut on 5 additional rats. Results are expressed as medians with interquartiles and comparisons versus CLP-NaCl were realized using Kruskall-Wallis or ANOVA test.
RESULTS. CLP-lactate presented an improved mesenteric microcirculation (735.5 [407.4-878.8] vs 240.6 [209.3-390.8]UI/pixel, p=0.0006) with higher cardiac output (0.34 [0.28-0.43] vs 0.14 [0.10-0.18] mL/min, p<0.0001) and higher left ventricular shortening fraction (55.2 [46.2-73.2] vs 39.1 [32.9-51.8] %, p=0.009). PV loops also showed raised dP/dt max slope (6.3 [3.3-12.1] vs 2.7 [2.0-3.9] mmHg/ms, p=0.04), suggesting an improved inotropism, and a lower Left Ventricular End-Diastolic Pressure-Volume Relation (1.9 [1.1-2.3] vs 3.0 [2.2-3.7] RVU/mmHg, p=0.005), suggesting an improvement in diastolic function independently from preload. Mean arterial pressure between CLP-NaCl and CLP-Lactate was similar at the end of infusion. Evans Blue diffusion was reduced in the gut and the lung for CLP-lactate (37.2 [31.0-43.3] vs. 112.7 [63.3-141.6], p=0.03 and 107.5 [82-174.3] vs. 272.7 [221.8-444.5] ng EB/mg of tissue, p=0.006). Plasma levels of lactate and 3OH-butyrate were higher in CLP-lactate (6.03 [3.08-10.3] vs. 3.19 [2.42-5.11] mmol/L, p=0.04; 400 [174-626] vs. 189 [130-301] µmol/L, p=0.03). Inflammatory response was reduced in CLP-lactate (IL-1β: 172.2 [119.0-446.3] vs. 927.7 [244.8-1470] pg/mL, p=0.004; TNFα: 17.9 [12.5-50.3] vs. 53.9 [30.8-85.6] pg/mL, p=0.005; IL-10: 351.6 [267.0-918.6] vs. 904.5 [723.1-1243] pg/mL) as well as VEGA-A plasma levels (198.2 [185.3-250.0] vs. 260.7 [249.8-268.9] pg/mL, p=0.009).
CONCLUSION. Hypertonic lactate fluids protect against cardiac dysfunction, mesenteric microvascular alteration and capillary leakage during sepsis, in association with a significant reduction in inflammatory process and kidney failure.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000778

INTRODUCTION. Intravenous fluid resuscitation was the mainstay treatment in early goal-directed therapy for sepsis, which measured static central venous pressure (CVP) in first 6 hours (hrs)1. Although several studies demonstrated that dynamic indices were more accurate than static indices for prediction of fluid responsiveness2, no landmark studies compared the efficacy of both types of indices for clinical outcomes.
OBJECTIVES. The primary objective is to compare the 30-day all-cause mortality rate of septic patients in whom fluid resuscitation was guided by dynamic inferior vena cava (IVC) diameter with static CVP measurement. The secondary objectives are to compare the proportions of patients achieving ≥1 macrovascular target(s), i.e., mean arterial pressure ≥65 mmHg and urine output ≥0.5 mL/kg/hr; and ≥1 microvascular target(s), i.e., central venous oxygen saturation (ScvO2) ≥70% and lactate clearance ≥10%, which were assessed at 6 hrs after treatment of sepsis, between those using dymamic and static parameters.
METHODS. A Single-blinded randomized controlled trial was conducted in Thammasat University Hospital between August 2016 and March 2019. The patients were stratified by APACHE-II (<25 or ≥25) and randomized using block of 2 and 4, to either dynamic IVC diameter measurement by ultrasound (US) or static CVP measurement. We recorded clinical parameters at baseline, during resuscitation and until completion of 6 hrs, including the vital status at 30 days, macrovascular and microvascular targets.
RESULTS. A total of 91 patients was enrolled, but one withdrew. Forty-three patients were randomized to dynamic IVC diameter measurement, while 47 patients were randomized to static CVP measurement. The baseline characteristics between two groups were not different. The 30-day mortality rates between IVC-guided group and CVP-guided group were not different (39.5% vs. 44.7%, p=0.622). The proportions of patients who achieved ≥1 macrovascular target(s) at 6 hrs were not different between both groups (65.1% vs. 63.8%, p=0.899). The proportions of patients achieving ≥1 microvascular target(s) at 6 hrs were also not different between both groups (83.7% vs. 66.0%, p=0.054), but the proportion of patients in IVC-guided group achieving ScvO2 ≥70% was higher than that of the other (77.1% vs. 48.6%, p=0.013).
CONCLUSION. Dynamic US-guided fluid resuscitation does not affect the mortality of patients with sepsis, however, it may help more patients achieve ScvO2 ≥70%, compared to static CVP-guided resuscitation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000809

INTRODUCTION. Thrombosis in critical states is known to be connected with the formation of Extracellular Traps (ETs), which are produced by blood phagocytes [1]. ETs activate platelets and visa versa: activated platelets prime phagocytes to undergo ETosis.
Development of common methods of ETosis determination in blood is actual. We developed the method for the assessment of phagocyte circulating in blood that are transformed during ETosis, using standardized blood smears [2]. Method implies preparation of smears with monolayer of cells with strictly specified parameters, providing the standard conditions for heterogenic lysis of circulated phagocytes, transformed during ETosis.
OBJECTIVES. The aim of the study is to evaluate the connection between ETs level and hemostasis indicators with sepsis outcome.
METHODS. ETs levels in standardized blood smears [2], platelets count and antithrombin III (AT III) activity in blood were determined for 73 patients in intensive care unit with verified sepsis in dynamics, using hematological analyzer PENTRA 120 (Horiba Medical, France) and ACL TOP analyzer (Instrumentation Laboratory, USA).
RESULTS. Among septic patients survival rate was 60% (29 cases of lethal outcome and 44 cases of recovery). We compared maximal ETs level during all time of observation of each patient; at this moment hemostasis indicators were assessed. In group with lethal outcome ETs level was in average – 24.6% (95% CI: 17.7-31.5%), platelet count – 152×10^9/L (95% CI: 112-192×10^9/L), AT III activity – 67.5% (95% CI: 58-77%). In recovery group ETs level was in average – 9.2% (95% CI: 7.6-10.8%), platelet count – 272×10^9/L (95% CI: 223-321×10^9/L), AT III activity – 77.4% (95% CI: 70-84%). The differences in ETs levels and platelet counts between the groups were statistically significant according to Mann-Whitney U-test (fig. 1). Thrombocytopenia (<120×10^9/L) was observed in 48.3% cases of lethal outcome and 13.6% cases of recovery.

CONCLUSION. Maximal level of extracellular phagocyte traps as well as platelet count significantly differ in the groups of recovered and died septic patients, they both are significant mortality predictors, while antithrombin III is not. These preliminary data ensure us in the significance of future studies of the connection between considered cellular markers in dynamics.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000820

INTRODUCTION. Sepsis is the primary cause of mortality in intensive care units. It can be treated effectively, but it is essential treated it early. However, differentiate sepsis from non-infectious SIRS at the early stage has become a challenge. In this context, presepsin is a new biomarker with better sensitivity and specificity in the diagnosis of sepsis that other biomarkers.
OBJECTIVES. Evaluate the sensibility and specificity of presepsin for the diagnosis of positive blood cultures and the prognostic value in patients with suspected sepsis.
METHODS. Prospective study, carry on in the ICU of the Hospital Italiano de Buenos Aires, Argentina, between August 2015 and March 2017. Patients in ICU with more than 48 hours of hospitalization, with new diagnosis of suspected sepsis, have been included. Patients with any antibiotic treatment or SIRS of any cause until three days before the inclusion were excluded and so were burned, immunodepleted, pregnancy and subjects who have a do not resuscitate status. Presepsin were obtained at suspect sepsis, 24 and 72 hours after.
RESULTS. 144 patients have been recruited. Mean age was 64 and mean APACHE II 15. The main infectious sources were respiratory (33%) and abdominal (14%). 28 blood cultures (BC) were positive (19%), with 19 rescues of gram-negative bacilli and 9 gram-positive cocci. Baseline presepsin in patients with positive BC was greater (1655 pg/ml, SD+/-1137) than patients with negative BC (mean 1015 pg/ml, SD+/-893), (p=<0.001) (Figure 1). In patients with renal failure (RF), values of presepsin did not have significative differences (positive cultures: mean of 2520 pg/ml, SD+/-3025; negative cultures: mean of 2789 pg/ml, SD+/-2476), (p=0.49). The cut point of 400 pg/ml had the best relationship between sensitivity (96.4%) and specificity (19.8%), with an area under the ROC curve (AUC) of 0.72. In patients with RF, the AUC was 0.59. Global mortality in UCI was 21% (31 patients). Values of basal presepsin, at 24 and 72 hs had a significative correlation with the probability of death in UCI (Figure 2). Progression of presepsin between basal values and 72 hs values did not correlate with the probability of death (in 41% of patients that death in ICU the presepsin values decreased at 72 hs, against 49% in patients that survive).
CONCLUSION. Presepsin has good sensitivity for the diagnosis of positive BC in ICU-sepsis, but only in patients without RF. That is a significant problem because it is a common comorbidity in ICU patients. Also, presepsin values had a good correlation with the risk of dying in ICU.

Monitoring tissue antibiotic concentrations with microdialysis: Determination of in-vivo tissue meropenem recovery

K. Tam[1], I. Longo[2], D. Brealey[3], M. O'connell[4], M. Singer[5]
[1]Intensive care medicine, University College London, London, United Kingdom; [2]Anaesthesia and intensive care medicine, Azienda Sanitaria Universitaria Integrata di Trieste, Trieste, Italy; [3]Critical care, UCL Hospitals NHS Foundation Trust, London, United Kingdom; [4]Director, Probe Scientific Ltd, Thurleigh, Bedford, UK, Thurleigh, United Kingdom; [5]Bloomsbury institute of intensive care medicine, University College London, London, United Kingdom
Correspondence: K. Tam
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000841

INTRODUCTION. Therapeutic drug monitoring of antibiotics is very limited at present and no bedside test is available to offer rapid results. Tissue microdialysis (MD) is a minimally invasive technique that measures only the free (unbound), active fraction of antibiotics in the interstitial fluid of target tissues [1,2]. However, concentration of drug within the microdialysate samples reflects only a fraction of the total unbound concentration in that tissue. This ratio is called relative recover [3]. For accurate determination of true tissue concentration, the analyte concentration measured in microdialysate must be corrected to the relative recovery (%).

OBJECTIVES. The aims of this study are to describe in-vivo microdialysis recovery of meropenem in multiple tissues in healthy rats ,and to compare these levels against those found in early and late stages of sepsis.
METHODS. Healthy male Wistar rats (300-350g), were allocated into three study groups: sham, 6 hour sepsis and 24 hour sepsis. Sepsis was induced by faecal slurry injected intraperitoneally. MicroEye® probes (Probe Scientific Ltd, Bedford, UK) were implanted into 6 tissues: muscle, subcutaneous, liver, peritoneal cavity, trachea and jugular vein. Probes were perfused with meropenem 10 μg/mL at a rate of 1 μL/min. Microdialysate from each tissue was sampled every 10 minutes for 120 minutes' duration. Meropenem concentration was determined using High Performance Liquid Chromatography (HPLC, Agilent 1260II). MD recovery was calculated as [(Cin-Cout/Cin)*100) [3]. ANOVA with post-hoc Dunn's test were used to seek statistical significance.
RESULTS. MD recovery in most tissues in sham rats ranged from 35-41%, except for muscle (23%, p<0.0001) and trachea (27%, p<0.05). At 6 hours' sepsis, recoveries were increased to 35-50% (p<0.05), except endotracheally (9%, p<0.0001). At 24 hours' sepsis, recoveries were significantly lower in all tissues (9-34%, p<0.0001) [Figure 1].
CONCLUSION. We conclude that MD drug recovery in tissues are significantly different in health and at different timepoints in sepsis. This highlights the importance of in-vivo determination of drug recovery prior to conducting a MD study, to avoid inaccuracies in true tissue drug concentration measurement.

INTRODUCTION. Predicting fluid responsiveness for elder patients, especially with acute respiratory distress syndrome or arrhythmia or severe cardiac dysfunction, is still a daily challenge in intensive care unit. Based on heart-lung interaction, cardiac output (CO) will be changed derived from occlusion of respiratory.
OBJECTIVES. The study was aimed to explore the feasibility of occlusion of end-inspiratory or end-expiratory in prediction of fluid responsiveness for elder septic patients.
METHODS. 30 elder septic hypotension patients with mechanical ventilation were enrolled. The ratio of positive fluid responsiveness (PFR) and negative fluid responsiveness (NFR) was 1:1. After analgesia and sedation, all of them were suffered end-inspiratory/end-expiratory occlusion for 15s. Parameters of CO (CI/SVI and LVOT-VTI/Vmax) were dynamic monitored via noninvasive pulse contour and echocardiography. PFR were identified as $^{\triangle}$CI≥15% after 500ml saline of fluid challenge. T-test or Mann-Whitney test and receiver operating characteristic curve (ROC) were applied for data analysis, and then calculated the diagnostic parameters with regarding to the cutoffs.
RESULTS. Occlusion of end-expiratory increased CO significant in PFR patients than negative patients; and vice versa, occlusion of end-inspiratory decreased CO significant in PFR than NFR. ROC for predicting PFR showed that CO parameters had considerable predictive value (C-statistics, 0.849-0.951). In addition, CI/SVI decreased ≥5.52%/6.52 or LVOT-VTI/Vmax decreased ≥7.43%/4.24% derived by occlusion of end-inspiratory and CI/SVI increased ≥4.52%/9.52 or LVOT-VTI/Vmax increased ≥8.59%/3.88% derived by occlusion of end-expiratory had 100% reliability to predict PFR in our elder septic patients.
CONCLUSION. Occlusion of end-inspiratory or end-expiratory may be used as a promising method to predict fluid responsiveness for elder septic patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000858

INTRODUCTION. In septic shock patients, fluid therapy has been fostered as one of the pillars of resuscitation. Inadequate fluid resuscitation can lead to tissue hypoperfusion, while indiscriminate fluid administration can induce pulmonary edema, abdominal hypertension, acute kidney injury, among other complications. Fluid responsiveness (FR) tests are dynamic bedside evaluations that allow identifying the position of the patient in the cardiac function curve(1).
Despite that these tests are widely available, extensively described in the literature and almost cost-free, recent surveys have shown that the minority of intensive care practitioners effectively use them to guide fluid therapy(2).
In the recently published ANDROMEDA-SHOCK trial, a comprehensive resuscitation protocol was applied to early septic shock patients with two different perfusion targets (lactate and capillary refill time). The protocol included the evaluation of FR as a mandatory aspect of the hemodynamic profiling of patients(3)
OBJECTIVES. To determine the use of FR testing, its' impact on fluid therapy and on perfusion endpoints during initial septic shock resuscitation of patients included in ANDROMEDA-SHOCK trial.
METHODS. A secondary analysis of ANDROMEDA-SHOCK study was performed. 424 patients were divided into three groups according to baseline FR status: Responders (FR+), non-responders (FR-) and not analyzable. The first two groups were considered the sample size for this study. Macrohemodynamic, fluid therapy and perfusion variables were compared in both groups during the first 24-h of the study protocol. Non-parametric testing was used.
RESULTS. At ICU admission, FR could be determined in 82% of patients, while 25% of patients enrolled were FR– after pre-ICU fluid loading. The most frequent methods used to determine FR were pulse pressure variation (43%), passive leg raising (42%) and inferior vena cava distensibility (10%).
Both groups presented similar baseline demographic, severity and macrohemodinamic characteristics. FR+ had higher CRT at baseline. (Table 1)
FR+ received significantly more fluid bolus than FR– during the first 2 hours (1000[500-1500] vs 0[0-0], p<0.001) and 8 hours (1500 [1000-2500] vs 0[0-500], p<0.001) of protocol. Figure 1 shows the evolution of FR in both groups.
CONCLUSION. During initial resuscitation of septic shock patients, withholding fluids in FR– patients doesn't seem to delay hypoperfusion resolution. Evolution of FR is dynamic and should be assessed at every clinical evaluation to avoid unnecessary fluid loading and potential adverse effects.

INTRODUCTION. Sepsis involves inflammatory and immunity mediation. Several mediators, alone or in combination, were proposed to characterize individual response, but none was proven to have good external validity.
OBJECTIVES. The aim of this work was to establish whether some combinations allow to predict occurrence of nosocomial infections in patients with sepsis, using the data collected in the Captain multicenter cohort which method and first results were previously published (1).
METHODS. The Captain cohort included 279 patients prospectively at the time of sepsis criteria, 188 (67%) of whom having confirmed infection. Community acquired pneumonia was causal in 70% of infections. SAPS2 score = 55 [50-61], age = 65 years [57-78], male sex = 64 %. 203 patients followed for more than 3 days, in whom usual ICU clinical and biological parameters were collected, as well as 29 plasma biomarkers and 10 leucocyte associated RNAs. Patients were classified according to the occurrence of pneumonia and/or bacteremia after day 5. A non-supervised principal component analysis of the maximal values of biomarkers assessed on first 2 days of sepsis, and a Varimax rotation was performed on the selected components using the SAS software.
RESULTS. Out of 203 patients, 33 developed pneumonia and/or bacteremia after day 5. Five components explain 57 % of the variance of the biomarkers on the entire cohort. The second component of the Varimax rotation is significantly linked to pneumonia occurrence ($p = 0.02$) or bacteremia ($p = 0.02$). Those biomarkers which are determinants of this component are HLA-DR RNA (correlation coefficient 0.79), CD74 RNA (0.76), CRP (-0.62), CX3CR1 RNA (0.63), CD3D RNA (0.59), Matrix Metallo Proteinase-8 (MMP8) (-0.58), IL-10 RNA (-0.57) and Pancreatic Stone Protein (PSP) (-0.50).
CONCLUSION. In our cohort, using a non supervised analysis, we could detect a biomarker association which predicts secondary infection occurrence. Some of these markers are among those which are regularly considered as describers of the peripheral alteration of the immune system observed during sepsis.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000891

INTRODUCTION. Sepsis represents life-threatening organ dysfunction caused by a dysregulated host response to infection [1]. Cardiovascular, neural, coagulation, hormonal, bioenergetic, metabolic, inflammatory and immune pathways are variably deranged [2]. Depending on their hydrocarbon chain lengths, degree of unsaturation, number, position and orientation of their double bonds, fatty acids (FAs) have differential effects on immune functions [3].
OBJECTIVES. This study aims to determine the immunomodulatory effects of palmitate (long-chain, saturated), alpha-linolenic acid (ALA) (long-chain, unsaturated) and butyrate (short-chain, saturated) in human peripheral blood mononuclear cells (PBMCs) exposed to lipopolysaccharide (LPS) or clinical strains of bacteria.
METHODS. PBMCs from 5 healthy donors were cultured in RPMI 1640 GlutaMAX medium containing 10% FCS and 1% pen-strep at 37°C in 5% CO2. PBMCs were incubated overnight with LPS (100 ng/ml), heat-killed *Staphylococcus aureus* or *Escherichia coli* O18 (PBMC:bacterium ratio 5:1) in the presence of palmitate, butyrate or ALA (0.4, 1.8 or 0.3 mM, respectively - concentrations based on physiological and sepsis range ([4,5] (unpublished data)). Supernatants were collected to quantify IL-6, IL-10 and TNF concentrations by ELISA. The MTT assay was used to assess metabolic activity. Non-parametric one-way ANOVA tests with Dunn's correction were used for statistical analyses.
RESULTS. PBMCs stimulated with bacteria or bacterial product showed a metabolic activity similar to controls (data not shown) but secreted appreciable levels of cytokines contrary to unstimulated cells. FAs variably affected cytokine secretion [Figure 1]. Palmitate strongly reduced IL-10 secretion, butyrate markedly inhibited all cytokines, whereas ALA increased bacteria-induced IL-6 secretion but inhibited IL-10.
CONCLUSION. Palmitate, butyrate and ALA display proinflammatory, immunosuppressive and mixed effects, respectively. The variable immune effects suggest that FA supplementation should be tailored according to the patient's inflammatory phenotype.

De-escalation treatment for methicilin-resistant Staphylococcus aureus (MRSA) in culture-negative community or nosocomial extra-ICU infections

ML. Cantón Bulnes, J. Garnacho-Montero
Intensive Care, Hospital Universitario Virgen Macarena, Sevilla, France

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000935

INTRODUCTION. In sepsis and septic shock administration of broad-spectrum antibiotics is the mainstay of therapy. De-escalation (DE) of antimicrobials has been proposed as a safe strategy associated

with a lower mortality. This approach most commonly occurs with the positive culture results. However, for many patients with sepsis, cultures remain negative, making de-escalation to a targetable pathogen difficult.

METHODS. All patients admitted from January 2012 to December 2018 were included. This is a retrospective analysis of a prospectively collected database (Spanish national registry ENVINHELICS). At ICU admissions, all patients are screened for the nasal MRSA carriage. DE was defined as anti-MRSA agent discontinuation within 4 days of initiation. We analysed variables concerning demographic characteristics, comorbidities, clinical presentation, duration of mechanical ventilation, need of renal replacement therapy, ICU and hospital length of stay and mortality. Acute Physiology and Chronic Health Evaluation II (APACHE II) score and Glasgow Coma Scale (GCS), were used to asses baseline severity of illness.

Results are expressed in mean value and standard deviation (SD) for numerical variables and percentage over total patients for categorical variables. Analysis was performed using chi-square or exact Fisher test for qualitative variables and Student t test or Mann-Whitney U test for quantitative variables when appropriate. P values of less than 0.05 were regarded as statistically significant.

RESULTS.

Of 9342 patients analysed, 3043 fulfilled criteria of sepsis: 1527 had positive cultures and 1516 all cultures were negative. Of them, 141 were excluded for being positive for nasal MRSA carriage. Finally, 103 patients were analyzed (59 received empirically vancomycin and 44 linezolid), 36 patients who had anti-MRSA agent de-escalated (vancomycin in 22 and linezolid in 14), and 67 patients in whom de-escalation did not occur. The main infection foci were pneumonia and soft tissue infection in both groups. The results are shown in tables 1 and 2.

CONCLUSION. Anti-MRSA agent can be safely accomplished in culture-negative community or nosocomial extra-ICU sepsis and septic shock in non-MRSA nasal carriers.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000950

INTRODUCTION. An early diagnosis of sepsis can significantly affect outcome.[1] However, up to date there is still a lack of understanding in time response of sepsis markers after cardiac surgery.

OBJECTIVES. We investigated in a close-meshed analysis differences in the perioperative time response of Interleukin-6 (IL-6), Procalcitonin (PCT) and C-reactive protein (CRP) during and after elective cardiac surgery in patients developing postoperative sepsis or not.[2]

METHODS. A prospective cohort study in 100 patients undergoing elective cardiac surgery with cardiopulmonary bypass (CPB) at the Medical University of Vienna was performed. IL-6 and PCT were measured simultaneously and consecutively at 19 timepoints until the 10th postoperative day (POD). Additionally, CRP was measured from POD 1 to 10. Patients were divided into two groups, Sepsis and no-Sepsis, according to Sepsis-3 guidelines.[3]

RESULTS. 96 patients (four patients dropped out for analysis), with a mean age of 67.4±11.2 years were analysed. CABG, valve and combined procedures were performed in 16.7% (N=16), 28.1% (N=27) and 55.2% (N=53), respectively. Sepsis was found in 8.3% of patients (N=8). Mean SOFA score at ICU admission was 8.6±1.8 in septic and 7.7±2.3 in patients without sepsis (*P*=0.1905). Septic patients had a prolonged ICU stay (Sepsis: 8.1±4.2 days vs. no-Sepsis: 2.5±2.1 days; *P*=0.0062). IL-6 increased continuously during the procedure with reaching a plateau 2 to 6 hours after CPB until POD 1 in both, patients with and without postoperative sepsis. Four hours after CPB we found significantly different median IL-6 values between both groups (393.9 [IQR 179.9; 484.0] pg/ml, 164.70 [IQR 108.80; 251.00] pg/ml, respectively; *P* = 0.0374). PCT began to increase four hours post CPB with reaching a peak on POD 1 in both groups (Sepsis: 1.91 [IQR 1.01; 5.00] ng/ml vs. no-Sepsis: 0.37 [IQR 0.21; 0.76] ng/ml; *P*= 0.0066). Patients without Sepsis returned to baseline earlier, compared to those with postoperative Sepsis. We found significantly different median PCT values 6 hours post CPB between both groups (0.57 [IQR 0.2725; 1.16] ng/ml, 0.17 [IQR 0.09; 0.34] ng/ml, respectively, *P=0.01648*). Median CRP levels reached a peak on POD 3 in both groups, whereas the difference did not reach statistical significance (23.57 [IQR 19.48; 27.6] mg/dl, 17.22 [IQR 12.97; 21.87] pg/ml, respectively, *P=0.05525*).

CONCLUSION. Earlier increases in IL-6 were found in patients developing later postoperative sepsis, compared with more traditional used inflammation parameters. Nevertheless, rapid changes in IL-6 plasma concentrations make it difficult to detect peak values in contrast to PCT. Therefore, increased IL-6 concentrations may earlier indicate the risk of postoperative sepsis, bu t strong interindividual differences make it difficult for routine clinical use.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000954

INTRODUCTION. Clinical features are still the cornerstone in diagnosis of sepsis, nevertheless, there are various biomarkers which can help physicians to confirm or question sepsis. Study of Kauppi et al. identified myristic acid as a metabolite with highest predictive value in the metabolome of septic patients with bacteremia, with sensitivity 1,00 (95% CI 0,85-1,00) and specificity 0,95 (95% CI 0,74-0,99) [1]. Cambiaghi et al. observed its significant decrease in non-responders to the treatment of septic shock [2].
OBJECTIVES. Authors present pilot study of correlation of myristic acid serum levels with diagnosis of sepsis and its comparison with control group.
METHODS. The levels of myristic acid, were determined by gas chromatography/mass spectrometry (GC/MS) method in deep-frozen serum samples in the first five days following sepsis diagnosis. Kruskal-Wallis test was used for evaluation of statistical differences between sepsis group in each time interval and control group. Wilcoxon signed-rank test was used to evaluate the statistical significance of differences in values between time intervals.
RESULTS. Values of myristic acid levels are presented as a median and interquartile range - IQR (1st quartile; 3rd quartile).
In healthy subjects (n = 66) myristic acid concentration was 18.9 μmol/l (16.2; 22.8), in septic patients (n = 25) in time T0 56.4 μmol/l (34.9; 80.9) with decreasing level trend until day 5. Myristic acid levels were in all measurements in septic patients significantly higher than levels in healthy controls ($p < 0.001$). Statistical significance of difference in myristic acid levels in individual measurements in septic group is shown in Figure 1.
CONCLUSION. Preliminary results show elevated concentration of myristic acid (vs. control group) at the time of sepsis diagnosis with gradual decrease towards day 5 from sepsis onset.
We conclude that myristic acid may be a promising biomarker in the early identification of septic patients. It is currently being systematically evaluated [3].

INTRODUCTION. Recent studies have shown excess mortality in intensive care unit (ICU) patients with hyperoxemia, particularly after stroke or cardiac arrest [1]. The effect of hyperoxemia in sepsis is unknown and few studies have been conducted on the subject [2]. The objective of our study was to evaluate the impact of hyperoxemia on mortality during septic shock.

METHODS. Design of a retrospective study using the Medical Information Mart for Intensive Care III (MIMIC-III) database provided by the Massachusetts Institute of Technology (MIT) with the approval of the MIT Ethics Committee and the Beth Israel Deaconess Medical Center in Boston. The inclusion criteria were: age ≥ 18 years admitted in polyvalent surgical or medical ICU, SEPSIS 3 septic shock criteria, and ICU stay with invasive ventilation ≥ 24 hours after admission. O2 exposure was defined by the average PaO2 over the first 24 hours of ICU stay with distinction between two groups: normoxemia (PaO2 70-120 mmHg) and hyperoxemia (PaO2 > 120 mmHg). The primary endpoint was ICU mortality. The variables are reported as mean (standard deviation) or median [interquartile range]. Univariate analysis was performed by Student or Wilcoxon tests for continuous variables and Pearson Chi2 tests for categorical variables. A multivariate analysis was performed by logistic regression adjusting for age, gender, and clinical or demographic parameters with $p < 0.1$ between groups. Gross and adjusted Odds Ratios could thus be calculated. The analyses were carried out bilaterally, taking a significance threshold of $p < 0.05$.

RESULTS. Between 2001 and 2012, 628 patients were included, 225 in the normoxemia group and 403 in the hyperoxemia group. The epidemiological data are presented in Table 1. The mean PaO2 in the normoxemia group was 99.8 ± 12.8 mmHg compared to 166.2 ± 41.4 mmHg in the hyperoxemia group. Hyperoxemia was associated with lower ICU mortality in univariate analysis (34.2% versus 42.7%, OR = 0.69 [0.50-0.98]; p = 0.045) but not in multi-variate analysis (OR = 0.94 [0.65-1.35]; p = 0.72). The parameters associated with mortality in multivariate analysis were initial severity (SAPS II, OR = 1.02 [1.00-1.04]; p = 0.024 and APACHE III, OR = 1.01 [1.00-1.03]; p = 0.022) and duration of norepinephrine treatment (1.00 OR = [1.00 - 1.01]; p = 0.003).

CONCLUSION. In this population of patients with septic shock, hyperoxemia was not an independent factor of mortality. These data are in contradiction with those previously published in other ICU patient populations. Thus, a prospective study in septic patients with a direct analysis of the impact of hyperoxemia appears necessary.

INTRODUCTION. Acute alterations of acid-base equilibrium are common in septic patients.[1] Non-carbonic buffers (albumin and phosphates in plasma with the addition of hemoglobin in whole blood) contribute protecting the human body against metabolic acid-base disorders, while they are the only buffer system during respiratory derangements. The ability of these molecules to minimize pH variations due to acute pCO_2 changes has been defined as non-carbonic buffer power (β).[2] Septic patients have significantly lower values of hemoglobin and albumin, i.e., the major non-carbonic buffers of whole blood.[3] Moreover, albumin is a macromolecule whose structure might change significantly during pathological conditions such as inflammation.[4] It is currently unknown if and how pathological changes of protein structure affect its buffering function.

OBJECTIVES. To compare the β of blood and plasma of septic patients and healthy volunteers and compute the molar β of plasma (βmol PL) in order to evaluate the buffering capacity of albumin.

METHODS. Whole blood and isolated plasma collected from septic patients and healthy controls were tonometered at 2, 5, 12 and 20% of CO_2 in air. Blood gases, pH, albumin and hemoglobin were measured. For blood and plasma of both groups, variations of [HCO_3-] over pH were modeled according to a polynomial multilevel model with random intercept at subject level and random slope at pH level. For each model, a function describing β was obtained as β(pH)=–d[HCO_3-]/dpH, and a representative β at pH=7.40 was calculated. The same analysis was performed after normalizing [HCO_3-] variations for millimolar albumin concentration (βmmol PL). Patients and controls were compared by t-test or rank-sum test, as appropriate. Data are reported as mean ± SD or as median and interquartile range.

RESULTS. Eighteen septic patients (61% with septic shock [1]) and 18 controls were studied. Patients had lower albumin and hemoglobin than controls (3.0 [2.8-3.2] *vs.* 4.7 [4.6-4.9] g/dL, p<.001 and 10.5±0.8 *vs.* 14.3±1.0 g/dL, p<.001, respectively). The β of both blood and plasma of septic patients was significantly lower as compared to healthy volunteers (Fig.1). Furthermore, the βmmol PL of septic patients was also significantly lower (Fig.2).

CONCLUSION. Septic patients are less protected against acid-base derangements, as the β of both blood and plasma are significantly reduced. Besides lower buffer concentrations, it is conceivable that the buffering function of albumin is altered during sepsis.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000975

INTRODUCTION. Sepsis is the leading cause of death in U.S. hospitals, and the second most common cause of 30-day hospital-readmission. The "sepsis bundle" was developed by the Surviving Sepsis Campaign with the goal to reduce mortality and morbidity from sepsis. Sepsis bundle compliance is associated with lower risk and reliability-adjusted mortality. A recent update to the Surviving Sepsis Campaign guidelines, including a 'hour-1-bundle' recommends the administration of broad spectrum antibiotics to patients presenting to the emergency department (ED) with possible sepsis. This has raised concerns over possible unintended consequences of inappropriate antibiotic administration in non-septic patients, such as higher rates of *Clostridium difficile* infection (CDI).
OBJECTIVES. We aimed to retrospectively assess the incidence of CDI in non-septic patients who received antibiotics in the ED for suspected sepsis. We hypothesized that early antibiotic administration combined with antibiotic stewardship would not be associated with an increased risk of CDI.
METHODS. This was a single center, retrospective cohort study. All adult patients admitted from the ED from 2017 to 2018 were included in the analysis. Patients were identified that (i) presented with two or more criteria of the systemic inflammatory response syndrome (SIRS), (ii) received intravenous antibiotics in the ED, (iii) received intravenous antibiotics for less than and more than 48 hours, (iv) discharged from the hospital with and without a diagnosis of sepsis, and (v) diagnosed with CDI within two months of admission.
RESULTS. 25,863 non-trauma patients were admitted from the ED during the study period. 7,432 (28.7%) patients received antibiotics in the ED, of which 4,259 (57.3%) patients presented with two or more SIRS criteria and 1372 (32.2%) patients presented with two or more SIRS criteria and were discharged with a diagnosis of sepsis. Of 4,259 patients that presented with two or more SIRS criteria and received antibiotics in the ED, 1,387 (29.2%) patients had antibiotics discontinued within 48 hours. The CDI incidence of non-septic patients administered antibiotics in the ED after presenting with two or more SIRS criteria, and had antibiotics discontinued within 48 hours was 0.67%, compared to 2.29% in those in whom antibiotics were not discontinued ($p = 0.0028$). In comparison, the CDI incidence of septic patients administered antibiotics in the ED after presenting with two or more SIRS criteria and treated with antibiotics for more than 48 hours was 5.1% ($p < 0.001$). The CDI incidence in patients not administered any antibiotics throughout their emergency department or inpatient stay was 0.33% ($p = 0.1$).
CONCLUSION. With appropriate antibiotic stewardship, the administration of antibiotics to non-septic patients in the emergency department does not increase the incidence of CDI.

Metabolism of tryptophan and kynurenine in septic patient: association with the hypotension severity and prognosis

S. Redaelli[1], F. Nespoli[1], F. Fumagalli[2], M. Magnoli[2], L. Ruggeri[2], G. Ristagno[3]
[1]School of medicine and surgery, University of Milano-Bicocca, Monza, Italy; [2]Cardiovascular research, Istituto di Ricerche Farmacologiche Mario Negri IRCCS, Milano, Italy; [3]Fisiopatologia medico-chirurgica e dei trapianti, University of Milan, Milano, Italy
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000983

INTRODUCTION. Indoleamine 2,3 dioxygenase 1 (IDO1) metabolizes tryptophan (TRP) through the kynurenine (KYN) pathway (KP) and it is induced when systemic inflammation is present, as in sepsis. The upregulation of the KP has been identified as a hypotension culprit in *in vivo* models of sepsis and septic shock [1] and associated to increased mortality in critically-ill patients [2].
OBJECTIVES. We investigated the KP in septic patients to determine if it was involved in sepsis severity. We evaluated the association between IDO1 activity and the severity of sepsis-induced hypotension and we analyzed the association between the plasma concentration of KP metabolites and mortality, both at ICU discharge and at 90 days.
METHODS. We performed analysis on a subgroup of patients (n=100, 50 survived and 50 deceased at ICU discharge), previously enrolled in the randomized controlled trial Albumin Italian Outcome Sepsis [3]. TRP, KYN, kynurenic acid (KYNA) and 3-hydroxyantranilic acid (3-HAA) concentration were determined through liquid chromatography mass spectrometry on ICU day 1, 2 and 7. We used KYN/TRP ratio as a surrogate of IDO1 activity. We considered the *inotropic score* (*IS*) (dopamine + adrenaline x 100 + noradrenaline x 100 [μg/kg/min]) as the expression of pressors need for keeping a mean arterial pressure above 65 mmHg. We applied univariate and multivariate models adjusted for age, sex, sepsis source, SOFA and SAPS II at ICU admission to determine associations among variables.
RESULTS. TRP concentration was halved at ICU admission, while KYN, KYNA, and 3-HAA were increased by 2-10 times, compared to the physiological values. TRP decrease suggested IDO1 activation, as confirmed by the sevenfold increase of the KYN/TRP ratio. IDO1 upregulation and TRP catabolism remained unchanged during all the 7 days, as shown by constantly high KYN, KYNA, 3-HAA and KYN/TRP ratio. *IS* increased by 1.68 points [95%CI 1.18–2.41, P=0.006] for each twofold KYN/TRP ratio increment. KYN and its metabolites were increased in the deceased with respect to the survivors, either at ICU discharge or at 90 days (P<0.05). The univariate model showed KYN and KYNA associated to ICU discharge mortality (P<0.01), whereas KYN, KYNA and 3-HAA associated to 90-day mortality (P<0.01). The multivariate model showed KYNA associated to ICU discharge

mortality (HR 1.30, [95%CI 1.10–1.54, *P*=0.002] for each twofold concentration increase). Moreover, KYN, KYNA and 3-HAA were independent predictors of 90-day mortality and the hazard ratios were 1.50 [95%CI 1.06–2.13, *P*=0.02], 1.27 [95%CI 1.08–1.49, *P*=0.004] and 1.23 [95%CI 1.04–1.46, *P*=0.02] respectively, for each twofold increase of the metabolites concentration.
CONCLUSION. The KP was upregulated in septic patients. IDO1 activation was associated to the severity of sepsis-induced hypotension and KYN, KYNA and 3-HAA high concentrations were independent risk factors of mortality in septic patients.

TLR-2 and TLR-4 predicts early mortality in pediatric patients with spinal muscular atrophy treated with noninvasive positive pressure ventilation

D. Dmytriiev
Grushevskogo 21/15, Vinnytsia, Ukraine
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000012

INTRODUCTION. Patients with **spinal** muscular atrophy (SMA) who are unresponsive to appropriate medical treatment, are often treated with Noninvasive PositivePressure Ventilation (NPPV). Clinical predictors of the outcome of this treatment are scarce. Therefore, we evaluated the role of the biomarkers TLR-2 and TLR-4 in predicting 90-day mortality in patients with SMA who receive treatment with NPPV.
METHODS. The study population were 17 patients treated with NPPV for SMA. Clinical and background data was registered and blood samples taken for analysis of inflammatory biomarkers. TLR-2 and TLR-4 were selected for analysis, and related to risk of 90-day mortality (primary endpoint) using Cox proportional hazard models adjusted for gender, age and various clinical parameters.
RESULTS. Of the 17 patients, there were 2 subgroup in regards to primary diagnosis: **spinal** muscular atrophy TYPE 1 (SMATYPE1, n = 17), **spinal** muscular atrophy TYPE 2 (SMATYPE2, n = 7). There was significant difference in the basic characteristic of the subgroups, but not in the clinical parameters that were used in treatment decisions. 10 patients died within 90 days of admission (58,82%). The Hazard Ratio for 90-days mortality per 1-SD increment of TLR-4 was 4.498 (95% CI 2.34-8.04, p < 0.001). When TLR-4 values were divided into tertiles, the highest tertile had a significant association with 90 days mortality, HR 10.012 (95% CI 1.29-78.17, p for trend 0.022), compared with the lowest tertile. This correlation was maintained when the largest subgroup with SMATYPE1 was analyzed. TLR-2 was correlated in the same way, but when put into the same model as TLR-4, the significance disappeared.
CONCLUSION. TLR-4 is a target to explore further as a predictor of 90 days mortality, in patients with SMA treated with NPPV.

ICU patients' and relatives' experiences of a peer support group

C. Jones[1], R. Endacott[2], P. Gibb[1]

Correspondence: C. Jones
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000041

INTRODUCTION. Patients recovering from critical illness involving a stay in an Intensive Care Unit (ICU) and their family and friends may struggle when they go home from hospital. There can be significant physical, psychological and cognitive sequelae for patients (1). A recent study of 4943 ICU survivors found that 46% fulfilled the criteria for anxiety, 40% for depression and 22% for post traumatic stress disorder (PTSD), whilst 18% met the caseness threshold for all three psychological conditions (2). Relatives can also suffer from psychological problems, referred to as post intensive care syndrome (PICS) and post intensive care syndrome – family (PICS-F) (3). ICUsteps started at one peer support group in Milton Keynes, UK, and has grown to 23 support groups around the UK and Ireland. Anecdotally patients and families report finding it helpful to attend a support group meeting but as yet no research has been undertaken examining experiences of attending.
OBJECTIVES. The aim of the study was to explore the positive and negative experiences of attending a peer support group meeting.
METHODS. A survey was undertaken to explore reasons for attending a support group, benefits and negative aspects of attending. ICUsteps has a system already established for advertising studies for external researchers from across the English speaking world. This involves the study being advertised by email to a list of research volunteers (both ex-patients and family) and, where needed, to the organisers of the 23 ICUsteps support groups. This system was used to advertise this study and questionnaires sent out by email to respondents. The results were analysed using qualitative thematic methods.
RESULTS. A total of 40, 37 ex-ICU patients and 3 family members, returned the questionnaire. Thematic analysis resulted in six benefits:- 1. Being able to talk to others who have been through the same experience 2. Normalisation of physical and psychological problems 3. Getting information about ICU and recovery 4. Making new friendships 5. Getting support from others 6. Giving something back for all their care. Over half of the respondents, including the 3 relatives, (n= 26) reported no negative aspects of attending support groups meetings. The remaining 14 patients identified some negative aspects. 1. Feeling overwhelmed revisiting old memories. 2. Feeling left behind or sidelined. 3. Finding the time or place of the meeting difficult. 4. Finding it difficult to see others in the group being upset. 5. Finding it difficult to ensure everyone had time to talk. 6. Feeling really angry. While all the respondents felt they had benefited from attending, 42% reported some negative experiences that would need addressing by group organisers
CONCLUSION. Peer support works for some but not all. This is the first research to look at the benefits and negative aspects of attending an peer support group meeting. While some patients, families and friends thrive in a group situation, others may need one to one support and others may find the information available on the internet meets their needs. Although the survival rate from critical illness has significantly improved, there remain unanswered questions about how peer support can best enhance survivorship.

Outcomes of patients with severe bronchopulmonary dysplasia requiring prolonged mechanical ventilation beyond term corrected gestational age who were transferred to the pediatric intensive care unit

YH. CHOI, DP. June
Department of pediatrics, Seoul National University Hospital, Seoul, Republic of Korea
Correspondence: Y.H. CHOI
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000113

INTRODUCTION. Some of preterm infants with severe bronchopulmonary dysplasia (sBPD) may require long-term mechanical ventilation beyond term corrected gestation age (CGA), and therefore continue to care after referral to paediatric intensive care unit (PICU). At referral unit, deciding final respiratory support of those patient is the focus of strategy to shift toward less intensive care, rather than routine neonatal care. However, since the number of this patient population is small at any single center, there is very little data regarding the overall outcomes and consideration factors for determining final respiratory support
OBJECTIVES. Our aims was to define the character and outcomes of preterm infants with sBPD who was required for referral to PICU due to weaning failure beyond 40 weeks CGA, and to determine the clinical factors associated with decision timing of final respiratory support.
METHODS. This study is a retrospective review of preterm infants with sBPD, who was transferred to PICU of a tertiary hospital from nationwide neonatal intensive care unit (NICU) because of weaning failure between January 1, 2014 and September 30, 2018.
RESULTS. Of 14 eligible patients, the median gestational age at birth was 26 (25-29) weeks, and birth weight was 875 (642.5-855.0) g. The median (range) CGA at referral was 47 (43-55) weeks and the median length of stay in previous NICU was 154 (10.8-202.3) days after birth. All of patients had endotracheal tube, and 12 patients (85.7 %) required mechanical ventilation at the time of referral. After referral, based on multidisciplinary approach to chronic respiratory failure, the following problems was found that make wean difficult; large airway malacia, 7 (50.0%), peripheral airway obstruction, 6 (42.9 %), significant upper airway obstruction, 3 (21.4 %), and pulmonary arterial hypertension were discovered 8 (57.1 %) respectively. Finally, 8 of 14 patients (57.2%) was successfully extubated without tracheostomy, and remaining 6 patients underwent tracheostomy. Final respiratory support of all patients was determined at median 56 (48-63) weeks CGA. One patient was died after tracheostomy, and the patients requiring tracheostomy had a significantly longer stay in PICU during admission than patients without tracheostomy (187.63 vs. 297.67 days, p=0.033). Multivariable analysis showed that length of stay in previous NICU ($p<0.05$) and tracheostomy placement (p=0.021) were each associated with the decision time of final respiratory support. Until 56-57 weeks CGA, the 75th percentile of the patient not requiring tracheostomy was liberated from mechanical ventilation. On the other hands, less than 25th percentile of the patient who eventually failed to weaning process underwent tracheostomy until that time (Log rank test p=0.008).
CONCLUSION. There was not uncommon to be successful extubation after 40 weeks CGA among preterm infant with BPDs requiring prolonged mechanical ventilation. However, in patients who finally underwent tracheostomy, decision of respiratory support tended to be delayed and the overall outcomes was poor.

Positive impact od sedation standarization on pediatric intensive care unit patients' outcome

T. Hazwani, Y. Kazzaz, F. Dawoud
Pediatric Intensive Care, King Abdulaziz Medical City, Riyadh, Saudi Arabia
Correspondence: T. Hazwani
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000121

INTRODUCTION. Optimal sedation for mechanically ventilated pediatric patients is integral to the practice of pediatric critical care, because both under- and oversedation may have negative effects while achieving a good level of sedation and analgesia will reduce anxiety, pain, and agitation, enhance synchronization with mechanical ventilation (1-4). Accidental extubation events were reported many times in our Pediatric Intensive Care Unit (PICU), root cause analysis identified sedation is an issue. There is protocol to evaluate the pain and sedation level in our PICU, but there is a lack of standardized practice of sedation strategy for those patients, which may lead to increase mechanical ventilation days and its associated complications (4-8).
OBJECTIVES. Pediatric Intensive Care Unit in King Abdulaziz Medical City, Riyadh, KSA is 25-bed capacity, Sedation and analgesia are necessary components in our patients, especially those requiring mechanical ventilation. The aim of this project was to develop and implement guidelines for sedation management in PICU and evaluate the impact of these as a part of quality and patients' safety program.
METHODS. This project used a pre-post design for data collection. All PICU ventilated patients receiving continuous sedation infusion were enrolled over three months for baseline data collection.
Guidelines for sedation and analgesia management for critically ill children including algorithm and assessment tools have been implemented. One month post-implementation data has been collected for three months. In addition to key outcome variables (length of stay, ventilation time, sedation duration, successful Extubation rate, unplanned Extubation rate), process measures data (Sedation boluses use average, Percentage of patients under sedated, Percentage of patients over sedated) were evaluated. A sample of patients post implementation: control phase has been collected and analyzed every two months for one year.
RESULTS. 37 patients have been enrolled in the pre-implementation phase, and 36 patients also included in the post-implementation phase, while 19 patients had been included in the control phase. The decrease of sedation boluses requirement average prior to implementation from 7.7 Bolus/patient/day to 5.7 post-implementation, with a remarkable decrease in the percentage of high pain score (above 4) per day from 19.0% to 15.4% (Graph1) approached significance. As well, there was observed a decrease in sedation assessment average by bedside nurses from average 18.9 of pain assessment/patient/day to 14.1 of pain assessment/patient/day (Graph 2). Decrease sedation days is noted in results, in the control phase, but this needs further evaluation (Graph 3).
CONCLUSION. The sedation standardization project demonstrated better pain and sedation control by achieving a target comfort level with fewer sedation boluses, which has a positive impact on patient's outcome in PICU. This standardization reflected also on bedside nurses' work as the sedation assessment become less frequent, and more organized overall. The importance of the findings of this project indicates that guidelines can be used to manage the PICU patient's comfort and pain without compromising the quality of care.

Prognostic Factors of ICU Mortality in Pediatric Hemato-oncology Patients with Pulmonary Complications

K. Kim, Y. Nali, Y. Jong-Seo
Department of pediatrics, College of Medicine, The Catholic University of Korea, Seoul, Republic of Korea
Correspondence: K. Kim
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000153

INTRODUCTION. The objective of this study was to determine prognostic factors related with mortality in pediatric hemato-oncology patients admitted for pulmonary complications on the ICU.
METHODS. This was a retrospective cohort study of patients below 21 years old with underlying hemato-oncologic diseases admitted for pulmonary complications at the ICU of a tertiary referral hospital in Korea between April 2009 and March 2017. Patients admitted for perioperative management or non-pulmonary complications were excluded. Demographics, laboratory parameters, and clinical parameters such as Glasgow Coma Scale (GCS), the pediatric version of the Sequential Organ Failure Assessment (pSOFA) score and the Pediatric Logistic Organ Dysfunction (PELOD) score, etc., were extensively reviewed.
RESULTS. A total of 110 pediatric hemato-oncology patients were admitted at the ICU for pulmonary complications. The median age was 13 (IQR, 8–16) years old, and 62 (56.3%) were boys. The median duration of ICU hospitalization was 8 (IQR, 4.25–16) days, and 45 patients (40.9%) were applied mechanical ventilation. The mortality rate was 59.1% (65/110 patients). Factors with a significant association to increased mortality in a multivariable logistic regression analysis were as follows: low GCS scores, low SpO2/FiO2 ratio, low hematocrit levels, and increasing total bilirubin levels. The pSOFA score and PELOD score assessed on the third day of admission had significant discrimination for in-ICU mortality with an area under the curve of 0.87 (95% CI, 0.80-0.95) and 0.83 (95% CI, 0.74-0.92), respectively.
CONCLUSION. The GCS score, SpO2/FiO2 ratio, hematocrit level, and total bilirubin level, pSOFA scores, and PELOD scores are useful factors for the prediction of an increased risk for mortality in pediatric hemato-oncology patients with pulmonary complication.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000154

INTRODUCTION. Critically ill patients and their closest relatives often suffer from post traumatic stress, anxiety and depression after the patient is discharged from the intensive care unit (1). This may be related to the traumatic situation of being critically ill and fighting for survival. Intensive care unit diaries have been proposed to help relatives and patients to process the experience and find meaning.
OBJECTIVES. To achieve a more comprehensive understanding of how relatives' diaries for intensive care unit patients work.
METHODS. A convergent mixed methods analysis (2) of data from a randomized controlled trial exploring the effect of an intensive care unit diary on posttraumatic stress symptoms in patients and relatives (3) and two hermeneutic phenomenological studies of patients' and relatives' perceptions and uses of the diary after discharge from the hospital (4,5).
RESULTS. The mixed methods analysis expanded the results of the underlying studies by identifying that writing a diary is a preventive measure against posttraumatic stress symptoms for relatives. The process of expressing feelings and thoughts in the critical situation combined with an opening for discussing the difficult time with the patient after discharge and having this experience acknowledged by the patient may have resulted in the lower levels of posttraumatic stress symptoms found in relatives who wrote a diary. For patients, the diary did not prevent posttraumatic stress symptoms but helped the patient interpret fragmented and disturbed memories of the intensive care unit into a coherent story within the framework of the relatives' diary. This strengthened the bonds between patients and relatives. However, some patients do not welcome the diary and want only to look forward.
CONCLUSION. Writing a diary supports the relative and patients during recovery and furthermore prevents posttraumatic stress symptoms in relatives. Offering the relative a diary should take relatives preferences into account and guide relatives on how to or whether to share the diary with the patient.

Correspondence: X. Zhang
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000207

INTRODUCTION. Data that indicate vitamin A status in critically ill children with sepsis are sparse. The association between serum vitamin A levels and the clinical outcomes of sepsis has not been well assessed.
OBJECTIVES. The aim of this study was to assess the prevalence of vitamin A deficiency in critically ill children with sepsis and to reveal its association with the clinical outcomes.
METHODS. Critically ill children with sepsis admitted to the studied pediatric intensive care unit (PICU) were engaged in this prospective study. Sex- and age-matched approximate-health children form the Department of Pediatric Surgery were enrolled as the control group. Blood samples were collected from all patients in the first 24 hours of admission for measurement of serum vitamin A status. We compared vitamin A status between sepsis group and control group. Then, we compared the clinical characteristics of two the subgroups of septic patients with vitamin A deficiency and those without vitamin A deficiency. Univariate and multivariable methods were used to evaluate the association between vitamin A deficiency and septic shock.
RESULTS. One hundred and sixty septic children, and forty-nine approximate-health children were enrolled in this study. Serum VA levels in sepsis group were significantly lower than control group (0.19±0.11 vs 0.34±0.12, p<0.001). Vitamin A deficiency was found in 94 (58.8%) subjects in studied group and 6 (12.2%) subjects in the control group (P<0.001). In septic patients, 28-day mortality and hospital mortality in patients with vitamin A deficiency were higher than that in patients without vitamin A deficiency, but the difference was not significant (P>0.05). Vitamin A deficiency was associated with septic shock with an unadjusted odds ratio (OR) of 3.297 (95% confidence interval (CI), 1.169 to 9.300; P=0.019). In a logistic model, vitamin A deficiency (OR, 4.630; 95% CI, 1.027-20.866; P=0.046), procalcitonin (OR, 1.029; 95% CI, 1.009-1.048; P=0.003), and the Pediatric Risk of Mortality scores (OR, 1.132; 95% CI, 1.009-1.228; P=0.003) were independently associated with septic shock.

CONCLUSION. The prevalence of vitamin A deficiency was high in children with sepsis. Serum vitamin A levels were independently associated with septic shock.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000216

INTRODUCTION. In pediatric health care, moderately high levels of nursing burnout risk were found (Pradas-Hernàndez et al., 2018), with potential negative impacts on professional wellbeing and patient care (Tawfik et al., 2017). The quality of care has been investigated in several studies, analysing nurses' perception about the risk of adverse events, highlighting how this perception matched the actual incidence of the adverse events (Winning et al., 2018).
OBJECTIVES. To investigate the relationship between nursing burnout and the perception of the risk of adverse events in Newborn and Pediatric Intensive Care Units (NICUs and PICUs) in Italy.
METHODS. Data were extracted from RN4CAST@IT-Ped, a larger cross-sectional observational study involving nurses and pediatric nurses, through convenience sampling of 13 hospitals affiliated to the Italian Pediatric Hospitals Association. Burnout was investigated using the Maslach Burnout Inventory, and the nurses' perception of the risk of adverse events was assessed through questions regarding the frequency of six adverse events. Data were analysed through descriptive analysis and logistic regression with IBM SPSS 22.0 software.
RESULTS. The responses of 451 NICU and PICU nurses were analyzed. An increase in 'Emotional Exhaustion' increased nurses' perception of the risk of medication errors (p=0.002; OR=1.081) and of the onset of pressure ulcers (p=0.004; OR=1.051). An increase in 'Depersonalisation' increased nurses' perception of the risk of pressure ulcers (p=0.040; OR=1.079) and pneumonia (p=0.018; OR=1.097).
CONCLUSION. Develop improvement interventions to increase staff wellbeing and patient safety in the health care system based upon our results, which are consistent with international literature, could improve the overall quality of nursing care in NICU and PICU.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000217

INTRODUCTION. ICU survivors have a 1-year mortality rate of 30% (1), and a reduced quality of life associated with post-ICU syndrome (2); a triad of cognitive decline, physical weakness and psychiatric disorders. Early rehabilitation improves outcomes, leading to greater independence. The NICE CG83 guidelines instruct the provision of rehabilitation information to critical care patients on discharge. Currently, only a third of UK trusts meet these guidelines (3).
OBJECTIVES. Within 20 weeks, we aimed to achieve 100% patient and therapist satisfaction with the rehabilitation information given to patients at risk of physical morbidity on discharge from critical care at Medway Maritime hospital.
METHODS. Critical care patient and therapist satisfaction was assessed using questionnaires at baseline and after each PDSA cycle. In PDSA1, a generalised rehabilitation information booklet was introduced. In PDSA2, a personalised rehabilitation plan for pre-discharge completion by the therapists was added.
RESULTS. A shift was observed in critical care patient satisfaction scores, indicating a significant change in the median from 20% at baseline to 70% after PDSA2. This was also reflected in the therapist satisfaction scores which increased significantly from 60% at baseline to 80% after PDSA2.
CONCLUSION. The introduction of a generalised information booklet, supplemented with a personalised recovery plan, is an effective way of increasing critical care patient and therapist satisfaction with post-discharge rehabilitation information provision. This should translate to greater critical care patient engagement with rehabilitation and improved long-term outcomes. To further increase satisfaction, the addition of psychiatric input to the booklet is currently underway.

INTRODUCTION. Pediatric intensive care units (PICU) has been established in many developed countries in order to provide specific intensive cares for children. However, inter-hospital transport to PICU has been still needed because PICU has been scarce even in developed countries. Deterioration of outcomes associated with inter-hospital transport has been concerned [1].
OBJECTIVES. The aim of this study was to evaluate whether inter-hospital transport for severe pediatric patients was associated with in-hospital mortality.
METHODS. This study was a multicenter retrospective cohort study. Data were derived from the Japanese Registry of Pediatric Acute Care (JaRPAC) from 2013 to 2017. Inclusion criteria for this study were patients who aged 16 years and under and admitted to the PICU. Patients after elective surgery were excluded. The primary outcome was in-hospital mortality. The secondary outcome was deterioration

of pediatric cerebral performance category (PCPC) at PICU discharge compared with at admission. Collected data included institution type of referral hospital, patient's baseline characteristics, supportive therapies, PCPC, in-hospital mortality, and length of PICU stay. We defined the patients admitted PICUs from their hospitals as "In-House" group and transferred from others (referring hospitals) as "Transfer" group. To adjust for inherent characteristics, severity, and diagnosis at admission, we conducted a propensity score matched analysis.
RESULTS. A total of 4,011 patients were eligible for our study criteria. Among those, The Transfer group was 1,603 children and the In-House group was 2,408 children. The Transfer group was higher PIM2 score than the In-House group. Transfer group needed more mechanical ventilation, inhaled nitric monoxide, extracorporeal membrane oxygenation, and continuous hemodiafiltration. ICU length of stay was longer in the Transfer group (median) than that in the In-House group (median [IQR]5 [3–9] vs. 3 [2–7], P<0.001). Crude in-hospital mortality was 27/1603 (1.7%) in the Transfer group and 62/2408 (2.6%) in the In-House group (*P*=0.06), In the propensity matched cohort, the Transfer group was not associated with in-hospital mortality compared with the In-House group (12/913 (1.3%) vs 22/913 (2.4%), P=0.08) Moreover, the Transfer group was not associated with deterioration of PCPC compared with the In-House group (84/913 (9.2%) vs 69/913 (7.6%), P=0.21)
CONCLUSION. Inter-hospital transport was not associated with unfavorable outcomes among children who admitted to PICU. Transport of severe pediatric patients to the PICU may be feasible.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000287

INTRODUCTION. The Pediatric Sequential Organ Failure Assessment (pSOFA) scoring system is based on the Multiple Organ Dysfunction Syndrome and it has been shown to be useful in predicting outcome in critically ill children. Also, nutritional status on admission to the pediatric intensive care unit (PICU) has been associated with outcomes in critically ill children.
OBJECTIVES. To assess nutritional status and organ dysfunction by pSOFA on children on admission to the PICU and its association with outcomes.
METHODS. Retrospective cohort study of children admitted to the PICU at Texas Children's Hospital (01/2016-06/2016) with a length of stay (LOS) > 3 days; nutritional status assessed by weight for length/Body mass index (WFL/BMI: acute malnutrition), z-scores by WHO (0-24 months) and CDC (2-19 yrs), respectively. Malnutrition defined as mild, and moderate-severe if z-scores were < -1,< -2, respectively. Hospital and PICU LOS, risk of mortality (ROM) by the Pediatric Index of Mortality 2 (PIM2), and mortality were obtained. Organ dysfunction was defined as pSOFA score > 5, and were collected on day 1.
RESULTS. A total of 358 children (202 males/156 females) were included; with age 2.6 yr. (0.7-10.3; median (25-75th IQR)). PICU LOS, 7.1 (4.7-11.4) days, Hospital LOS, 19 days (11-42); PIM2 ROM (%), 3.3 (1.0-5.0), PSOFA score on day 1 was 5 (4-7), for a 46% prevalence of organ dysfunction. WFL/BMI z-scores of 0.08±1.34 (SD); the prevalence of acute malnutrition was 25.1%. A total of 294 (82%) patients required mechanical ventilation on admission to the PICU and mortality was 7.5%. Patients with organ dysfunction on day 1 vs. pts without organ dysfunction had: PICU and Hospital LOS of 8.1 days (4.9-13.3) vs 6.8 days (4.4-10.3) (p< 0.05) and 21 days (11-47) vs 17 days (11-29) (p=0.1796), respectively; PIM2 ROM (%) of 3.86 (1.37-8.09) vs 2.91 (0.92-4.43) (p<0.0001); and were associated with older age (> 2 years) Odds ratios (OR) (95% CI) 1.56 (1.02-2.38) (p<0.05); need of ventilatory support on admission, 2.80 (1.53-5.10) (p < 0.001) and mortality 2.50 (1.09-5.74) (p < 0.05). Patients with underweight and overweight/obesity vs. normal nutritional status were more likely to have organ dysfunction; (OR) (95% CI); 2.73 (1.37-5.40) and 2.05 (1.29-3.26) (all p<0.005), respectively.
CONCLUSION. Organ dysfunction was prevalent in critically ill children and was associated with longer PICU length of stay, higher severity of illness, older age, need of ventilator support and mortality. One out of every 4 children had malnutrition and malnourished children were more likely to have organ dysfunction on admission to PICU.

INTRODUCTION. The prevalence of overweight and obesity in hospitalized US children has been increasing in the last decade and obesity has been associated with poor outcomes.
OBJECTIVES. To assess nutritional status on children on admission to the pediatric intensive care unit (PICU) and its association with outcomes.
METHODS. Retrospective cohort study of critically ill children < 5 yr of age admitted to the PICU at Texas Children's Hospital (01/2016-12/2017); nutritional status assessed by weight for length/Body mass index (WFL/BMI: z-scores by WHO. The BMI was categorized as: normal (NOR), underweight (UND), (BMI < 2 SD); overweight (OVE), (BMI > 2 SD), and obese (OBE), (BMI > 3 SD). Hospital and PICU length of stay (LOS), risk of mortality (ROM) by the Pediatric Risk of Mortality (PRISM III), ethnicity, and mortality were obtained.
RESULTS. A total of 2101 children (1210 males/891 females) were included; with age 1.17 yr (0.41-2.56; median (25-75th IQR)). PICU LOS: 2.10 (0.99-6.16) days, Hospital LOS: 10 days (4-22); PIM2 ROM (%) 1.14 (0.75-3.86). The prevalence and median age for NOR, UND, OVE and OBE was: 58.6%, 11.1%, 17.4%, and 12.8%, respectively, and 1.1 yr. (0.4-2.5), (median (25-75th IQR)), 0.7 yr. (0.2-2.6), 1.3 yr. (0.7-2.6), and 1.3 yr. (0.5-2.7), respectively (p<0.0001). The Hispanic group vs. the Caucasian and African-American, and Asian groups had the highest prevalence of UND, OVE, and OBE at: 35.9%, 42.9%, and 48%, respectively (p<0.005). The PICU and Hospital LOS for NOR, UND, OVE, and OBE groups were: 2 (1-6), 2.5 (1-7), 2 (1-6), and 2.4 (1-8), respectively; (p<0.05); and 10 (4-22), 11(5-23), 10 (5-20), and 11 (5-28), respectively. Children with UND, OVE, and OBE vs. the normal BMI group were associated with a higher PRISM III ROM (%) and need of ventilator support on admission; Odds ratios (OR) (95% CI) 1.10 (0.79-1.53), (p=0.5750), 1.53 (1.18-1.99) (p<0.005), and 1.64 (1.22-2.19) (p< 0.005), respectively; and 1.24 (0.93-1.67) (p=0.1472), 0.94 (0.74-1.19), and 1.34 (1.01-1.78) (p<0.05), respectively. Hospital Mortality was 4.05% and was not associated with BMI status.
CONCLUSION. More than half of the patients had a normal BMI and almost a third were overweight or obese on admission to PICU. Younger children were underweight and older children were overweight or obese. The Hispanic group had a higher prevalence of underweight, overweight and obesity compared to the other ethnic groups.

Overweight and obese children were more likely to have a higher risk of mortality on admission and the obese group was associated with need of ventilator support on admission. Underweight children had a longer PICU LOS. Mortality was not associated with BMI status.

INTRODUCTION. ICU-acquired weakness (ICU-AW) is a widespread involvement of diffuse and symmetrical muscular weakness that can develop among ICU patients without any other cause that can justify it. The incidence is different according to some studies, 25-50% in ventilated patients, reaching 50-100% in septic patients, and it is associated with an incomplete and variable functional recovery.
OBJECTIVES. 1- To analyze the incidence of ICU-AW in critically ill patients receiving invasive mechanical ventilation (IMV) for at least 24 hours.
2- To analyze the functional consequences of ICU-AW at ICU discharge and one month later.
METHODS. Single-center, prospective study (May-December 2017). Inclusion criteria: adult critically ill patients, who required>24h of IMV. Exclusion criteria: previous Barthel score <70, any neurological disease, trauma patients, and prior cognitive disease.
Patients were consecutively recruited at ICU admission. ICU-AW and functional capacity were assessed at ICU discharge, and one month later. Three groups were pre-defined according to the Medical Research Council scale (MRC): MRC> 48, Non-ICU-AW; MRC 36-48, mild-moderate ICU-AW; MRC < 36, severe ICU-AW. Muscle strength was also evaluated with dynamometry (handgrip strength), ambulation ability with the Functional Ambulation Categories (FAC) scale, and functional independence was assessed using the Barthel index for activities of daily living.
A descriptive analysis is presented (median, inter-quartile range and/or percentages). Comparisons among groups were performed using non-parametric tests.
RESULTS. We included 52 patients, 46% were women, mean age 69 (51 -74) years old. In 77% of patients, the reason for admission in the ICU were urgent medical conditions. The incidence of ICU-AW was 63.5%, severe in 11.5% of cases. As compared to Non-ICU-AW, patients with ICU-AW showed lower strength in handgrip, lower Barthel Index and lower walking capacity at discharge from ICU, and one month later. These functional alterations were significantly more pronounced in the group of severe ICU-AW. Patients with MRC <36 showed severe functional limitations with values of handgrip 10.5% (9.5-30.6) as compared to healthy population, Barthel Index values of 10 (8.7-17.5), and none of them were able to walk autonomously. At one month of ICU discharge, the Non-ICU-AW group showed normal functional capacity values while severe limitations persisted in the MRC group <36.
CONCLUSION. Incidence of ICU-AW is high in patients requiring IMV, and its functional impact is associated to its severity.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000328

INTRODUCTION. With the development of medical technology, clinical alarms from diverse medical devices, are becoming a new issue in intensive care units (ICU). An excessive number of alarms will reduce the efficiency of medical staff, cause alarm fatigue and compromise patient safety.
Among the devices of the ICU, the patient monitor is known to generate the most alarms.
OBJECTIVES. To examine the effects of patient monitor alarm management education on nurses' performances of alarm management, frequency of false alarms, and alarm fatigue.
METHODS. A quasi-experimental study was conducted on 19 nurses in ICU at a single teaching hospital.
A preliminary survey was conducted on the frequency and type of ICU alarm and We analyzed the frequency of false alarms and the effect of alarm fatigue after patient monitor alarm management education.
RESULTS. After the intervention, nurse performance of alarm management was increased from 17.95±1.47 to 23.84±5.40 (t = -5.68, p = 0.001), and the frequency of false positive alarms also decreased significantly from 4.42±5.01 to 0.83±1.60 (Z = -4.42, p < 0.001). There was no significant difference in the frequency of valid alarms. (1.15±2.02 vs. 1.06±2.07; Z = -0.16, p = 0.870). The nurse 's alarm fatigue level also decreased significantly after education (25.84±4.59 vs. 21.10±6.09; t = 2.71, p = 0.014)
CONCLUSION. The patient monitor alarm management education proved to have beneficial effects on the level of performance of alarm management and alarm fatigue of the nurses. In addition, the frequency of false positive alarms is reduced, but there is no difference in the frequency of false alarms, which is helpful for safe patient monitoring.

INTRODUCTION. The visits that patients receive promote feelings of support, help and reassurance. On the other hand, there is little literature regarding the wishes of patients on intensive care unit (ICU) visits. In recent years is the trend to liberalize access for visits to patients admitted to the ICU. Experience has demonstrated that neither the patient's clinical situation nor the structural barriers of the ICU impede restriction-free visits, but it is due mainly to cultural factors.
OBJECTIVES. Explore the topic of visits during ICU hospitalization by analysing patients' wishes and the nurses' points of view.
METHODS. Qualitative research with thematic analysis of the collected data was done in an ICU. The sample involved in the study was 8 patients and 12 nurses. Informed consent was signed by everyone. Data were collected through 8 semi-structured interviews for patients and 2 focus groups (FG) for nurses. The data analysis was performed with the NVivo 10 software.
RESULTS. From the analysis of the data have been identified 22 nodes from interviews and 28 nodes from FG. The nodes have been grouped into themes and macro-themes. It emerged:
2 macro-themes from interviews:

Patient experiences related to visits: highlights the presence of strong emotions, often negative, sometimes in conflict with each other.
Patients' thoughtson visits: ideas and advice for nurses who could help the patient in managing visits or making changes to approach.
3 macro-themes from FG:
Patient visits seen by nurses: the behaviours, seen and interpreted by the nurses, that the patients showed with their relatives or staff, the perceptions during the visits, the patients' experience or wishes.
Patients' visit experiences seen by nurses: the team's perspective was privileged then attitudes, behaviours and perceptions regarding patient visits were included.
Needs/suggestions offered by nurses: the improvement ideas emerged from the team compared to those derived from the patients tofully understand the problem.
CONCLUSION. The ICU is seen by patients and nurses as a place where the management of emotions and feelings is complicated. The patients want the visits because they help to face emotions and to overcome the physical and psychological insult created in ICU. The visits maintain contact with the world outside.
The nurses emphasize the importance of clear information to regulate the access.
It would be desirable during the admissions in ICU prompted patients their wishes, wherever possible, about the visits and that this cannot be taken for granted and absolutely necessary.
Ideally, every structure, follow a path of awareness of this issue in order to adequately support the wishes of patients without neglecting the suggestions and needs of healthcare staff.

INTRODUCTION. Prevalence of sepsis is high, affecting millions of people around the world each year. Previous studies demonstrate that early antibiotics administration directly reduces mortality. However, because sepsis is sometimes hard to diagnose promptly, the initial treatment is likely to be delayed. For break through the current situation, the qSOFA was induced as a rapid screening tool before the ICU to facilitate the identification of patients with suspected infection in the SSCG 2016.
OBJECTIVES. The objective of this study is to evaluate the impact of a nurse-initiated quality improvement (QI) by the primary screening using qSOFA on the sepsis management at the ER and improvement of patient's outcome.
METHODS. We conducted a before and after study. Patient older than 20 yrs who were suspected infection in ER were enrolled this study. Phase 1: In the before phase, consecutive eligible patients were enrolled from February 2017 to July 2017. Subsequently, educational intervention for sepsis treatment was provided to the all nurses from August 2017 to October 2017. Phase 2: From November 2017 to April 2018, nurses performed primary screening with qSOFA to make a diagnosis of sepsis for patients who were suspected infection, and the results were reported to doctors and positively proposed for blood cultures obtained and administration of antibiotics. Phase 3: From May 2018 to October 2018, ER physicians were incorporated to this study. Primary outcome was the antibiotic administration rate after visiting the ER, and secondary outcome was the 28th day mortality.
RESULTS. A total of 592 patients were included in this study (table1). The antibiotic administration rate after visiting the ER was improved significantly as the phases went on. The time to the initial antibiotic administration after visiting the ER was significant improved as the phases went on (table2). In multivariable logistic regression analysis, intervention for nurses was independently associated with antibiotic administration rate. 28 th day mortality were not significant between each phase, and there was no association between early antibiotic administration and 28 th day mortality.
CONCLUSION. A nurse-initiated QI improved the early administration of antibiotic for the patients with suspected sepsis. However, there was no association between early antibiotic administration and mortality.

INTRODUCTION. The implementation of an early mobility (EM) protocol in an ICU is a difficult process that requires change in culture and the overcoming of many barriers. But do we really know what the actual implementation of a protocol is to assess its impact? Clinical information systems (CIS) can help us in this situation to detect the different problems in adherence to a protocol.

OBJECTIVES. To evaluate the adherence to the protocol of early mobilization (EM) in an ICU through the Clinical Information System (CIS).
METHODS. Descriptive study in a polyvalent ICU of 30 beds during a period of two years (January 2017-December 2018). Patients who met the criteria for inclusion in the EM protocol were included. The analyzed variables: sex, age, APACHE II, reason for admission, length of ICU stay, proportion of EM days, EM start day, Medical Research Council (MRC) and EM level. The reasons why EM was not performed were analyzed. The data was extracted from the CIS by means of extraction, transformation and loading (ETL) processes with the Qlikview® software tool. The mining of the data was done with R.
RESULTS. Of the 1961 patients admitted to the ICU in the study period, 819 (41.76%) required mechanical ventilation (MV), of which 510 received MV > 48h and 272 fulfilled the inclusion criteria, representing a total of 3940 stays. The majority were men (72%), with a median age of 63 (53-72) years, a median APACHE II of 24 (18-29), a median SOFA of 7 (5-9) and a median LOS of 10 (6.8-17.3) days. The most frequent reason for admission was respiratory failure 21.7%, followed by monitoring and post-operative monitoring 20.22% and septic shock 19.12%. The average ratio of EM days to total stay was 25%. The causes why it was not carried out were: 47.2% for not meeting the criteria of clinical stability, 38.9% for being weekend, 4.4% for lack of physiotherapist, 3.1% because patient was out of ICU or rejecting physiotherapy and 6.4% the cause is unknown. In 26% of patients with inclusion criteria it was never started; 58% did not meet criteria for clinical stability, 1% for lack of physiotherapist, 28% for being weekend and in 16% the cause is unknown. The median MP start day was 5.8 days and the patients who were not started had an average stay of 6.13 days. We analyzed the number of patients who underwent the MRC and the level of MP they reached, at 96 (35.29%) and 151 (65.51%) patients respectively. Of the 151, the proportion of patients who arrived at each level at ICU discharge were: 11.26% (17) level I, 21.85% (33) level II, 7.95% (12) level III, 20.53% (31) level IV and 38.41% (58) level V.
CONCLUSION. The evaluation of the process allowed us to analyze the adherence to the MP protocol observing that its implementation is 74%. The results allow us to identify the improvement actions, adjust the indications and monitor their impact.

INTRODUCTION. Due to the side effects of the given different immuno-suppressive treatments for ANCA-associated vasculitis (AAV) or disease activation, these patients may deteriorate rapidly and intensive care unit (ICU) follow-up can be required (1). There is a need for a scoring system that can predict the ICU prognosis of patients with AAV, but the literature has limited data related with it.
OBJECTIVES. For this reason, the prognostic importance of clinical scoring systems was investigated in patients who had AAV activation.
METHODS. All adult patients who had to be followed up in ICU due to AAV activation in the last ten years in four reference university hospitals in Turkey were included in this study. Demographic information, immunosuppressive therapies, Birmingham Vasculitis Activity Score (BVAS) at the time of vasculit diagnosis and BVAS, APACHE II, SOFA and SAPS II scores at the ICU admission, treatments and clinical data were recorded in all patients.
RESULTS. Total 34 patients from 4 study centers were included. The mean age was 60.5 (42.2-70.2) years, 64.7% of patients were male. The most common causes of ICU admission were infection with 94.1 percent (82.4% pneumonia) and massive hemoptysis (58.8%). Twenty patients (58.8%) died in ICU follow-up. All non-survivors had septic shock. The most commonly identified bacteria related with septic shock were multidrug resistant Acinetobacter baumannii (%35) and Escheria coli (%30). There was a significant difference between survivors and non-survivors according to APACHE II (p=0.003) and SAPS II (p=0.045) scores, serum ALT levels (p=0.012) and platelet counts (p=0.001). But, there was no significant difference according to BVAS (p=0.545) and SOFA (p=0.099) scores. APACHE II score was found to be an independent risk factor for ICU mortality in logistic regression analysis (RR=1.239, CI=1.021-1.503, p=0.030). When the ROC curve analysis was performed, APACHE II score greater than 20.5 could predict ICU mortality with 80% specificity and 70% sensitivity in this patient group (AUC=0.8, p=0.004, like hood ratio=2.6).
CONCLUSION. APACHE II score can be used as a predictor for ICU mortality in AAV patient group. This result suggests that mortality of patients with AAV is caused by other problems that may occur during follow-up in ICU instead of disease activation.

The Use of Serum Albumin as a Non Respiratory Predictor of Outcome of Weaning in Critically Ill Patients

MJ. Canillas-Amancio[1], ME. Blanco-Limpin[1], A. Guzman-Banzon[1], E. Aventura[2]
[1]Pulmonary and Critical Care Division, Philippine Heart Center, Quezon City, Philippines; [2]Pulmonary medicine, The Medical City, Pasig, Philippines

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000059

INTRODUCTION. Serum albumin is the most abundant protein and is essential in maintaining the oncotic pressure needed for proper distribution of body fluids between blood vessels and body tissues. Serum albumin concentration is altered in critically ill patients especially with septic shock and after major surgery. Elevated hospital morbidity and mortality has been linked with hypoalbuminemia, which has been recognized to be a dependable prognostic indicator among critically ill patients.
METHODS. This was a prospective cross sectional study done at the intensive care unit of the Philippine Heart Center. Patients' ≥19 years old that require the use of invasive mechanical ventilation were included in the study. Demographic profile and clinical characteristics were recorded. Blood extraction for albumin determination was collected 24 hours after attachment to mechanical ventilator and prior to weaning. Patients outcome was categorized into; Group 1-short weaning, patients who had successful weaning within 24 hours; Group 2-difficult weaning, patients who completed weaning more than 24 hours but less than 7 days; Group 3, prolonged weaning, patients who completed weaning from ventilator after 7 days and Group 4, no weaning, patients with no weaning attempt in 4 weeks or separation attempt failed.
RESULTS. 120 patients were included in the study who met the selection criteria. Patients with higher albumin level had a shorter duration of weaning (group 1) while a lower albumin concentration

upon recruitment was shown in groups 2, 3 and 4 compared to prior to extubation (p-value 0.000, 0.000, and 0.029 respectively). Serum albumin of 27.9 g/L has shown to predict the weaning outcome in mechanically ventilated patients (82.47% sensitivity and 86.96% specificity). Those with lower albumin levels have a higher SOFA score (r= 0.4256; p-value <0.001) thus indicating a higher relative probability of mortality.

CONCLUSION. Serum albumin has been recognized as a clinical non-respiratory marker which provides a good predictor of weaning in mechanically ventilated critically ill patients. An admitting albumin level of >27.9 g/L has shown to predict the weaning success among critically ill patients with a sensitivity of 82.47% and specificity of 86.96%. While the association between the decrements in albumin concentration and higher SOFA score predicts a higher relative probability of mortality.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000073

INTRODUCTION. Delirium, acute consciousness disturbance with variable course of impaired cognitive function, is common in ICU. It is very important to prevent early onset of delirium. The E-PRE-DELIRIC model has recently received great attention as a scale to predict delirium at the start of ICU stay. The E-PRE-DELIRIC model consists of nine predictors assessed on ICU admission. It is studied to verify its usefulness is various western populations. However, its usefulness has not been established in East Asians.

OBJECTIVES. We examined the E-PRE-DELIRIC model in a single facility to clarify usefulness in Japan.

METHODS. The present study was designed as a retrospective cohort study in a single center. Enrolled patients were all adult over the age of 18 years. For evaluation of delirium, CAM-ICU was used. Patients who had delirium at ICU entry and who cannot be evaluated as delirium were excluded. The E-PRE-DELIRIC model was calculated and subjected to following analysis. Patients were divided two groups: delirium and non-delirium groups. Primary outcome was to determine the cut off values of the E-PRE-DELIRIC model. Secondary outcomes were to compare each factor of the E-PRE-DELIRIC model between two groups.

RESULTS. We enrolled 740 subjects, 137 for delirium and 603 for non-delirium. The incidence of delirium was 18%.

The cut off value of The E-PRE-DELIRIC model score 21 could predict delirium development with 0.871 and 0.606 as specificity and sensitivity, respectively, and AUC was 0.792 (95%CI 0.749 to 0.835). A comparison between the two groups of each factor is shown in the table. Logistic analysis indicated that cut off value was independently associated with 1.10 times (95%CI 1.05 to 1.15, p<0.001)

CONCLUSION. The E-PRE-DELIRIC model could predict delirium development in Japanese ICU patients, but its sensitivity remains modest.

Table 1 (abstract 000073). See text for description

	Delirium (N= 137)	Non delirim (N= 603)	p value
Age, median (IQR, range)	77 (70 – 85)	70 (63 – 78)	<0.001

Presence and importance of the agitation psychomotor on the maxillofacial surgery postoperative

R. Padilla[1], M. Dalorzo[1], F. Moran[1], M. Sanchez Casado[1], R. Martin[2]
[1]Icu, Virgin Health Hospital, Toledo, Spain; [2]Maxillofacial surgery, Virgin Health Hospital, Toledo, Spain
Correspondence: R. Padilla
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000094

INTRODUCTION. Patients undergoing elective and major maxillofacial surgery are one of the groups of greater risk of psychomotor agitation. It is associated with a greater frequency of complications, longer stay in ICU and hospital stay.

OBJECTIVES. Evaluate the presence of the psychomotor agitation in the postoperative of maxillofacial surgery and it repercussion in clinical evolutive variables.

METHODS. Retrospective revission in the clinical histories of the patients entered into ICU in the postoperative of mayor maxillofacial surgery in the last 6 years.

It was recorded basal variables, personal history, clinics and evolutive. To determinate the agitation it was used Riker scale and AgitatedBehaviorScales (ABS) scale. We define psychomotor agitation as a ABC value bigger than or equal to 21. The cuantitative data are expressed like medium (interquartile range) and cathegorics like counting (percentage).

RESULTS. We got 60 patients, of wich 86,7% were males, with ages of 60,5 (54-65,5) years. 28 of them, (46,7%), presented agitation in ICU. The agitation appeared in the 2nd (1,5-3,5) days of evolution, at the beginning of 1st weaning (1-2 days), and last 3 (2-3) days. They presented a result in Riker's agitation scales 6 (5-7); ABS 42 (25-51). The treatment used were benzodiacepines (96,4%), tiaprizal (82,1%), haloperidol (71,4%), physical restrictions (53,6%), b-blockers (35,7%), other atypical antipsychotics (25%) and dexmedetomidine (21,4%), associating some of them in the most of the cases.

If there are agitation in ICU, is associated with the most presence of agitation at plant (3,6% vs 32%; p=0,006), so that the 88,9% of the patients with agitation at plant, have presented it before in ICU.
CONCLUSION. The presence of agitation on maxillofacial surgery postoperative is very frequent, affecting almost half of the patients, and with high intensities, presenting a start pattern from the awakening, and that usually needs a combination of some drugs. That presence predict the repetition of the agitation at plant in the same patient.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000097

INTRODUCTION. Cardiac surgery for structural heart disease has poor outcomes in the presence of cardiogenic shock and/or multisystem organ failure. The mortality rate remain high, despite progress in pharmaceutical therapy, invasive cardiology, and surgical techniques.
OBJECTIVES. We applied venoarterial extracorporeal membrane oxygenation (ECMO) as a bridge to surgery to restore end-organ function and resuscitate patients before high-risk cardiac operation.
METHODS. We reviewed all patients with structural heart disease and cardiogenic shock who have been admitted to our institute during one-year period (2018) and have been resuscitated by ECMO preoperatively. Nine patients were included in to present study.
RESULTS. Mean age was 52 ± 17 years. Before surgery, patients were placed on ECMO for 3.7 days (average 2-7 days). Comorbidities included acute renal failure (n =7), inotropic support (n = 9), intra-aortic balloon pump (n = 5) and acute liver injury (n=3). With ECMO support, vasopressor requirement decrease, organ perfusion improved with decreased lactate levels from 67 mg/dL mmol/L to 19 mg/dL, (p = 0.01), normalized arterial pH (7.24 vs. 7.38 (p < 0.04) and mean arterial pressure (64 mmHg vs. 83 mmHg, p < 0.01).Follow, patients were undergoing different surgical procedures: AVR for severe aortic stenosis (n=1), MVR for severe mitral regurgitation (n=4), TVR+PFO closure (n=1) and closure of acute post-infarct ventricular septal defect (n=3). Average length of follow-up is 4 months, with 2 patient deaths at 12 and 7 days and the rest of the patients survived. Complications included acute kidney injury - yet no patients required dialysis at discharge- and one patient was underwent above knee amputation as a result of lower limb ischemia.
CONCLUSION. ECMO can be used as a bridge to heart valve or septal defect surgery in severely decompensated patients, suffered from cardiogenic shock. Through recovery of end-organ function, ECMO may allow surgical correction of structural heart disease in patients considered inoperable or convert a salvage situation to an elective operation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000102

INTRODUCTION. In the next decades an expansion of surgical services to address unmet needs is likely to increase total global deaths, of which 1.9 million would be in low-middle income countries[1]. Current evidence suggests that intraoperative management of major elective gastrointestinal surgery should consider cardiac output (CO) monitoring and goal-directed therapy[2]. However, cost restrains may determine low adherence to these practices in low resource settings. We hypothesized that central veno-arterial difference of CO2 [P(v-a)CO2] could serve as a surrogate for CO monitoring during GDT.
OBJECTIVES. We aimed to evaluate the impact of the use of P(v-a)CO2 as a surrogate of cardiac output in an algorithm of GDT on major complications and 90-day mortality.
METHODS. The study was a quasi-randomized controlled and explanatory trial performed in a tertiary university hospital in patients undergoing elective major gastrointestinal surgeries. In the interventional group a treatment algorithm aiming to keep mean arterial pressure > 65 mmHg, SpO2 > 94%, CO2 gap lower than 6 mmHg and pulse-pressure variation (PPV) lower than 13% using fluids, dobutamine and noradrenaline was applied in addition to the standard practice. The control group comprised all the consecutive patients that received traditional standard of care from the same team of surgeons and anesthesiologists in the period before the intervention phase.
RESULTS. A total of 204 patients were included in this study; 102 in each group. Measurements of P(v-a)CO2 were lower in the GDT group than in Control group at T0 (30-60 min after induction): 5.9 ± 2.1 vs. 6.7 ± 2.7 mmHg, p=0.031; T1 (2 h ± 30min): 6.4 ± 2.6 vs. 7.0 ± 2.3 mmHg, p = 0.033 and T2 (4 h ± 30min):5.9 ± 2.1 vs. 7.1 ± 3.4 mmHg, p = 0.036. Central venous saturation (ScvO2) was significantly higher throughout the intraoperative period in the GDT group, and there was a moderate correlation between P(v-a)CO2 and ScvO2 (P<0.001 at all-time points and at ICU admission). The number of patients with major complications was lower in GDT group than in the control group and there was a significant decrease in 90-day mortality in the GDT group (22.5% vs. 9.8%, p=0.014).
CONCLUSION. Minimization of P(v-a)CO2 and PPV as therapeutic targets during elective major gastrointestinal surgeries seems to determine better postoperative outcomes. Testing lower cost alternatives during GDT is extremely important for low-resource settings and countries and its value should be evaluated in prospective randomized trials.

INTRODUCTION. Postoperative hypotension is a common occurrence following major non-cardiac surgery. There is evidence of substantial variation in the management of postoperative hypotension between centres, countries and continents. In preparation for an international prospective observational cohort study concerning the use of postoperative vasopressor infusions ('**Squeeze**'), we surveyed clinicians from perioperative and intensive care medicine regarding use of vasopressors after surgery.
METHODS. With the assistance of staff and resources of ESA and ESICM we shared a link to a SurveyMonkey questionnaire of our design. Questions in the survey included location of vasopressor use after surgery, frequency of vasopressor use, and choice of vasopressors after surgery. Ethical approval was not required.
RESULTS. Between July 2018 and Feb 2019, we received 2052 complete responses with 97.5% of respondents regularly, or occasionally, taking care of postoperative non-cardiac patients. Respondents were from 102 countries, with the greatest number of replies from Germany, UK, Spain and Italy (each >100 replies). 27.3% worked in hospitals with 250-499 beds, 33.7% with 500-999 beds and 19.8% >1000 beds.
Respondents answered "Non-cardiac surgery patients receive vasopressor infusions after surgery:" 'occasionally' in 58%, and 'frequently' in 22%. Postoperative patients received infusions of vasopressors in a range of differently described environments including PACU, ICU, and HDU; only 7.2% responded that vasopressors could be used on a normal postoperative ward. Respondents answered "Non-cardiac surgery patients receive vasopressor infusions after surgery:" 'occasionally' in 58%, and 'frequently' in 22%.
The most common choice of vasoactive drug used was noradrenaline (used always or frequently by 76%) and phenylephrine (used always or frequently by 18%)"
CONCLUSION. Vasopressor infusions are commonly used in patients following surgery. There is variation in choice of drug and location of treatment. Patient-level data are needed to better understand practice patterns and outcomes associated with vasopressor use.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000116

INTRODUCTION. Critical illness can cause severe cognitive impairments. Studies frequently find more than half of critical illness survivors to have substantial cognitive impairments, often lasting for years or for a lifetime, significantly affecting quality of life (1). No effective preventive measures have been established. Delirium seem to be the most important risk factor for long-term cognitive impairment. Less sedation is encouraged and might lead to less delirium and less cognitive impairments following critical illness.
OBJECTIVES. The objective was to assess the effect of non-sedation versus sedation with a daily wake-up call during mechanical ventilation on cognitive function in adult survivors of critical illness.
METHODS. Single center sub-study of the multicenter, randomized NONSEDA trial. Participants were randomized within the first 24 hours from intubation to either non-sedation with sufficient analgesia or to light sedation with a daily wake-up call during mechanical ventilation. Three months after ICU-discharge survivors were tested for cognitive function in-person by a neuropsychologist.
RESULTS. A total of 205 critically ill, orally intubated and mechanically ventilated adults were included; 118 patients survived to follow-up and 89 participated (75%). The participating survivors in the two groups did not differ regarding baseline data or premorbid cognitive impairments. Sedated patients had received more sedatives, whereas doses of morphine and antipsychotics were equal. We found more patients with delirium in the sedated group (96% versus 69% of patients, p=0.002) and increased duration of delirium in sedated patients (median 5 days versus 1, p< 0.001). Delirium sub-types were equally distributed between groups, with hypoactive delirium most frequent (61%), followed by mixed delirium (39%). Primary outcome: No significant difference was found in number of patients with mild/moderate cognitive impairments (non-sedated: 6 patients vs sedated: 4) or severe cognitive impairments (non-sedated: 16 patients vs sedated: 17, p=0.71). Two hypothetical worst-case scenarios where all survivors and all included patients, respectively, who had not participated in the follow-up assessment were assumed to have severe cognitive impairments, were analyzed, but still no difference between groups was found (p=0.98 and 0.87, respectively). Secondary outcomes were 1) cognitive test scores, and 2) effect of delirium on cognitive function, where no differences were found between groups in either. In both groups a wide array of cognitive domains was found to be affected, and in both groups visuo-spatial construction was most seriously affected, followed by executive function and then visual learning/memory. The distribution of affected domains did not vary between groups (p=0.64).
CONCLUSION. Non-sedation did not affect cognitive function three months after ICU-discharge.

INTRODUCTION. Critical illness can cause impaired physical function and lead to dependence of help in everyday activities. In recent years, intensive care unit (ICU) acquired weakness and its possible prevention have received much attention, although the pathophysiology is still not clear. Generally, lower levels of sedation, focus on pain relief, patient comfort and early mobilization (known as the eCASH concept) are encouraged (1).
OBJECTIVES. The objective of this study was to assess the effect of non-sedation on physical function.
METHODS. This study was a single-center sub-study of the NONSEDA trial, a multicenter randomized trial, assessing harms and benefits of non-sedation versus sedation with a daily wake-up call during mechanical ventilation in critically ill adults. All patients from one NONSEDA trial-site (the ICU in Kolding, Denmark) were included. At extubation, ICU discharge and 3 months after ICU discharge survivors were assessed for physical function.
RESULTS. A total of 205 patients were included, 118 survived to follow-up and 116 participated (98%) to the extent they were able. The two groups did not differ significantly regarding baseline data. Sedated patients had received more sedatives, but doses of morphine, corticosteroids and neuromuscular blocking agents were equal, as was mean blood glucose. Primary outcome: Three months after ICU-discharge, health-related quality of life (SF-36, physical component score) did not differ significantly between groups (non-sedated 38.3 vs sedated 36.6, p= 0.3), but a tendency to better function in activities of daily living (Barthel Index) was found in the non-sedated group (19.5 vs 18, p=0.08). Secondary outcomes: Non-sedated patients had a significantly better Barthel Index at ICU-discharge (median 7 vs 4, p=0.01). There were no differences between groups regarding handgrip strength, walking distance, muscle size or biomechanical data on lower extremity function 3 months after ICU discharge. Explorative outcomes: Handgrip strength at extubation and ICU-discharge was significantly better in non-sedated patients.
CONCLUSION. Non-sedation did not lead to significantly better quality of life or better function in activities of everyday living 3 months after ICU discharge, however non-sedated patients generally had a better physical function, especially in early phases (extubation and ICU discharge).

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000145

INTRODUCTION. Success of NIV mainly depends on patient's cooperation with the technique. Use of analgesic and sedative drugs during NIV is not a common practice due to the high risk of respiratory depression. Dexmedetomidine (DEX) has a sedative, analgesic and anxiolytic effect and preserves oropharyngeal reflexes. Due to those effects it could became the ideal sedative drug for patients comfort under NIV
OBJECTIVES. to compare effectiveness of DEX regarding SCP in ARF under NIV. It will be assess tolerance, patient´s degree of satisfaction, safety profile and acute respiratory failure evolution
METHODS. A phase IV multicentre, randomised, open label, parallel-group, controlled clinical trial, from 1/12/16 to 31/10/18. Approved by Ethics Committee. Clinical Trials NCT02958150. **Inclusion Criteria**: >18 years, ARF secondary to Pulmonary Oedema, pneumonia or high risk of post-extubation failure. **Exclusion Criteria**: ARF needing intubation, HR<50, AVB 2º-3º, neurocritical patients. Drug allergy. **Groups**: SCP: no drugs or midazolam (0,03-0,05 mg/kg) and/or propofol (0,25 mg/kg iv), morphine (3-5mg) and/or fentanyl (50-100µg) bolus or remifentanil 6 µg/kg/h. DEX: 0,4-1,4µg/kg/h para RASS(0 -1) ± SCP iv bolus. Categorical variables as percentages % and compared using X2 o Fisher, continuous variables as mean ±SD/median IQR and compared using two samples T-test. P<,05.
RESULTS. DEX vs SCP: *N*= 22 vs 27. *Age (years)* 72.7±8.3 vs 69.0±11.5 (p.23). *Female %:* 33.3 vs 37.0 (p=1). *ARF etiology %*: COPD/ Heart failure: 41vs 37; Pneumonia 32 vs 26; Post-extubation/others 27vs 37 (p.76). *Oxygen support pre-NIV Fi02>50* % 52.6 vs 61.9 (p.75). *SOFA score*: 6.48±4,4 vs 6.19±3.5 (p.80). Non-respiratory dysfunctions 85.7 vs 100. Other sedatives/analgesics administered: DEX/SCP None 59.1 vs 57.7 (p.92). Dexmedetomidine dose: 0.87±0.33 µg/kg/h
NIV Tolerance %: Nausea 4.8 vs 0 (p.48). Aspiration pneumonia 0 vs 0 (p=1). CAM-ICU+: 14.3 vs 32.0(p.16). Agitation (RASS>+2) 28.5 vs 19.2 (p.45). Interface intolerance 19.0 vs 11.5(p.68). VNS ≥4 14.3 vs 19,2 (p.71). **Adverse effects %:** Respiratory depression 0 vs 0. HR<60 28.5 vs 16.0(p.30). HR<40 solved with reduction of perfusion 9.5 vs 0 (p.20). SBP<80 28.5 vs 16.0(p.30). TAS>160 4.7 vs 4.0 (p=1). FC>140 8.0 vs 0 (p.49) **Patient satisfaction %**: *Rested during ventilation:* agree (A) 87.5 vs 25.0 (p<.00); *Comfortable* (A) 80.0 vs 36.6 (p.02). Unpleasant memories of ventilation (A) 21.4 vs 27.0 (p=1). *Sedated with the same drug?* (A) 85.7 vs 44.4 (p.06). **Dyspnea** (2point decrease)**%:** pre-1hpostNIV: 95.4 vs 77.7 (p.11). pre-6hpostNIV: 95.4 vs 88.8 (p.61). **ARF course:** pC02 pre 50.8±16.2 vs 54.7±12.5 (p.36). 6h post 45 (34.5-49) vs 46 (38-55) (p.31**). Pa02/Fi02** preNIV144,8 vs 148,6 (p.87). P/F 1hpostNIV 197 (155-235.25) vs 213.5 (147.25-269.75) (p.64). P/F 24h postNIV 226.5 (208.75-304) vs 187 (147-257) (p.01). **Hours of NIV**: 15 (9.5-25.5) vs 18 (8.1 -39) (p.44). **ICU stay** (d): 5 (3-9) vs 8 (3-15) (p.25). **Endotracheal intubation** %: 23,8 vs 20.0 (p.75**). ICU mortality** % 15.7 vs 19.0 (p=1)
CONCLUSION. DEX vs SCP provided higher degree of satisfaction and better oxygenation to patients under NIV with ARF without improving side effects and percentage of intubation or ICU mortality. Use of DEX vs SCP could reduce ICU stay and NIV duration

Differences in 90-day mortality of delirium subtypes in the intensive care unit: a retrospective cohort study

P. Rood, F. Van De Schoor, K. Van Tertholen, P. Pickkers, M. van den Boogaard
Intensive care, Radboud University Medical Center, Nijmegen, Netherlands
Correspondence: P. Rood
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000162

INTRODUCTION. Many intensive care unit (ICU) patients suffer from delirium which is associated with deleterious short-term and long-term effects, including mortality.
OBJECTIVES. We determined the association between delirium and the different delirium subtypes and 90-day mortality.
METHODS. Retrospective cohort study of ICU patients admitted between 2015-2017. Delirium, including its subtypes (i.e. hyperactive, hypoactive, mixed and rapidly reversible delirium), was determined using the confusion assessment method-ICU (CAM-ICU) and Richmond agitation sedation scale (RASS-)scores. Exclusion criteria were insufficient assessments and persistent coma. Cox-regression analysis was used to determine associations of delirium subtypes with 90-day mortality, including relevant covariates (i.e. APACHE-IV, length of ICU stay and mechanical ventilation).
RESULTS. 7,362 ICU patients were eligible of whom 6,323 (85.9%) were included. A total of 1,600 (25%) patients were prevalent ICU delirium cases of which the mixed subtype occurred the most frequent (36%). The crude hazard ratio (HR) for overall prevalent delirium with 90-day mortality was 2.84 (95%CI:2.32-3.49), and the adjusted HR 1.29 (95%CI:1.01-1.65). The adjusted HR for 90-day mortality was 1.57 (95%CI:1.51-2.14) for the mixed subtype, 1.40 (95%CI:0.71-2.73) for hyperactive 1.31 (95%CI:0.93-1.84) for hypoactive and 0.95 (95%CI:0.64-1.42) for the rapidly reversible delirium subtype.
CONCLUSION. After adjusting for covariates, including the competing risk factor length of ICU stay, only the mixed delirium subtype was significantly associated with 90-day mortality.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000163

INTRODUCTION. Delirium is a frequently occurring syndrome which burdens Intensive Care Unit (ICU) patients. The effect of prophylactic haloperidol use on long-term quality of life is unknown.
OBJECTIVES. To evaluate the effects of prophylactic haloperidol use on long-term quality of life in critically ill patients at high risk for delirium, and to explore which factors are associated with change in quality of life.
METHODS. A pre-planned secondary analysis of long-term outcomes of the REDUCE study was conducted. In this multicenter randomized clinical trial, non-delirious ICU patients were assigned to the prophylactic haloperidol or placebo group. Long-term outcomes were assessed using the Short Form-12 questionnaire at ICU admission (baseline), and after 1 and 6 months. Quality of life was summarized in the physical component summary (PCS) score and mental component summary (MCS) score. Differences between the haloperidol and placebo group, and factors associated with changes in quality of life were analyzed.
RESULTS. Of 1789 study patients, 1245 ICU patients were approached of which 887 (71.2%) responded. Long-term quality of life did not differ between the haloperidol and placebo group mean (±SD) PCS score 39.3±11.0 and 38.9±10.6, respectively; P=0.35, and mean MCS score 50.3±10.1 and 51.1±10.0, respectively; P=0.68). Factors associated with physical decline after 6 months were age (odds ratio [OR] 1.02; 95%CI:1.01-1.04), medical admission (OR 2.08; 95%CI:1.39-3.10), trauma admission (OR 5.34; 95%CI:1.65-17.27), baseline PCS score (OR: 1.06; 95%CI:1.04-1.08) and number of sedation-induced-coma days (OR 1.15; 95%CI:1.05-1.25). Factors associated with mental decline after 6 months were age (OR 1.03; 95%CI:1.01-1.04), medical admission (OR 2.09; 95%CI:1.43-3.03), baseline MCS score (OR 1.03; 95%CI:1.01-1.05) and the number of sedation-induced-coma days (OR 1.09; 95%CI:1.01-1.17).
CONCLUSION. Prophylactic haloperidol use does not affect long-term quality of life in critically ill patients at high-risk for delirium. Several factors, including the modifiable factor number of sedation-induced-coma days, are associated with decline in long-term outcomes.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000179

INTRODUCTION. Pleural adhesions, upper lobe resections and low forced expiratory volume in one second (FEV1) were proposed as predictors of prolonged air leak after lung resection surgery. Increased ventilatory drive may be associated with dynamic hyperinflation and may therefore also contribute to the development of prolonged air leak after lung resection surgery.
OBJECTIVES. We hypothesized increased ventilatory drive, characterized by the slope of minute ventilation to carbon dioxide output (VE/VCO2), predicts prolonged air leak after pulmonary lobectomy. Accordingly, aim of this study was to compare ventilatory and gas exchange parameters during exercise in patients with and without air leak after pulmonary lobectomy.
METHODS. Consecutive lung resection (lobectomy) candidates were recruited in this prospective bicenter study. All of the recruited patients underwent pulmonary function tests and cardiopulmonary exercise testing prior surgery. Prolonged air leak was defined as presence of air leak from the chest tube on the 5th postoperative day. Student t-test, Mann-Whitney U test and two-tailed Fisher exact test were used for comparison. Stepwise logistic regression analysis was performed for evaluation of parameters association with postoperative prolonged air leak. Data are summarized as mean ± SD; $p< 0.05$ was considered as significant.
RESULTS. A total of 96 patients were included. Prolonged air leak was observed in 28 (29%) of patients. Between groups, there was no significant difference in age, sex, ASA class, type of surgery (thoracotomy/video-assisted thoracoscopic surgery) and side of surgery (right/left lung; upper/lower lobes). Patients with prolonged air leak had significantly longer hospital (14 ± 7 vs. 9 ± 6 days; $p<0.01$) and intensive care unit length of stay (7 ± 5 vs. 5 ± 4 days; $p<0.01$), lower FEV1 (82 ± 21 vs. 91 ± 18 %; $p=0.03$), longer duration of surgery (210 ± 67 vs. 187 ± 72 min; $p=0.04$), more frequent pleural adhesions (50% vs. 21%; $p=0.01$) and higher VE/VCO2 slope (35 ± 7 vs. 30 ± 5; $p<0.01$). Stepwise logistic regression showed only presence of pleural adhesions (OR= 3.9; 95% CI 1.4-10.9; $p=0.01$) and VE/VCO2 (OR 1.1; 95% CI 1.0-1.2; $p<0.01$) to be independently associated with the prolonged air leak. VE/VCO2 values above 45 were highly specific for the prediction of prolonged air leak (specificity 96%, sensitivity 18%).

CONCLUSION. Increased ventilatory drive during exercise (VE/VCO2 slope) may predict prolonged air leak after pulmonary lobectomy.

Prognostic value of procalcitonin after gynecological surgery: a preliminary retrospective cohort study

Y. Fujita, M. Okumura, A. Hashimoto, Y. Sato, Y. Fujiwara
Anesthesiology and intensive care medicine, Aichi Medical University Hospital, Nagakute, Japan

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000183

INTRODUCTION. Procalcitonin (PCT) is a well-known prognostic marker after elective cardiac surgery. Klingele et al. (1) demonstrated that measurement of PCT seems to be useful for identification of patients at risk of delayed complications despite an initially uneventful postoperative course. However, the prognostic value of PCT after non-cardiac surgery remains unknown.
OBJECTIVES. We chose gynecological surgery as a non-cardiac surgery with which to evaluate whether PCT is useful for predicting a risk of delayed complications.
METHODS. In total, 1,015 patients who underwent gynecologic surgery in our institution were retrospectively evaluated. The serum PCT concentration was measured the morning after surgery. All patients were screened for the occurrence of delayed complications. Delayed complications were defined as in-hospital death, intensive care unit readmission, or a prolonged hospital stay (>10 days). Odds ratios with 95% confidence intervals were calculated by logistic regression analysis and adjusted confounders. The confounders used to calculate the odds ratios were age, sex, diabetes mellitus, hypertension, past stroke, coronary artery disease, hepatic disease, renal disease, past cancer, active cancer, chronic obstructive disease, allergy, estimated glomerular filtration rate, American Society of Anesthesiologists physical status, and emergency operation.
RESULTS. Among 1,015 patients, 101 developed delayed complications. The PCT level was significantly higher in these 101 patients (1.01ng/ml) than in the remaining 914 patients (1.01 vs. 0.31 ng/ml, respectively; $p = 0.0089$). We divided the patients into two groups using the normal cutoff level for PCT (0.5 ng/ml). Patients with a PCT level of >0.5 mg/ml on the first postoperative day had a highly increased risk of delayed complications (adjusted odds ratio, 5.73; 95% confidence interval, 3.57–9.20; $p < 0.0001$).
CONCLUSION. In our preliminary study, a single measurement of PCT seems to be a useful marker to identify patients at risk of delayed complications after gynecological surgery.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000185

INTRODUCTION. Pain management and sedation are important aspects in the treatment of hospitalized patients, especially those mechanically ventilated. In many hospitals, such patients are treated not only in intensive care units, but also in other wards. In the nineteen eighties, numerous studies demonstrated a wide array of misconceptions and inadequate knowledge related to commonly used sedative, analgesics and muscle relaxants which may prevent appropriate treatment. Since these publications, multiple studies have shown that appropriate sedation and analgesia are associated with improved clinical outcomes, educational programs were developed and guidelines published. Whether the personnel's knowledge kept up with these changes is unknown.
OBJECTIVES. To determine the current rate of misconceptions and knowledge gaps regarding commonly used sedative, analgesic and neuromuscular drugs.
METHODS. We conducted a prospective, observational, cross-sectional e-questionnaire survey among physicians and nurses who routinely treat mechanically ventilated patients. The study was performed in Rambam Health Care Campus ,Haifa, Israel, a 1000-bed academic hospital, serving a population of over two million residents.
RESULTS. 355 questionnaires were returned. The response rate was 42.49% (181/ 426) for physicians and 30.05% (174/ 579) for nurses. Only 82.54% knew that midazolam has no analgesic effect. Only 71-72% were familiar with the sedative effect of opiates. 27% believed that propofol has analgesic properties. 30.52% thought that rocuronium has a sedative effect and 10.17% believed that it has analgesic proporties. As much as 40% of emergency room personnel and 17% of ICU staff believed that muscle relaxants have a sedative effect.
CONCLUSION. Our findings demonstrate that although a lot has been done during the last decades in order to improve the treatment of critically ill patients, the rate of misconceptions regarding pharmacological characteristics of commonly used drugs is unacceptably high. These basic misconceptions are in contrary with the guidelines recommending an analgesia- first sedation strategy and may lead medical personnel to provide excessively deep sedation and lack of analgesia on one hand, and to treat patients receiving opiates with unnecessary midazolam or propofol, on the other hand. Using muscle relaxants without concomitant sedatives or analgesics may cause a situation in which patients are aware of their surroundings and feel pain without having the ability to express it. This terrifying scenario is one of the biggest fears people have when they are about to undergo a medical procedure.
Our findings call for immediate action to improve patients' care in our hospital and other institutes. It seems crucial to promote new educational programs, protocols, and guidelines in ICU and other wards. More rigid "safeguards" such as daily clinical pharmacist review of sedatives, analgesics and paralytics administered as well as incorporation of automated clinical decision support tools into an electronic health record system of mechanically ventilated patients should be considered.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000194

INTRODUCTION. Renal transplant (RT) is considered the treatment of choice in End-Stage Renal disease(ESRD).Besides graft characteristics, an important factor in determining immediate graft function is the intravascular volume maintained during surgery.(1) Infusion of fluid targeting Central venous pressure(CVP) values are routinely used. The controversies of CVP to accurately predict fluid status initiated the use of dynamic parameters of fluid responsiveness like Pulse Pressure Variation (PPV).Our study was to determine the utility of PPV to guide fluid therapy during RT.
OBJECTIVES. Primary aim-To determine the ability of PPV guided fluid therapy as an alternative to CVP in RT surgeries by comparing the total volume of fluid administered during surgery.
Secondary aim-To compare the adequacy of tissue perfusion by measuring blood lactate levels and to find out the volume of fluid administered in two groups in the post-operative period.
METHODS. Consenting ESRD patients aged 18-60 years scheduled for RT receiving kidney either living donors or from cadavers were randomly allocated in one of the two groups -Group C (CVP assisted fluid therapy) and Group P (fluid therapy by PPV).General anesthesia was administered.Fluid resuscitation in group P was to maintain a PPV of <6% at the time of declamping and in group C, fluid infusion was done to target CVP of 10-12 mm of Hg at the same time point. Post operatively signs of fluid overload such as conjunctival edema and fluid requirement for the first 24 and 48 hours were noted. Urine output,urea,and serum creatinine values in the first 24 and 48 hours were also obtained. A sample size of 70 (35 patients in each group) was calculated assuming a 30% effect size and 80% power at 5% level of significance for the mean outcome of the volume of crystalloids administered.
RESULTS. Out of 77 randomised patients,70 completed the study-Group P (*n*-35) and Group C (*n*-35) (Figure1).The total volume of crystalloids infused intra-operatively was 1345.71±337.24 (mean±SD) ml in Group P which was 29% lesser than 1901.4 ± 379.34 (mean±SD) ml in Group C ($p = 0.000$). Intra operative lactate levels and postoperative fluid, urine output, serum urea, and creatinine levels were comparable (Figure2). Conjunctival edema was significantly higher in group C.
CONCLUSION. Administering fluid guided by PPV decreases the intraoperative fluid requirement by 29 % when compared to CVP guided therapy with no adverse effect on immediate graft function. This modality of fluid therapy can be a judicious alternative in RT surgery.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000167

INTRODUCTION. Delirium is a frequent problem is the intensive care unit (ICU) and is associated with adverse outcomes, such as longer hospital length of stay, cognitive impairment and potentially higher mortality. Haloperidol and atypical antipsychotics are often used to treat delirium in the ICU. Antipsychotics can lead to severe adverse effects, such as arrhythmia, pneumonia, orthostatic hypotension and falling. When antipsychotics are administered for delirium in the ICU, patients are at risk of having antipsychotics continued at ICU and hospital discharge, even though they are no longer indicated. No European data on hospital discharge of patients with newly administered antipsychotics is available.
OBJECTIVES. This study aims to determine the incidence of ICU and hospital discharge with newly administered antipsychotics for ICU delirium, to identify risk factors for discharge with antipsychotics and to evaluate follow-up of patients with antipsychotics upon ICU and hospital discharge.
METHODS. This retrospective observational study was performed in a tertiary care center. Patients older than 18 years who received antipsychotics for delirium in the ICU during 2016 were included. Preliminary risk factors were determined by performing chi-square tests for categorical variables and univariate binary logistic regression tests for continuous variables. Preliminary risk factors were included in a multivariate binary logistic regression model to identify independent risk factors. Results are expressed as odds ratios with 95% confidence intervals.
RESULTS. A total of 196 patients met the inclusion criteria, of which 104 (53.1%) were discharged from the ICU with continued antipsychotics, and 41 (20.9%) patients were discharged from the hospital with continued antipsychotics. At ICU discharge, continuation of antipsychotics was independently associated with a lower Charlson comorbidity index (0.84 [0.73 – 0.97]), treatment with quetiapine (7.14 [3.06 – 16.67]), less days between antipsychotic treatment initiation and ICU discharge (0.95 [0.91 – 0.99]), and a higher ICDSC score at ICU discharge (1.21 [1.04 – 1.39]). At hospital discharge, admission to the medical ICU (2.97 [1.37 -6.41]) and treatment with quetiapine (5.81 [1.63 – 20.83]) were independently associated with continuation of antipsychotics. Sixteen (39.0%) patients who were discharged from the hospital with continued antipsychotics had no mentioning of these antipsychotics in their hospital discharge letter. All of these patients were discharged from a surgical ward.
CONCLUSION. One out of five patients were discharged from the hospital with continued antipsychotics. This result is comparable to previous, albeit all US, studies. There is a lack of systematic follow-up of antipsychotics. Hospital policies should implement systematic strategies for better follow-up of antipsychotics at transitions of care.

Cooling methods in exertional heatstroke; combined methods with an extra-cooling device or conventional approaches

Y. Iwasaki, K. Noguchi, K. Kasai, K. Hirukawa, M. Kawakami
Emergency and Critical Care Center, Ome Municipal General Hospital, Tokyo, Japan
Correspondence: Y. Iwasaki
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000065

INTRODUCTION. Heatstroke is a life-threatening illness which occurs in hot environment, especially in the summertime. The summer of 2018 was remarkable, because emergency transport to medical facilities of heat-related illness casualties hit the highest record in history at Tokyo, Japan.
Rapid and effective cooling is essential for victims of heatstroke. However, there is little clinical evidence about treatment with new cooling devices.
We compared combined methods with an extra-cooling device (Arctic Sun 5000®, Medivance, USA) to conventional approaches (e.g. lukewarm water spray, electric fan and cooling fluid infusion) for treatment with heatstroke.
METHODS. Patients (aged >16 years) with heat-related illness transported to our emergency department (ED) via emergency medical service (EMS) from June to September of 2018 were included in this study.
We used the Japanese Association for Acute Medicine (JAAM) criteria for definition and classification (grade I to III) of heat-related illness. Treatment and clinical outcome of exertional heatstroke cases were examined. Data was derived from prehospital records and electronic health record (EHR).
RESULTS. The total number of emergency transport was 1764. Fifty-one (2.9%) patients presented to ED via EMS with symptoms of heat-related illness.
With the JAAM criteria, the number of grade III (severe) heat-related illness that corresponds to heatstroke was 9 (18%). Among them, 4 (7.8%) cases were diagnosed with exertional heatstroke.
With severe exertional heatstroke, three (5.9%) presented with hyperthermia (deep body temperature over 40 C). One was treated by combined methods with Arctic Sun 5000®, and the other two were treated by conventional approaches. All of three case were treated

under mechanical ventilation and use of sedatives and muscle relaxants at intensive care unit (ICU).
The time required for reaching to target body temperature was shorter with combined methods than with conventional approaches. Also, no rebound of body temperature was observed with combined methods with Arctic Sun 5000®.
Arctic Sun 5000® was considered minimally invasive and easy to introduce at ED. Overall clinical courses were fine without neurological dysfunction.
CONCLUSION. Treatment with extra-cooling devices combined with conventional approaches may be beneficial to patients with exertional heatstroke. Further investigations including large clinical trials are required.

INTRODUCTION. Increased intracranial pressure (ICP) is one of the major clinical complications of acute brain injuries (ABIs) and correlates with poor outcome. ICP monitoring (ICPm) is the most common neuromonitoring modality used in intensive care units (ICUs). The indications for ICPm are mostly based on traumatic brain injury (TBI), whereas uncertainties remain for ICPm in non-TBI (acute subarachnoid haemorrhage (SAH) and intracerebral haemorrhage (ICH)). Moreover, practice about indications and use of ICPm in patients with ABIs is highly variable in high-income countries (HICs), while data on ICPm in low- (LICs) and middle-income countries (MICs) is scarce or inconsistent.
OBJECTIVES. SYNAPSE-ICU is an international, prospective, observational, cohort study (NCT03257904) designed to describe the current practice of ICPm using a worldwide sample. Aim is to quantify practice variations in ICPm and management in HICs, MICs and LICs, and to provide a correlation between ICPm and neurological clinical outcome (GOSE: Glasgow Outcome Scale Extended).
METHODS. From March 2018 to April 2019, all patients fulfilling the following inclusion criteria were recruited: age >18 years; ABI due to primary haemorrhagic stroke or TBI; Glasgow Coma Score (GCS) with Motor score (M) $\leq$ 5 at ICU admission or within the first 48 hours. Data related to clinical examination and to ICP interventions was recorded at ICU admission, at day 1, 3 and 7. GOSE was collected at discharge from ICU, from hospital and at 6-month follow-up.
RESULTS. To date, 41 countries around the world enrolled 2302 patients in 143 active sites (95 in Europe, 28 in America, 15 in Asia, 3 in Australia and 2 in Africa).
We described the main characteristics of the first 1000 recruited patients (68.0 % males, 32.0 % females, mean age 55.0 years ± 19.2) enrolled in HICs (87.5%), in upper-MICs (U-MICs) (6.7%) and in lower-MICs (L-MICs) (5.8%). Primary diagnosis was TBI in 56.0% of patients and non-TBI in 44.0% of them (19.1% SAH and 24.9% ICH). In the first week of ICU stay, ICP was measured in 585 patients (90.8% in HICs, 5.1% in U-MICs, 4.1% in L-MICs), whereas ICPm was never applied in 415 patients. ICPm patients had a 6-months lower mortality compared to no ICPm ones (40.0% vs 56.1%).
CONCLUSION. The high number of enrolled patients and the distribution of active ICUs will represent the worldwide variability in ICPm practice variations. Further analysis will be presented at the end of the study period.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000188

INTRODUCTION. Severe traumatic brain injury (TBI) patients may develop acute respiratory failure or acute respiratory distress syndrome (ARDS) (1-2). Optimal ventilatory strategies in this setting are not well established.
OBJECTIVES. To survey practices in the respiratory management of adult TBI patients with and without ARDS.
METHODS. An electronic questionnaire, including 40 items and 3 different clinical scenarios (PaO2/FiO2: >300, 150-300, <150), was available on the European Society of Intensive Care Medicine (ESICM) website between November 2018 and March 2019. The survey was endorsed and promoted by ESICM.
RESULTS. Respondents (RSP) were 687 [472 (69%) from Europe]; mainly intensivists [328 (48%)] and anesthesiologists [206 (30%)]. A standard protocol for mechanical ventilation in TBI patients was utilized by 277 (40%) RSP and a specific weaning protocol by 198 (30%). The most frequently reported ventilator settings and respiratory targets according to acute lung injury severity are summarized in Table 1. The most frequent rescue strategies utilized in case of refractory hypoxemia despite conventional ventilator settings are represented by neuromuscular blocking agents [406 (88%)], recruitment maneuvers [319 (69%)] and prone position [292 (63%)].
CONCLUSION. Different practices on respiratory management of adult TBI patients with and without ARDS are identified in this survey. These findings may be helpful to define future investigations in this topic.

Platelet distribution width as a predictor for in-hospital mortality in intracranial hemorrhage

AY. Wang[1], CK. Chang[2]
[1]Department of Critical Care Medicine, Taipei Medical University Hospital, Taipei City, Taiwan; [2]Department of neurosurgery, Shuangho Hospital, New Taipei City, Taiwan
Correspondence: A.Y. Wang
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000234

INTRODUCTION. Platelet distribution width (PDW) reflects the variation and heterogeneity of platelet size, and elevation of PDW indicators of platelet activation. Elevated PDW was associated with poor prognosis in thromboembolic diseases. However, little is known about the association between platelet activation and clinical outcome of intracranial hemorrhage.
OBJECTIVES. To study the role of PDW as a prognostic marker of acute intracranial hemorrhage.
METHODS. This was a retrospective cohort study conducted in emergency department intensive care units between April 2015 and December 2016. Patients admitted with diagnosis of acute traumatic and non-traumatic intracranial hemorrhage were included. The demographic data, hemorrhage type, platelet count, mean platelet volume (MPV), PDW were compared between survivors and nonsurvivors.
RESULTS. A total of 120 patients with acute intracranial hemorrhage were included, 65% (78/120) were traumatic cause. In our cohort, overall mortality was 15.4% (16/104). There was no difference in age, gender, antiplatelet, anticoagulant use, platelet count and MPV level between survivors and non-survivors. In multivariate logistic regression model, PDW was an independent predictor for in-hospital mortality (Odds ratio = 6.07; 95% confidence interval (CI.)=[1.17-31.41], p = 0.031) after adjusting APACHE II score, GCS, mechanism and hemorrhage type. The receiver-operating characteristic area under the curve (AUC) of PDW was 0.71 (95% CI=[0.55-0.87], p=0.006). The PDW level is lowest in aneurysmal SAH group and highest in spontaneous ICH group.
CONCLUSION. PDW is simple, inexpensive and available in routine blood sampling. Our study revealed the potential value of PDW as a predictor for in-hospital mortality in intracranial hemorrhage.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000240

INTRODUCTION. Takotsubo cardiomyopathy (TTC) is an acute, usually reversible heart failure syndrome, precipitated by emotional or physical stressors. The initial presentation of TTC has similar features to acute coronary syndrome, however, coronary angiography usually shows an absence of significant coronary artery disease. TTC has been previously described as a notable complication of SAH because of its impact on cerebral blood flow.
OBJECTIVES. The aim of our prospective observational study was to investigate the incidence, predisposing factors and cardiac biomarkers of TTC associated with SAH. Our secondary goal was to evaluate its effect on outcome.
METHODS. This study was conducted in our neurosugical intensive care unit between March 2015 and June 2018 (Clinical trials reg. Nr: NCT02659878). We enrolled non-traumatic SAH patients without a history of cardiac disease, who were admitted within 48 hours from symptom onset. On admission we noted the severity of the haemorrhage (modified Fisher score) and neurological state (Hunt-Hess and WFNS scores) and transthoracic echocardiogram was performed. Patients with wall motion abnormality (WMA) were diagnosed as TTC, TTC patients with ejection fraction lower than 40% were classified as severe TTC (sTTC), patients without WMA served as control group (CG). Cardiac necroenzyme detection and transcranial colour duplex was performed on a daily basis. Each patient went through follow-up echocardiograms. We evaluated Glasgow Outcome Scale (GOS) and Barthel Scale (BS) 30 days and 6 months after the onset of SAH.
RESULTS. During the study period 136 patients fulfilled inclusion criteria. Incidence of TTC was 28,7% (n=39), sTTC was found in 8,1% (n=11) of the cases. TTC was more common among females than males (female/male: CG 50/47 vs. TTC 30/9, p=0,007). Higher modified Fisher score was more frequent in the TTC group (modified Fisher>2: TTC 32/39 vs. CG 54/97; p=0,004). Higher Hunt-Hess (H-H>3: sTTC 8/11 vs. CG 29/97; p=0,012) and WFNS-score (WFNS>3: sTTC 9/11 vs. CG 29/97; p=0,002) was characteristic for sTTC. Serious vasospasm had higher incidence in the sTTC group (sTTC 3/11 vs. CG 5/97; p=0,04). We found significantly elevated cTnT and NT-proBNP levels in TTC patients. On 1 and 6 month follow-up sTTC was related to increased mortality (sTTC vs. CG: 7/11 vs. 15/95, p<0,001; 8/11 vs. 24/93, p=0,004) and lower GOS score (GOS<4: sTTC vs. CG 11/11 vs 44/95, p=0,002; 9/11 vs. 32/93, p=0,007). At 30th day lower quality of life was observed in the sTTC group (BS<50: sTTC 4/4 vs. CG 23/79, p=0,016).
CONCLUSION. TTC is a common cardiac complication of SAH, especially in serious SAH with severe neurological symptoms. cTnT and NT-proBNP properly signs the presence of TTC. The harmful effect of TTC on cerebral circulation may contribute to increased mortality and disability.

INTRODUCTION. Spontaneous subarachnoid haemorrhage (SAH) is frequently a devastating type of acute cerebral bleeding which, despite continuous improvements in treatment and care, often remains a disease with high mortality and poor functional outcome.
OBJECTIVES. To understand and map all contributing factors regarding epidemiology, treatment with outcome in patients with both aneurysmal SAH (aSAH) and non-aneurysmal SAH (non-aSAH).

METHODS. This retrospective cohort study was carried out in a tertiary university hospital. Data regarding demographics, Intensive Care Unit (ICU) stay and functional outcome were collected for all patients during a period of eleven years (2007-2017). Univariate logistic regression was carried out in order to assess the influence of each variable on the occurrence of vasospasm/delayed cerebral ischaemia, the ICU and hospital survival. Univariate multinominal logistic regression was used for the analysis on the modified Rankin Scale (mRS), a functional outcome scale taken five to eight months after SAH.
RESULTS. A total of 498 SAH patients were identified, of which 421 were diagnosed with aSAH. Female gender, being an active smoking, problematic alcohol use and hypertension are all more prevalent in aSAH patients than in non-aSAH patients. 65.1% of aSAH and 23% of non-aSAH patients had polyuria, which was significantly associated with vasospasm. 24.5% of aSAH and 5.3% of non-aSAH patients experienced vasospasm, which was significantly related to poorer outcome. Most aSAH patients (88.8%) were treated with coiling, versus only 5.5% who were clipped. Epileptic insults occurred in 12.3% of aSAH opposed to 2.3% in non-aSAH patients. Infections occurred in 50.1% of aSAH, and 20% of non-aSAH patients. Location of the aneurysm at the posterior communicating artery, and hyponatraemia (Na<135 mmol/L) during ICU stay were associated with a better ICU and hospital outcome. Hypernatraemia (Na>150mmol/L) and increased lactate levels (at admission, at 48 hours) were associated with poor outcome. The hospital mortality of 133 patients (26.7%) presenting with poor grade SAH (Hunt & Hess scale 4-5) was 38.3%. Overall mortality was 15.5%. Hospital survival decreased substantially in patients over 80 years. Most aSAH patients (68.3%) had a good functional outcome (mRS 0-2).
CONCLUSION. Patients with SAH still have a substantial mortality and often a poor functional outcome. aSAH and non-aSAH patients demonstrated distinct characteristics in epidemiology and outcome. Analysis identified multiple variables which were associated with vasospasm, ICU and hospital survival and functional outcome.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000323

INTRODUCTION. The serum lactate level is a useful predictor of mortality in critically ill patients. However, little is known about the association between the serum lactate level and mortality in patients admitted to neuro-intensive care units (NCUs).
OBJECTIVES. The present study aimed to investigate the association between the initial lactate level and 90-day mortality in NCU patients.
METHODS. This retrospective observational study was conducted by reviewing the medical records of adult (age ≥18 years) patients admitted to the NCU at a single tertiary care academic hospital during 2013–2017. The initial lactate level (mmol L-1) was defined as the serum lactate level measured within 6 hours following NCU admission.
RESULTS. The final analysis included 2,737 patients, of whom 280 (10.2%) died within 90 days of NCU admission. In a receiver operating characteristic (ROC) analysis, the estimated area under the curve (AUC) for the initial lactate level in predicting overall 90-day mortality was 0.55 [95% confidence interval (CI): 0.52–0.59]. The corresponding values for neurologic and non-neurologic disease-related 90-day mortality were 0.76 (95% CI: 0.71–0.82) and 0.49 (95% CI: 0.45–0.53), respectively. In a multivariable Cox regression analysis, a 1-mmol L-1 increase in the initial lactate level was associated with 1.17- and 1.22-fold increases in overall and neurologic disease-related 90-day mortality, respectively, but not with non-neurological disease-related 90-day mortality (*P*=0.422).
CONCLUSION. Elevated lactate levels were related with an increase in overall 90-day mortality among NCU patients. This association was specifically attributed to neurologic disease-related 90-day mortality.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000329

INTRODUCTION. The optic nerve sheath diameter (ONSD) is considered an indirect marker for intracranial pressure (ICP). Many studies investigated the normal range of ONSD, the cut-off for increased ICP and what can affect these values including age and sex. However, questions remain about the differences of ONSD versus age and sex, among healthy and brain injured population.
OBJECTIVES. The aim of this study is to investigate the values of ultrasonographic ONSD in healthy volunteers of different sex and age and to assess whether there are differences in sex and age in a cohort of brain injured patients.
METHODS. We prospectively recruited 122 healthy volunteers undergoing pre-assessment evaluation and compared age/sex dependence of ONSD to 95 patients aged >18 years old with severe traumatic brain injury (TBI) requiring intubation and invasive ICP monitoring. The two groups were stratified for sex and age. Age was divided into 3 subgroups (18-44 years; 45-64 years; >65 years).
RESULTS. In healthy volunteers, ONSD was significantly different between males and females (mean ONSD 4.26 vs 4.00 mm, [p = 0.01]). ONSD showed a statistically significant correlation with age (R=0.50, p <0.0001). In TBI patients, no differences in ONSD were found for sex and the correlation between age and ONSD was non-significant (R=0.13 p = 0.20).
CONCLUSION. ONSD correlates with age and is significantly different between males and females in healthy volunteers. However, these findings do not persist in TBI patients.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000359

INTRODUCTION. The incidence of delirium in the ICU ranges from 45% to 87%. Several scales are used to assess the presence of delirium among which two are most widely used – Confusion Assessment Method-ICU (CAM-ICU) and Intensive Care Delirium Screening Checklist (ICDSC).
OBJECTIVES. To assess the frequency of manifestation and severity of agitation/sedation in patients with strokes with speech and without speech disorders; estimate the frequency of occurrence of delirium and its types.
METHODS. We conducted an observational study of 80 patients admitted to the stroke unit. In the first 24-48 hours from the moment of arrival, the presence of delirium was evaluated on the ICDSC scale. The degree of depression of consciousness was assessed according to the CGS and FOUR scales. The degree of agitation/sedation was assessed according to the RASS scale. The patients were divided into 2 groups - the 1st group (34 cases) of patients who had speech disorders in the form of total aphasia or motor/sensory aphasia and the 2nd group - patients without speech disorders (46 cases).
RESULTS. The degree of depression of consciousness from CGS and FOUR, the degree of sedation / arousal on the RASS scale are presented in Table.
In 1 group agitation (RASS +1 and more) was observed in 20 (59%) patients, in 2 group agitation was observed in 13 (28%) patients. We noted a statistically significant ($\varphi = 2.768$, $p \leq 0.01$) increasing in the frequency of occurrence of agitation in 1group assessed by the RASS scale and a statistically significant decreasing in the level of consciousness which was evaluated by the CGS scale. A more pronounced degree of depression of consciousness in patients when evaluated on the CGS scale compared to assessing the level of consciousness in them on the FOUR scale can be explained by the presence of verbal contact in the CGS scale, which is absent in the FOUR scale. In 2 group, where it was possible to assess the presence of delirium on the ICDSC scale, subsyndromal delirium was detected in 18 (40%) patients, delirium was diagnosed in 13 (29%) patients. At the same time, hyperactive delirium was diagnosed in 6 (14%) patients, in 7 (15%) - mixed delirium. Hypoactive delirium in patients was not observed by us.
CONCLUSION. The presence of speech disorders is the significant factor complicating the assessment of presence of delirium in patients with stroke. A statistically significant increase in the level of agitation in the assessment on the RASS scale in patients with speech disorders can be regarded as manifestations of delirium in patients of this group based on the frequency of delirium in patients of 2 group with agitation.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000368

INTRODUCTION. Age is not an exclusion criterion for thrombectomy (TRB) in acute ischemic stroke (AIS).
OBJECTIVES. To compare six-month mortalities and neurological statuses of AIS patients of different ages treated with TRB.
METHODS. Retrospective study (October 2013–July 2017) including AIS patients treated with TRB admitted to our ICU. Patients were divided in three groups based on age: group A (<65 years); group B (65-79 years) and group C (≥ 80 years). Complete reperfusion was defined by a IIb/III punctuation in the modified treatment in cerebral infarction score (mTICI). A difference ≥ 4 points between initial and before discharge National Institutes of Health Stroke Scale (NIHSS) scores was considered as favorable in-hospital neurological evolution. A modified Rankin Scale (mRS) score between 0–2 at six months was acknowledged as good neurological status. Univariate analysis: X2 or Fishers test (categorical) and Kruskall-Wallis (numerical). Multivariate analysis: logistic regression.
RESULTS. One hundred and sixty-five patients were included: 64 in group A; 66 in B and 35 in C. We found no differences in the prevalence of previous ischemic/hemorrhagic stroke, initial NIHSS, basilar artery involvement or initial CT findings evaluated by the Alberta Stroke Program Early CT Score (ASPECTS). Patients ≥ 65 years had more comorbidities [A: 2 (1-3) vs. B and C: 2 (2-3); $p < 0.05$] and higher APACHE II scores [A: 9 (7-12) vs. B and C: 13 (11-17); $p < 0.001$].
Regarding treatment characteristics and patient's evolution, the main reason for TRB across groups was thrombolysis failure and stent retriever was the most used technique. The interval symptom onset to reperfusion (min) was similar between groups [A: 285 (241 – 382) vs. B: 305 (252 – 355) vs. C: 313 (270 – 360); NS] as was the rate of complete reperfusion [A: 43 (78.2%) vs. B: 53 (82.2%) vs. C: 21 (63.6%)]. Even though no statistical differences were found, patients in group C had a longer AIS duration and a lower reperfusion rate. TRB was not feasible due to anatomical difficulties in seven patients (20%) in group C as compared to 1 (1.6%) and 2 (3%) patients in groups A and B. Forty-four patients (75.9%) in group A, 39 (72.2%) in B and 18 (64.3%) in C achieved a favorable neurological in-hospital evolution (NIHSS ≥ 4; NS).
When looking at 6-month mortality, after adjusting by confounding factors (number of comorbidities, APACHE II, initial NIHSS, basilar artery involvement, initial ASPECTS, interval symptom onset to reperfusion, TRB complications, hemorrhagic transformation, use of vasoactive drugs and mTICI < IIb), only patients below 65 years had a higher probability of survival [OR 0.04 (IC95 0.00 – 0.77); $p = 0.03$]. No differences were found when studying mRS (0-2) at six-months [group A: OR 0.24 (IC95 0.04 – 1.32); $p = 0.10$ and group B: OR 0.57 (IC95 0.11 – 2.80); $p = 0.49$. Reference category: Group C].
CONCLUSION. In our series, patients below 65 years of age with an AIS treated with TRB had better chances of six-month survival when compared to elder patients, but no differences in neurological outcomes at six-months were demonstrated. We believe age should be taken into account when TRB is being considered as part of the treatment for AIS.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000377

INTRODUCTION. Intensive Care Unit Acquired Weakness (ICUAW) is a common complication affecting peripheral nerves and muscles resulting in severe immobility and prolonged intensive care treatment with increased mortality [1]. Limited data are available for a possible impairment of the enteric nervous system in this

generalized neuromuscular dysfunction. Furthermore, the relevance of ICUAW for gastrointestinal dysmotility and impaired enteral nutrition was not studied before.
OBJECTIVES. We investigated gastrointestinal function and nutritional status in patients with and without ICUAW.
METHODS. In this retrospective analysis, we included critically ill patients (main inclusion criterion: SOFA-Score ≥ 8 for three consecutive days after intensive care unit (ICU) admission; main exclusion criteria: pre-existing neuromuscular disease or gastrointestinal dysfunction, present abdominal surgery) on two perioperative ICUs. The Medical Research Council-Sum Score (MRC-ss) was used to diagnose ICUAW (MRC-ss < 48 points) [2]. Within a 14-day observational period the following parameters for gastrointestinal function and nutritional status were collected: gastric residual volume (GRV), administered doses of laxatives, defecation frequency and days with enteral tube feeding.
RESULTS. Thirty patients were enrolled for an analysis. ICUAW was diagnosed in 14 patients (mean age 68.17 ± 11.3 years; APACHE-II 26.1 ± 3.5), 16 patients were ICUAW negative (mean age 59.75 ± 15.5 years, p=0.19; APACHE-II 22.9 ± 6.2, p=0.09). Patients with ICUAW were significantly longer sedated and mechanically ventilated. The mean cumulative GRV was higher in patients with ICUAW (1797.9 ± 1896.9 ml/patient vs. 835.9 ± 1101.2 ml/patient, p=0.058). Patients with ICUAW needed higher cumulative doses of laxatives (lactulose: 103.4 ± 41.3 g vs. 69.2 ± 57.2 g, p=0.07; sodium picosulfate: 60 ± 16.4 mg vs. 34.7 ± 28.3 mg, p=0.013; suppositories: 29 vs. 9, p=0.009) and the cumulative time of administration was longer (lactulose: 123 vs. 91 days, p<0.001; sodium picosulfate: 112 vs. 75 days, p<0.001). Patients with ICUAW were more frequently depended on enteral tube feeding after extubation (cumulative: 79/103 days [76.7%] vs. 42/172 days [24.4%], p<0.001) and after 14 days (11/14 [78.6%] ICUAW positive patients vs. 3/16 [18.8%] ICUAW negative patients, p<0.01). The cumulative defecation frequency was similar between both groups (87/195 days [44.6%] vs. 86/222 days [38.7%], p=0.26).
CONCLUSION. Gastrointestinal dysmotility was more frequent in critically ill patients with ICUAW and might result from an impairment of the enteric nervous system. Prolonged dependency of enteral tube feeding might point to a higher risk of nutritional impairment in patients with ICUAW, which should be further investigated.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000378

INTRODUCTION. Sedation is a first-line therapy used in intensive care unit (ICU) to control raised intracranial pressure in severe traumatic brain injury (TBI) patients. However, it remains unclear what the effect of different sedative drugs is on outcome. This analysis of the CENTER-TBI study uses comparative effectiveness research to fill this knowledge gap.
METHODS. The CENTER-TBI study (clinicaltrials.gov registration NCT02210221) is a prospective observational longitudinal cohort study including patients with TBI from 65 centers across Europe. Data were extracted from the CENTER-TBI database v1.1 with Neurobot v2.6. We included all patient who were admitted to the ICU with ICP monitoring and who had more than one day of mechanical ventilation. For every patient, the primary sedative (the sedative that the patient received most of the days) was selected. We focused on midazolam and propofol, since these were the most frequently used.
RESULTS. 4509 patients were included in the CENTER-TBI study: we selected 611 patients who received propofol, and 451 patients who received midazolam. There was a large variation between centers in choice of sedative drugs and length of sedation. The length of ICU stay was 0.84 time shorter (95% CI: 0.81 - 0.87) before adjustment, and 0.83 (95% CI: 0.80 - 0.86) after adjustment for major confounders compared to midazolam. Total adjusted hospital length of stay was similarly 0.97 time shorter (95% CI: 0.95 - 1.00) for propofol versus midazolam patients. The OR of propofol for a better functional outcome was 1.10 (95% CI: 0.83 - 1.45) before adjustment, and 0.93 (95% CI: 0.69 - 1.26) after adjustment.
CONCLUSION. There is large variation in length of sedation and choice of sedative drugs among European neurotrauma centers. Propofol is associated with a shorter ICU and hospital length of stay but similar functional outcome as midazolam.

Measurement of the diameter of the optic nerve sheath by Axial Tomography an Ocular Ultrasound: Non-Invasive evaluation of intracranial pressure

MJ. Dominguez Rivas[1], J. Navarro[2], ML. Carmona[1], S. Fernández[1], A. Casas[1], I. Valiente Aleman[1]
[1]Medicina intensiva, University Hospital of Puerto Real, Puerto Real, Spain; [2]Radiology, University Hospital of Puerto Real, Puerto Real, Spain
Correspondence: MJ. Dominguez Rivas
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000408

INTRODUCTION. Measurement of optic nerve sheath (ONSD) using ocular sonography is an accurate, non-invasive technique for the detection of intracranial hypertension (> 20 mmHg) in a heterogeneous group of patients with acute brain injury when performed by an experienced operator. ONSD ≥0.48 cm has the greatest accuracy. In the same way the Axial Tomography proves to be a good technique for demostrate intracranial hypertension with the increase ONSD. At present, these techniques are increasingly used in neurocritical patients.
OBJECTIVES. To determine the values of the diameter of the optic nerve sheath (ONSD) by computerized tomography (CT) and ocular ultrasound (OU), in neurocritical patients admitted to a polyvalent ICU without neurosurgery. ONSD values of intracranial hypertension are considered by CT> 5mm and by OU> 4.8mm (measured both at 3mm from the posterior wall of the eyeball).
METHODS. Cross-sectional prospective study from January 2017 to December 2018, in patients admitted consecutively with neurological pathologies, performing measurements of the ONSD by CT (SIEMENS, WW 2; WL 98; thickness of the cut 2mm) to 3mm of the posterior wall of the eyeball, and measurements of ONSD by OU (ESAOTE ultrasound, linear probe 7.5MHz) to 3mm of the posterior wall of the eyeball. Epidemiological variables are studied, and ONSD (bilateral) measurements are compared by both CT and OU. Statistical study with IBM SPSS statistics 20.0, determination of the T-Student for independent samples and Pearson correlation.
RESULTS. A total of 70 patients with a mean age of 65.23 years (35-86), males 45 (64.28%) were collected. Causes of admission: hemorrhagic stroke-17 (24,28%) Ischemic stroke-22 (31,42%) postanoxic encephalopathy-9 (12,86%) Meningitis-12 (17,14%) and Others-10 (14,28%). Mean initial GCS: 6,66 (3-13). They required mechanical ventilation: 44 (62,85%), APACHE II medium: 19,85 ± 7,14 (8-35). Deaths: 25 (35,71%).

CONCLUSION.

- In our patients there are no statistically significant differences when measuring ONSD by CT and by OU.
- There is a very good correlation in ONSD measurements by CT and OU (the correlation is significant at the bilateral 0.01 level) and they are good methods, to evaluate intracranial hypertension non-invasively.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000419

INTRODUCTION. Patients with aneurysmal subarachnoid hemorrhage (aSAH) frequently display elevated cardiac troponin-I (cTnI), often with cardiac transient regional wall motion abnormalities, both of which often resolve in the days after bleed. However, the peak level of cTnI associated with poor functional outcomes is not explicated.
OBJECTIVES. To evaluate the cut-point value of peak cTnI associated with poor functional outcomes as measured by the modified Rankin Score (mRS) at hospital discharge, and at 3 and 12 months after aSAH.
METHODS. We recruited 175 aSAH patients (inclusion: ages 21-75 years, Fisher grade >1; exclusions: chronic neurological deficit, history of myocardial infarction). Serum cTnI was measured daily, and the patients peak value from days 1-3 used in the analysis. mRS was obtained by trained study staff at hospital discharge by chart review, and at 3 and 12 months by interview, and dichotomized as good (scores 0-3) and poor (scores 4-6). Descriptive statistics were obtained, and the cTnI cut-point value associated with poor outcomes at the 3 time points estimated using Receiver Operating Characteristic Curve where the optimal cut-point maximized the sum of sensitivity and specificity for all possible values of the cut point.
RESULTS. The sample of 175 patients was primarily female (72%), with a mean age of 53 years (SD 11), and Hunt and Hess grade mean 2.9 (SD 0.7). As shown in Table 1, mean values of cTnI for patients with poor outcome were generally greater that 1.0 ng/ml (poor outcome pateints cTnI means of 1.78, 1.19 and 1.27ng/ml at discharge, 3 and 12 months respectively). Standard deviations were large, while median values for cTnI for patients with poor outcome were 0, 0.17 and 0.31 at discharge, 3 and 12 months. Cuttpoint values of cTnI associated with poor outcome were quite low, with poor to moderate sensitivity but good specificity (discharge cTnI cutpoint 0.33ng/ml, sensitivity 0.343, specificity 0.922; 3 month cTnI threshhold 0.28ng/ml, sensitivity 0.455, specificity 0.810; 12 month cTnI threshhold 0.28ng/ml, sensitivity 0.523, specificity 0.802). Of note, sensitivity of cTnI threshhold values associated with poor outcome improved slightly as time from injury lengthened.
CONCLUSION. All patients with a cTnI above 0.28ng/ml during days 1-3 after aSAH have a greater propensity towards poorer outcomes, but sensitivity for prognostic purposes is low.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000465

INTRODUCTION. Anticoagulation and antiplatelet medications are beneficial in the treatment/prevention of a range of conditions. An estimated 1-2% of the UK population is therapeutically anticoagulated. Recent evidence has demonstrated superiority of direct oral anticoagulant drugs (DOACs) over warfarin and there has been a sharp increase in the use of these medications. This is not without risk and European guidelines recommend a bleeding risk assessment (e.g. HAS-BLED score). It is estimated that DOACs will account for 5% of the NHS drug budget in 2020. This means that it is highly relevant to evaluate real-world data focussing on adverse events associated with these drugs, particularly intracranial haemorrhage. There have also been recent updates to evidence and guidance regarding aspirin, making it relevant to compare events in patients taking antiplatelet drugs.
OBJECTIVES. To assess prior anticoagulant or antiplatelet medication use in patients admitted with haemorrhagic stroke in a neurosciences critical care unit.
METHODS. Retrospective search of the local critical care admissions database covering the period April 2017 to March 2019. Patients admitted with diagnosis codes “Intracerebral haemorrhage" ("supratentorial" or "posterior fossa") were included. Subarachnoid haemorrhage and traumatic injury were excluded. Of the 178 records, 69 were excluded for secondary causes of bleeding or duplicate entries, resulting in 109 patients included in the analysis.
RESULTS. 26/109 (24%) of identified patients were on anticoagulant or antiplatelet therapy prior to admission. Of these, 14 (13%) were anticoagulated (7 DOAC, 6 warfarin, 1 heparin) and 14 (13%) were on an antiplatelet drug (11 aspirin [1 also on ticagrelor], 3 clopidogrel). 2 patients were on combination anticoagulation/antiplatelet therapy.

Indications for anticoagulation included atrial fibrillation (AF), venous thromboembolism (VTE) and metallic heart valve. Indications for antiplatelet therapy included coronary artery disease, stroke or transient ischaemic attack (TIA). 2 patients on aspirin had no clear indication to be on antiplatelet therapy. Mortality was 46% and not significantly different between patients on anticoagulant/antiplatelet therapy and those who were not (p=0.38), or between patients on aspirin versus DOAC (p=1.0).

CONCLUSION. A quarter of patients admitted to our ICU with haemorrhagic stroke were taking anticoagulant or antiplatelet medications. Mortality was high and not significantly different between patient groups. Aspirin use was more frequent than DOACs. This is perhaps surprising given that DOACs confer a higher intracranial bleeding risk, and recent trends of increasing DOAC use. One explanation is that patients on aspirin also have comorbidities that put them at particularly high risk of haemorrhagic stroke, and the likelihood that aspirin is still more frequently prescribed (for a variety of indications) than DOACs. Two patients on aspirin had no clear reason to be taking it. This highlights the importance of balancing risks and benefits, particularly with aspirin, which has been shown not to be of benefit in the primary prevention of cardiovascular disease, or for stroke prevention in AF. As use of DOACs increases, and specific reversal agents become more readily available, it will be interesting to observe for potential changes in rates and patterns of haemorrhagic stroke.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000538

INTRODUCTION. Transcranial Doppler (TCD) offers a view of brain hemodynamics through the measurements of Flow Velocities (FV) on cerebral arteries and vein system and the assessment of advanced parameters such as autoregulation, compliance and intracranial pressure. These parameters may vary with age and sex. Nowadays few studies describe normal ranges of flow velocities between different gender and ages especially involving the poorly explored venous compartment and the coupling between venous and arterial compartment.

OBJECTIVES. The aim of this study is to determine the normal range and coupling of flow velocities in the Straight Sinus and in the Middle Cerebral Artery according to sex and age.

METHODS. We prospectively recruited 122 healthy volunteers undergoing pre-assessment evaluation and 95 patients aged >18 years old with severe traumatic brain injury (TBI) requiring intubation and invasive ICP monitoring. The two groups were stratified for sex and age. Age was divided into 3 subgroups (18-44 years; 45-64 years; >65 years). Coupling between arterial and venous flow was assessed within different age groups and sex and between the two cohorts.

RESULTS. We found a significant correlation between arterial and venous systolic flows (FVs vs FVVs) in the whole population (R= 0.3953745; p-value < 0.0001) as well as in the females and males subgroups, suggesting the presence of physiologic coupling between arterial and venous flow in healthy volunteers. This correlation was significant even considering the effect of age. In TBI patients, no correlation between FVs and FVVs was found.

CONCLUSION. Arterial-venous coupling can be studied using TCD. This coupling is lost in TBI patients, maybe for the compression of the sinuses in high ICP and decoupling of flow from metabolism in the injured brain. Venous TCD could open new scenarios in the comprehension of brain physiopatology.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000218

INTRODUCTION. Primary percutaneous coronary intervention (pPCI) is the ideal method of reperfusion for acute STEMI. Although, in some areas it is very difficult to implement pPCI between two hours, and it is well-known that 'Time is myocardium'.

OBJECTIVES. To analyze the safety and efficacy of the pharmacoinvasive therapy protocol in a setting without primary percutaneous coronary intervention (PCI), Campo de Gibraltar (CG) area.

METHODS. Multicentre observational prospective study of consecutive patients with STEMI treated with fibrinolysis in the CG area and transferred to our intensive care unit for coronarography and PCI between January 1, 2012 and March 31, 2018, included in the ARIAM ANDALUCIA registry. We considered as effective fibrinolysis (EfFx) those with post-treatment TIMI 3 flow grade and early fibrinolysis (EarlyFx)those given in the first 3 hours from symptom onset.

Haemorrhagic complications were evaluated according to the Bleeding Academic Research Consortium classification.
RESULTS. 437 patients were included, mean age (sd) 59.79 (11.89), 242 were inferior STEMI and 194 anterior STEMI. Culprit arthery : none 44, RCA 192, DCA 163 and CXA 38.Distribution (n) of Killip grades I, II, III and IV were 383, 10, 13 and 31 respectively. Mean GRACE (sd) was 149.59(33.49)
80.3% of fibrinolysis treatments were given early and 79.4% in hospital, with a median symptoms-to-needle time of 95 minutes. TIMI 3 was achieved in 79.17% of the cases. 264 coronarographies were performed in the first 24 hours (76 rescue-PCI) and 188 in 48-72 horus. PCI were effective in 382 (87.8%) cases. In 48 (11 %) was not performed because of MINOCA, and 0.9% failed. . EfFx was associated with EarlyFx (p<0.001). Complication rates were 1.83% PCI-related and 2.28% haemorrhagic.
Procedural mortality was 2.3%, and mortality at 30 days was 3.1%.
CONCLUSION. The efficacy of both prehospital and in-hospital fibrinolysis in CG health services was related to its early administration. The Hemodynamics unit in the Puerto Real University Hospital ensured the success of the procedure. Pharmocoinvasive therapy with fibrinolysis and PCI has demonstrated to be a safe and effective alternative to primary PCI for CG patients unable to achieve a symptoms-to-ballon time lesser than 180 minutes.

INTRODUCTION. Left ventricle (LV) global longitudinal peak systolic strain (GLS) and peak systolic strain rate (SSR) are validated speckle tracking echocardiography indices of systolic function. They have been shown to be affected by loading conditions in cardiac and critically ill patients. Nevertheless, we made the hypothesis that patients with and without preload responsiveness behave differently due to the effects of the Starling law. In patients with preload responsiveness, indices of systolic function should increase because the stretching of the LV fibers with fluid loading enhances their shortening. This should not occur in preload unresponsive patients.
METHODS. We included septic shock patients undergoing a passive leg raising (PLR) test for clinical purposes. GLS and SSR were assessed before and during the PLR test and compared. The LV GLS and SSR were calculated as the average of the value obtained in the 4-chamber view and the value obtained in the 2-chamber and/or the 3-chamber view. Preload responsiveness was defined by a PLR-induced increase in cardiac output ≥10%.
RESULTS. We performed 24 measurements in 15 patients (SAPSII at admission = 46±13, SOFA at inclusion = 10±3, pneumonia in 67% of cases). PLR revealed 8 preload responder cases (R) and 16 preload non-responder cases (NR). In both groups, LV end-diastolic volume increased significantly during PLR (from 67 [57;85] to 75 [67;92] mL in R and from 62 [56;87] to 73 [67;92] mL in NR). During PLR, cardiac output increased by 21±9% in R and by 5±3% in NR. In R, GLS improved from -12.1 [-11.3;-16.4] to -13.7 [-12.1;-18.9]% (p=0.02). Similarly, SSR rose from -1.1 [-0.9;-1.2] to -1.2 [-1.1;-1.3] 1/s (p=0.03). In NR, GLS and SSR did not change significantly (p=0.30 and p=0.50, respectively).
CONCLUSION. The preliminary data of this ongoing study show that GLS and SSR depend on LV preload only in R. This suggests that they increase as a result of the Starling law.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000039

INTRODUCTION. Poor quality end-of-life(EOL) care is associated with psychological distress among dying patients and their families,and this has been contributed by the inadequacies in physician education and training.We therefore attempted to determine the competency levels of Anaesthesiology trainees,who manage surgical intensive care patients.
METHODS. A self-rated questionaire modified from Weissman[1] was used to evaluate the competency of physicians in managing 1)patient-family interactions,2)EOL patient care issues and 3)terminal discharge procedures was administered to all Anaesthesiology senior residents.
RESULTS. 34/51(67%) trainees responded to the survey with their baseline demographics in table 1.The comfort level of trainees on patient-family and physician-physican interactions and their proficiencies in EOL care issues are found in Figures 1 and 2.Trainees were generally comfortable discussing all aspects of treatment withdrawal with family over areas ranging from ventilation,transfusions,-feeding,RRT to vasopressor.
In decisions made by the medical team for a terminally-ill DNR(do-not-resuscitate) patient with no decision-making capacity,the trainees felt that the withdrawal of feeding/hydration was associated with violation of ethical and/or personal beliefs.In contrast,trainees had less issues when these decisions were made by the surrogate decision maker.
CONCLUSION. While our trainees are comfortable in basic EOL care,-most discomfort arises from conflicts management with other team members,families or personal values and beliefs.This could be as our current training system focuses largely on active management but does not prepare the trainee on how to transition to palliative care.This survey helps to identify the gaps in our training system and can help us to improve it.

The use of Vasopressors and Opioids in patients admitted to Intensive Care post-op Elective Gynaecological surgery

W. Saghir, M. White, R. Lewis
Anaesthetics & intensive care, Ipswich Hospital NHS Trust, Ipswich, United Kingdom
Correspondence: W. Saghir
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001276

INTRODUCTION. Opioid analgesics are commonly added to intrathecal bupivacaine to improve patient comfort during and after elective gynaecological procedures. The National Institute for Clinical Excellence (NICE) recommends diamorphine 0.3–0.4 mg for analgesia after elective Caesarean section in preference to morphine. Risk factors for development of respiratory depression include long-acting sedatives, known respiratory disease, increasing age and positive-

pressure ventilation. In addition to this the incidence of nausea, vomiting and pruritus is proportional to the dose of diamorphine used.

OBJECTIVES. We sought to discover if the quantity of opioid added to the spinal for elective gynaecological surgery influenced post-op respiratory function and requirement for vasopressors on intensive care.

METHODS. A retrospective cohort approach was used. The anaesthetic documentation of all patients admitted to intensive care post op gynaecological surgery over six and a half months was examined. Eighteen patients met the inclusion criteria. The age ranged from 43 – 91 years old. The average age was 71 years.

RESULTS. There were 94% planned admissions and 6% were unplanned. Sixty-seven percent of patients had had a Total Abdominal Hysterectomy + Bilateral Salpingo-oophorectomy. Seventeen percent of surgeries were complex involving the input of other specialties. ASA ranged from 2-4. Sixty-one percent of patients had both a general anaesthetic (GA) and spinal. Seventeen percent had GA only whereas 11% had GA and epidural. Of the anaesthetic charts that were available, Diamorphine was used in the spinals of 69% of patients. Doses ranged from 100 mcg – 1mg with an average dose of 780mcg. In 44% of patients, an additional opioid was used intraoperatively.

The CO2 on admission to intensive care was raised in 39% of patients. Metaraminol was required in 22% of patients. One patient required CPR immediately post-op. Average length of stay was 1 day.

CONCLUSION. There was a positive correlation between the dose of intrathecal diamorphine used and post-op CO2 on admission to intensive care. There was no correlation between intrathecal diamorphine dose and need for vasopressors on admission.

Correspondence: J. Colomina Climent
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001459

INTRODUCTION. Anemia is often found among patients undergoing cardiac surgery and it is associated with an increased risk of perioperative complications [1]. The most frequent cause of anemia is iron deficiency (ID), and it may have a role in transfusions requirements and clinical outcomes in these patients [2].

OBJECTIVES. To analyze the prevalence of preoperative iron deficiency in cardiac surgery patients, its association with preoperative anemia and packed red blood cells transfusions.

METHODS. Retrospective, observational, cohort study in which all adult patients undergoing elective or urgent cardiac surgery at Son Espases University Hospital were included from April to November 2018.

Anemia was defined as a hemoglobin (Hb) <12/13 g/dL (women/men) and iron deficiency as ferritin <30 µg/L or ferritin <100 µg/L + Transferrin saturation index (TSI) <20%.

Preoperative clinical variables, transfusions performed, hospital length of stay and global mortality were analyzed. Patients without preoperative iron profile study were excluded.

Quantitative variables are expressed as mean ± standard deviation (SD) and the Student's t-test was used to compare them. Those that do not follow a normal distribution, are expressed as median and interquartile range (IQR) and were compared using the Mann-Whitney U test. The qualitative variables were expressed as absolute value and percentage (%) and analyzed with Fisher's exact test. To asses the transfusion requirements, patients were stratified according to the presence or not of preoperative anemia.

RESULTS. From the initial sample of 231 patients, 48 were excluded. The most relevant baseline characteristics and clinical results are represented in **Table 1**. ID was present in 70 patients (30.3%), associated with anemia in 32 of them (45.7%) and without it, in 38 cases (54.35%). ID was more common in women and was associated with lower presurgical hemoglobin levels (p = 0.002). Preoperative ID anemia diagnosis was stablished only in 22 (9.5%) patients and 19 (8.2%) of them were treated previously with iron supplements. Patients with ID, stratified by preoperative anemia, received more packed red blood cells transfusions (p = 0.000) (**Figure 1**).

CONCLUSION. Preoperative ID is common in cardiac surgery patients, even in those without preoperative anemia. ID is associated with a greater amount of transfusions. Treating the ID could be a strategy to reduce preoperative anemia and the need of transfusions in this population.

Usage of psychotropic drug therapy in a polyvalent ICU: a retrospective study

L. Lopez, D. Díaz Diaz, M. Villanova, A. Martinez De La Gandara, T. Fariña, E. Palencia
Intensive care unit, Hospital Universitario Infanta Leonor, Madrid, Spain
Correspondence: L. Lopez
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**001588

INTRODUCTION. Acute brain dysfunction is very common in critical care patients, and may manifest as delirium, agitation, anxiety or coma. Other psychological conditions can develop in ICU patients: generalized anxiety, sleep disorders, alcohol/drug withdrawal syndromes, depressant symptoms, or previous psychiatric conditions among others. Because of it, the use of psychotropic drugs (PD) is common in ICU setting.
OBJECTIVES. To identify the different PDs used in a community hospital ICU. We analyze the use of different antipsychotics, BZDs, antidepressants and also alpha2 agonists. We did not include other sedative drugs.
METHODS. Retrospective study in a cohort of patients consecutively admitted to the ICU for more than 24 hours during 2018. We collected demographic data, reason for ICU admission, ICU LOS, CAM-ICU, mechanical ventilation (MV), use of the different PDs, duration of treatment (DOT) and the main indication.
RESULTS. Total of 325 patients (pts) were admitted in our ICU during 2018. PDs were used in 179 (55%). Average age was 65.3 years (SD 14.1), 53.6% were males. Mean (SD) ICU LOS 9.6 days (13.8). 80 patients (44.7%) had MV. CAM-ICU + in 43 patients (24%). Main results:

1. **Dexmedetomidine**: 23 pts (12,8%), alone or with more PD in 16 pts (72,8%). Mean (SD) DOT 3.7 days (3.3). CAM-ICU+ in 13 (59%). Mean (SD) dose: 0.40 (0.16) to 1.01 (0.42) mcg/kg/h. Indication: sedation (86.4%)
2. **Clonidine**: 11 pts (6.1%). Mean (SD) DOT 8.2 days (7.8). CAM-ICU+ in 7 (63%). Indication: withdrawal (36.4%), agitation/delirium (54.6%)
3. **Haloperidol:** 53 pts (29.6%). Mean (SD) daily dose. 5.1 (2.1) to 7.9 (4.4) mg
   Mean (SD) DOT 2.6 (2.4) days. CAM-ICU + in 34 (79.1%). Indication: agitation (82.7%)
4. **Quetiapine:** 59 pts (33%). Mean (SD) daily dose: 35.5 (35) to 83 (98) mg
   Mean (SD) DOT 6.9 days (8.6). CAM-ICU + in 37 pts (62.7%). Indication: Delirium (93%)
5. **Other antipsychotics:** 27 pts (15%). Tiapride 18 pts (10%), Olanzapine 5 pts (3%), Others 4 pts (2.5%). Indication: withdrawal 15 (58%), agitation/delirium 3 (8%). Mean (SD) DOT 2.7 (1.3)
6. **Benzodiazepines:** 116 pts (64.8%). Lorazepam 64 (36%), Clorazepate 21 (12%), Bromazepam 16 (9%), Diazepam 6 (3.5%), others 9 (4.5%). CAM ICU + in 43 pts (51.2%). Mean (SD) DOT 2 (1.8) days. Indication: hypnotic 65 (56%), anxiety 28 (24%), withdrawal 8 (7%), others 15 (13%)
7. **Antidepressants:** 35 pts (19.6%): Mirtazapine 17 (9.5%), Citalopram 5 (3%), Sertraline 5 (3%), others 8 (4.5%). Mean (SD) DOT 7.4 days (0.7). Indication: Usual medication 20 (57%), depression 9 (26%), hypnotic 6 (17%)

CONCLUSION. In our ICU DEX is used mainly for transition sedation. Delirium was usually treated with quetiapine and agitation with haloperidol. BZPs and antidepressants were also widely used, confirming the existence of a gap between Guidelines and the routine ICU clinical practice. Further investigations are required for the use of psychotropic drugs in the ICU.

INTRODUCTION. Management of pain in critical patients is one of the most important part of the treatment and it is necessary to improve it in order to get better prognosis.
OBJECTIVES. To describe the prevalence of pain, its quantification and the analgesic regimens in patients admitted to an Intensive Care Unit (ICU)
METHODS. Weekly registration of patients to an ICU over a month, type of admission, analgesic regimen and assessment of acute pain episodes through Visual Analog Scale (VAS), Behaviour Indicators of Pain, and Richmond Agitation Sedation Scale (RASS) as apropiate, as well as pharmacological and non-pharmacological interventions.
RESULTS. In a total of 92 patients, of which 62% of them were males, with an average age of 61.9 +-15.1 years, main causes of admission were: respiratory failure (50%), neurological disabilities (35.6%) and shock (10.9%).
Attending to severity, the average APACHE II was 16.13+-6.2 (2.31) and SOFA 5.6 +- 3.3. 61% of the patients were awaken and able to self-report pain and 39% of them were under sedation (25% had light sedation (RASS-2); 16,7% moderate (RASS-3); 25% deep (RASS-4) and 33% very deep (33%)). 70% of patients required Mechanical Ventilation (MV) (Invasive MV 78.5% and Non Invasive MV 21.5%) and 26.1% were tracheostomized. Attending to analgesic regimen: 98.9% had a established treatment: 53.3% of them had a fixed regimen plus adjuvant therapy during episodes of acute pain; 28.3% fixed regimen without adjuvant therapy; 17.4% were only prescribed in case of pain and 1.1% had no analgesic regimen. Acetaminophen was the most frequently prescribed analgesic (91.3%), followed by opiods (61%): (fentanyl 48.2%, morphine 42.9% and remifentanill 7.1%), metamizole (54.3%) and NSAIDs (3,3%).
Attending to pain: All of patients had at least one measurement of pain daily. There was also a explicit reference of that in 68% of nursery comments and in 76,1% of medical comments. 41% of patients did not show pain, 41,3% of them showed mild pain, and 19,6% registered relevant pain, being intense in 6% of them. 95% of these episodes were solved by adjuvant medication and 5% of them by other non pharmacological interventions. Regarding non pharmacological interventions: calm environment was detected in 85% of the registrations, adequate light in 96,7%, proper sound in 74% and pleasant termperature in 85%. Every patient had postural changes during the day (81,5% of them had more than five a day). Only 20,5% of patients were under physical therapy. Pain episodes were more frequent in patients with respiratory failure (30%) or shock (21%), specially in those without MV. Existence of tracheostomy did not imply more pain. Awaken and conscious patiens had higher risk of suffering pain episodes (RR 4). Physical therapy was related to more pain episodes, but it was not statistically significant. Environmental factors are not related to more pain episodes. Attending analgesic regimen, the one prescribed just in case of pain was related to more pain episodes (RR 2,4). Patients with higher risk of episodes of moderate or severe pain includes: those conscious and able to self-report pain, those with analgesic regimen conditioned to pain, those with more than 2 analgesic, those without MV and those not mobilized. This explanatory model shows a high discriminative power (AuROC 0.91, CI 0.84-0.97).
CONCLUSION. Pain monitoring and analgesic regimens are adequate, as well as mobilization of patients, with fewer episodes of severe pain. Physical therapy is not sufficient. Environmental factors are not

related to severe pain. Patients with higher risk of pain are those conscious and collaborative, with regimens conditioned to pain, without MV and not mobilized.

INTRODUCTION. Anemia is common in critically ill patients admitted to the intensive care unit (ICU). [1,2] The etiology is usually multifactorial, including a shortened red blood cell lifespan and impaired erythropoiesis. [3-5] Currently the most common therapy of anemia in ICU patients is red blood cell (RBC) transfusion which is known to be associated with adverse events. [6,7] Erythropoietin stimulating agents (ESA) could potentially reduce the need for RBC transfusion.
OBJECTIVES. The aim of this systematic review with meta-analysis is to summarize current evidence on the use of ESA in critically ill patients with anemia. Our primary outcomes are difference in RBC transfusion frequency and change in hemoglobin (Hb) concentration. Our secondary outcomes include adverse events, and mortality.
METHODS. A comphrensive literature search was performed in EMBASE, Cochrane and PubMed databases up to September 2018. We restricted inclusion to original studies with adult patients (>18 years of age) in which ESA were given as treatment for anemia of the critically ill. Case reports, case series, conference abstracts and literature studies were excluded. Articles were independently reviewed by two authors for inclusion and data extraction. A third author performed quality assessment for each outcome using the GRADE approach. [8] A random-effects model was used for the meta-analysis.
RESULTS. A total of 842 articles were identified of which 18 articles met the inclusion criteria for the qualitative synthesis. Eight of these studies were randomized clinical trials (RCT), with a total of 3387 patients. These studies were included in the meta-analysis. Comparing ESA versus control group, there was a small reduction in the proportion of patients who received one or more RBC transfusions (RR 0.88; CI 0.78-1.00, moderate certainty). The change in Hb concentration was trivial (mean difference -0.31 g/dL; CI -0.51 to - 0.05, high certainty). The number of serious adverse events (RR 1.02; 0.90-1.15, low certainty) and the overall short-term mortality were similar (RR 0.80; CI 0.61-1.05, low certainty). Subgroup analysis for trauma patients showed lower mortality rates in the ESA group (RR 0.49; CI 0.32-0.75, moderate certainty). If real, this advantage is not due to an increase in Hb since there is no reduction in RBC transfusions in the trauma population. The price of recombinant erythropoietin is around $0.0119 per unit. With an average of 40,000 units per dose, the price of one single dose is circa $450. [9]
CONCLUSION. Use of ESA resulted in a small reduction in proportion of patients transfused and a trivial increase in hemoglobin concentration. It is debatable whether these changes are clinically relevant. There was no overall difference in adverse events or mortality. Based on this meta-analysis and taking into account the cost of ESA there is insufficient evidence to recommend use of ESA as substitute for RBC transfusion in current standard treatment of anemia of the critically ill.

INTRODUCTION. The role of extravascular lung water (EVLW) measured by transpulmonary thermodilution (TPTD) in the management of critically ill patients remains a matter of debate. We performed a systematic review and meta-analysis of studies assessing the effects of elevated TPTD-estimated EVLW on mortality in critically ill patients with/without septic shock with/without acute respiratory distress syndrome (ARDS).
METHODS. MEDLINE, EMBASE and Cochrane Database were screened for original articles. Random effects meta-analyses estimated the

pooled relative risk of death associated with elevated EVLW, and the pooled area under the receiver operating characteristics curve (AUROC) of elevated EVLW as a predictor of mortality. Missing data were provided by the authors of the original studies.
RESULTS. Fifteen studies (1086 patients) were included. Elevated EVLW levels were associated with a pooled relative risk for mortality of 3.33 [2.21-5.03]. The pooled AUROC, estimated from 13 studies, was 0.84±0.04. The pooled sensitivity and specificity were 70[65-74]% and 69[65-73]%, respectively. Both the baseline and the maximal EVLW values were significantly different among survivors and non-survivors, as well as EVLW variation over time. Subgroup analyses comparing indexation of EVLW to actual vs. predicted body weight and specific populations of ARDS patients vs. other ones were consistent with primary analysis. According to the multivariable analysis performed in seven studies, the odds ratio of elevated EVLW for mortality ranged from 1.01 to 6.21.
CONCLUSION. The level of EVLW measured by TPTD and its changes over time are associated with mortality in critically ill patients, which may emphasize its clinical value.

Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000685

INTRODUCTION. Early mobility can improve patients' ability of activity and muscle strength, reduce duration of mechanical ventilation and improve patients' life quality after discharge,and the adverse events of early mobility were less than 1%.there is no uniform definition of early mobilization initiative time up to now which ranging from duration of mechanical ventilation less than 24 hours to more than one week of ICU admitted which hinder the widespread implementation of early mobilization in clinic.Therefore,Determine a initiative time to start early mobility is very important
OBJECTIVES. To evaluate the effects of different early mobilization initiative time on the intensive care unit(ICU) mechanical ventilated patients
METHODS. Chinese Biomedical Literature Database(CBM),Chinese Knowledge Infrastructure(CNKI),Wanfang Data,PubMed,Cochrane library,Web of Science,EMbase and other sources were carried out up to October,2018 about Randomized control trials(RCTs) examining the effects of early mobilization on ICU mechanical ventilated patients.Two investigators independently screened literature,extracted data and evaluated the risk of bias.Outcomes were incidence of ICU acquired weakness(ICU-AW),duration of mechanical ventilation and ICU length of stay.Network commands of mvmeta package in Stata 13.0 were used to perform statistical analyses
RESULTS. A total of fifteen RCTs involving 1,726 patients and eight kinds of initiative time to start early mobilization.The network meta-analysis showed that,on the incidence of ICU-AW,there were significant difference between early mobilization began on duration of mechanical ventilation≤24h,48h<duration of mechanical ventilation≤72h,72h<duration of mechanical ventilation≤96h compared with usual care,and no difference between other comparisons;The ranking results were,72h< duration of mechanical ventilation≤96h,duration of mechanical ventilation≤24h,48h<duration of mechanical ventilation≤72h,24h<duration of mechanical ventilation≤48h,usual care.On mechanical ventilation time,duration of mechanical ventilation≤24h,24h<duration of mechanical ventilation≤48h,48h<duration of mechanical ventilation≤72h,duration of mechanical ventilation>96h were all superior to ICU admitted>5 days and usual care,and no difference between other comparisons;The ranking results were,48h<duration of mechanical ventilation≤72h,duration of mechanical ventilation≤24h,24h<duration of mechanical ventilation≤48h,ICU admitted>7 days,duration of mechanical ventilation>96h,usual care,ICU admitted>5 days.And there were no difference between the 8 kinds of initiative time on decreasing ICU length of stay.
CONCLUSION. Based on the Network meta-analysis and ranking results,early mobilization start on duration of mechanical ventilation< 24h and 48h<duration of mechanical ventilation≤72h were superior to other time on improving the effects of ICU mechanical ventilated patients.

INTRODUCTION. High flow nasal cannula (HFNC) may be beneficial to patients in the pre-oxygenation and peri-intubation stages of orotracheal intubation by preventing hypoxemia. Despite a number of small randomized controlled trials (RCTs) examining this question, a comprehensive synthesis of the available data has not been conducted previously. Our objective was to conduct a systematic review and meta-analysis examining the role of HFNC in the peri-intubation period
METHODS. We performed a comprehensive search of relevant databases (MEDLINE, EMBASE and Web of Science) screening for randomized control trials that compared HFNC oxygen to any other non-invasive modality of oxygen delivery in the peri-intubation time period. Our primary outcome was severe desaturation (defined as SpO2 reading less than 80% during intubation procedure). Other outcomes included short-term mortality, peri-intubation complications, apneic time, and PaO2 before and after intubation. We performed meta-analyses using a random effects model. *A priori* we assessed for predefined subgroup effects based on patient population, risk of bias, and the comparator used. We assessed risk of bias (ROB) of individual RCTs using a modified Cochrane risk of bias tool and assessed overall certainty of pooled estimates using the Grading of Recommendations, Assessment, Development and Evaluation (GRADE) framework.
RESULTS. We identified 9 RCTs with a total of 917 patients that met eligibility criteria; 4 RCTs examined HFNC in pre-operative patients and 5 RCTs studied HFNC in acutely hypoxemic critically ill patients.

Two studies compared HFNC to non-invasive ventilation (NIV) while the remaining trials compared HFNC to facemask with bag mask ventilation. HFNC showed no effect on the incidence of peri-intubation hypoxemia (relative risk [RR] 0.93, 95% confidence interval [CI] 0.59 to 1.44, 0.9% absolute risk reduction, 95% CI 5.5% reduction to 5.9% increase; moderate certainty) when compared to NIV or conventional oxygen therapy and no effect on 28-day mortality (RR 0.91, 95% CI 0.72 to 1.12, 3.0% absolute risk reduction, 95% CI 9.3% reduction to 3.9% increase, moderate certainty). HFNC also showed no effect on serious peri-intubation complications (RR 0.87, 95% CI 0.70 to 1.08, 1.4% absolute risk reduction, 95% CI 5.0% reduction to 1.0% increase; low certainty,?) and ICU length of stay (mean difference [MD] 1.15 days less, 95% CI 2.45 days less to 0.16 days more; moderate certainty). Finally, there was no effect of HFNC on PaO2 measured after induction and pre-oxygenation (MD 2.7 mm Hg higher, 95% CI 4.1 mm Hg lower to 9.6 mm Hg higher, moderate certainty), or measured after intubation (MD 30.0 mm Hg higher, 95% CI 8.5 mm Hg lower to 68.6 mm Hg higher, moderate certainty) or in overall apneic time (MD 12.3 seconds higher with HFNC, 95% CI 11.9 seconds lower to 36.6 seconds higher, low certainty) as compared to conventional oxygen therapy or NIV. There were no credible subgroup effects.
CONCLUSION. We did not find evidence of an effect of HFNC on the incidence of hypoxemia, complications, oxygenation, ICU LOS, or overall survival when used in the peri-intubation period.

Comparison between femoral vein diameter and inferior vena cava diameter by ultrasound in estimation of central venous pressure in mechanically ventilated patients

D. zidan[1], A. Baess[2]
[1]University Hospital, Alexandria, Egypt; [2]Chest disease, University Hospital, Alexandria, Egypt
Correspondence: D. zidan
Intensive Care Medicine Experimental 2019, **7(Suppl 3):**000658

INTRODUCTION. Bedside ultrasonography is used as a noninvasive method for hemodynamic monitoring, Evaluation of inferior vena cava diameter by sonography provide an alternative tool for evaluation of intravascular volume. Femoral vein is a superficial compliant vessel, images can be easily obtained.
METHODS. We enrolled 100 adult patients in this study. During measurement, patient was in supine position. The CVP was uniformly measured at end of expiration and the pressure transducer having been zeroed at the level of mid axillary line. IVC image was obtained using General Electric ultrasound machine and 3.5 MHz convex probe. The transducer is placed in a vertical plane in the subxiphoid view. The intrahepatic portion of the IVC was visualized as it entered the right atrium. Approximately 3–4 cm from the junction of the IVC and right atrium the IVC diameter was obtained. Using M mode, the maximum and minimum diameter during inspiration and expiration diameter were recorded respectively In order to get the FVD, we scanned the femoral triangle starting at the inguinal crease using a linear array transducer (5-10 MHZ). FVD was measured just caudal to the sapheno-femoral junction.
RESULTS. , mean age was 56 y, mean CVP was 6 cm H2O, mean IVC diameter during inspiration was 15 cm, while during expiration was 13.6 cm and the of femoral vein diameter was 8.2 cm. There were significant correlations between CVP , IVC diameter (Insp, Exp)and FVD. CVP correlation with FVD was 0.59, IVC diameter during inspiration with FVD was 0.41 and IVC diameter during expiration was 0.42
CONCLUSION. FVD can be used as a noninvasive alternative method to assess intravascular volume status.

INTRODUCTION. Right ventricular (RV) failure is one of the most serious complications after heart transplantation (HTx). It is an independent risk factor of mortality. Ventricular Assist Devices (VAD) must be considered if conservative medical management fails.
OBJECTIVES. Describe our series of patients with RV failure after HTx that required VAD implantation.
METHODS. We performed a retrospective study from January 2011 to March 2019 in a third-level ICU with heart transplantation program. All patients that required VAD after RV failure followed by HTx were included. We examined demographics, previously hospitalized in ICU, preoperative VAD implantation, postoperative complications, and survival rate. Absolute number and frequency described qualitative variables and median and interquartile range (IR) described quantitative variables.
RESULTS. We collected a total of 10 patients. Demographic data is shown in Table 1. Causes of heart failure were dilated cardiomyopathy (4 cases), congenital cardiomyopathy (2 cases), ischemic cardiomyopathy (2 cases), hypertrophic (1 case) and restrictive cardiomyopathy (1 case). Six patients were transferred from the theatre, 2 from the ward, 1 from the emergency room and 1 from another centre. Five patients were hospitalized in ICU while waiting for transplantation, of whom 4 needed a pre-transplantation VAD: CentriMag Right VAD in 2 patients, central ECMO in 1 patient and Peripheral ECMO in 1 patient. The causes of hospitalization in ICU previous to HTx were acute decompensated heart failure in 2 cases, ischemic cardiogenic shock in 1 case and cardiac electric storm in 1 case. The most frequent VADs implanted after HTx were peripheral ECMO in 6 patients, followed by CentriMag Right Ventricular Assist Device and central ECMO in 2 patients each. VAD was placed as a bridge to recovery in all cases. The most frequent postoperative complications were acute kidney injury with renal replacement therapy (7 cases), critical illness polyneuropathy (6 cases) and stroke (2 cases). The overall mortality was 40%.
CONCLUSION. Admission in ICU before heart transplantation and VAD implantation is common in our series, being acute decompensated heart failure the most habitual cause of hospitalized, and CentriMag Right VAD the most frequent device placed. The most frequent VAD placed after RV failure followed by HTx was peripheral ECMO. More data is needed to gain a deeper understanding of these results.

INTRODUCTION. Heart transplant in Congenital Heart diseases is challenging, but it is the last option when the heart failure is end.stage.
OBJECTIVES. To describe Heart transplant in congenital Heart Disease patients in a third Level Hospital
METHODS. Retrospective observational study from 1997 to 2019 in a third-level cardiovascular ICU. We included all patients with Congenital Heart diseases who had a heart transplant. We included demographic data, cardiac catheterization data [pulmonary artery median pressure (PAPm), wedge pressure (PWP), pulmonary vascular resistance (PVR)]. Heart failure stage according to NYHA and FEVI, renal failure and liver failure before the transplantation. Complications during their stay in ITU after transplant were collected: any infection, renal failure develop, ECMO support needed, and global survive. Absolute number and frequency described qualitative variables and median and interquartile range (IR) described quantitative variables
RESULTS. We collected 14 patients, median age was 25,5 (20,7-32,25), 57,1% were males. 100% had a NYHA $^{3}3$ before transplant, Median FEVI was 37 (22,5-55). Cardiac catheterization values were: median PAPm was 19 (12-22,5); median PWP was 16 (13,5-19,5), median RVP 1,83 (1-4). During their stay in ITU 54,5%(6) presented an infection being respiratory tract infection the most frequent (50%). The 21,4 %(3) needed RRT and 36,4% (4) presented liver failure. 28,6 %(4) develop graft failure, which needs ECMO support, with a median of 6 days (1-17,5) and the mortality in that Group was 50%. Our global survival was 78,6 %(11)
CONCLUSION. The most frequent complication was the infection
Mortality in those who develop graft failure and need ECMO support is high.
Heart transplant in this population is a valid option with good global results.

INTRODUCTION. Mortality in cardiogenic shock remains high, despite advances in treatment, including mechanical circulatory support, using ECMO or other alternative systems (1).
METHODS. We performed a retrospective study, analysing the activity in cardio-pulmonary support via Extracorporeal Membrane Oxygenation (ECMO), from November 2015 to October 2018, in a mixed medical and surgical cardiac ICU. Data were collected from electronic and hard-copy archives.
RESULTS. Twelve patients were treated with ECMO (CardioHelp System, Maquet). All patients had a veno-arterial (VA) ECMO implanted, using a percutaneous, femoro-femoral technique, with a posterior tibial reperfusion cannula, for limb ischemia prevention. Left ventricular (LV) unloading was attempted using an intra-aortic balloon pump (IABP) on the contra-lateral leg. Implantation was done using either ultrasonographic or fluoroscopic guidance.
Refractory cardiogenic shock was the indication for ECLS in all cases: seven patients with post-cardiotomy shock, two patients with fulminant acute myocarditis, and three with ST-elevation myocardial infarction (STEMI), of which one had a mechanical complication – septal ventricular rupture.
Cardiac dysfunction was severe in all cases, either due to LV dysfunction (ejection fraction <25%), RV dysfunction or both, after attempting pharmacologic optimization and, in most cases, IABP. Mean serum lactate at the moment of implantation was 9,4 mmol/L (SD= 4,73).
Monitoring included lactate dynamics, continuous SvO2, daily echocardiography, either transthoracic or transoesophageal, near-infrared spectroscopy and a protocol of classic coagulation tests and viscoelastic point-of-care tests. Adequate multi-organ support was obtained in 11/12 patients.
ECMO support was maintained for a median of 12 days, with a minimum of 6 days and a maximum of 30 days. Seven out of twelve patients were successfully weaned off ECMO (bridge to recovery), another was bridged to long-term mechanical assistance via a left ventricular assist device (LVAD), using an echocardiography guided weaning protocol, and four patients died while on ECMO.
Five patients survived to discharge, three following cardiac surgery and two after recovering from myocarditis.
Complications related to cannulation or limb ischemia did not occur in any of the patients. One patient suffered a severe septic complication - acute gangrenous cholecystitis and underwent abdominal surgery while on ECMO. The same patient required oxygenator replacement due to fibrin deposition.
CONCLUSION. ECLS is a technique for multi-organ support in shock in the most severe of cases. In a case series of twelve patients with cardiogenic shock due to STEMI, myocarditis or after cardiac surgery treated with ECMO as a rescue therapy we report a 67% weaning success and 42% survival to discharge Careful monitoring and protocolized weaning can lead to positive outcomes in shock, despite severe illness (mean lactate 9,4 mmol/L).

INTRODUCTION. Acute coronary syndrome (ACS) frequently requires Intensive Care Unit (ICU) admission. Percutaneous coronary intervention (PCI) has relegated systemic fibrinolysis as a second line intervention. Delay in time to start the treatment may lead to cardiac complications.
OBJECTIVES. To analyze the differences observed in patients with ACS with ST-segment elevation (STEMI), depending on reperfusion treatment used patients in the ICU of Hospital Punta de Europa using ARIAM database.
METHODS. Retrospective descriptive analysis on a prospective cohort, performed in a 12-bed ICU for 6 years (2013-2018). Two groups were compared: fibrinolysis vs. PCI. Demographic variables, comorbidities, risk factors, initial Killip, extension, TIMI, GRACE, CRUSADE have been registered. Statistical analysis: categorical (frequencies and percentages) and numerical variables (mean and standard deviation). Comparisons: test of X2 (percentages), Student's t (means). Statistical significance with $p < 0.05$.
RESULTS. 293 patients diagnosed with STEMI were included. Those patients were compared according to the reperfusion strategy used: fibrinolysis n = 247 (84.3%) vs. PCI n = 46 (15.6%). There were no differences in terms of age, sex, cardiovascular risk factors or comorbidities. Creatinine (1.04 [± 0.27] vs. 1.21 [± 0.56], p <.001), TIMI (3.06 [± 2.45] vs. 3.88 [± 3.22], p=.024), CRUSADE (27.69 [± 14.42] vs 32.62 [± 20.03], p=.036). Use of clopidogrel during ICU stay: 42 (17%) vs. 1 (2.2%) p=.009. Infectious complications 2 (0.8%) vs. 3 (6.5%) p=.006. Transthoracic echocardiography 56 (23%) vs. 2 (4.3%) p=.004, defibrillation 8 (3.3%) vs 5 (10.9%), p=.022, invasive mechanical ventilation (IMV) 6 (2.5%) vs. 4 (8.7%) p=.033. Destination after ICU discharge (p <.001): hospital ward 217 (87.9%) vs. 31 (67.4%), another hospital 17 (6.9%) vs. 11 (23.9%), death 12 (4.9%) vs. 3 (6.5%). Initial TIMI: 0 66 (24.1%) vs. 19 (9.5%), I 98 (35.8%) vs. 80 (40.2%), II 70 (25.5%) vs 65 (32.7%), III 40 (14.6%) vs. 35 (17.6%), p=.001. ICU mortality: 4.9% vs 6.5%, p=.713. First contact-ICU income (minutes) 91.1 ± 150.4 vs. 172.2 ± 116.4, p=.005. ICU length of stay (LOS) (days): 3.4 ± 3.5 vs. 2.1 ± 3.2, p=.008.
CONCLUSION. No significant differences were found in terms of risk factors, comorbidities, non-infectious complications and mortality. Patients treated with primary PCI experienced significantly shorter ICU LOS.
